Somatoform disorders are conditions that suggest a medical disorder when no physical cause can be found for the patient's symptoms. Two of the most common disorders in this group are somatization disorder and conversion disorder. Both are associated with anxiety, depression, and threats of suicide. Treatment for both disorders often requires psychotherapy, which can address the emotional conflicts that manifest in these illnesses. No definitive causes for most of the somatoform disorders have been established. Contributing factors may include[21]:

- Genetic and environmental influences appear to contribute to somatization.
- Children raised in homes with a high degree of parental somatization may model somatization.
- Sexual abuse may be associated with an increased risk of somatization later in life.
- Poor ability to express emotions may result in somatization.

SOMATIZATION DISORDER

Somatization disorder is a condition in which an individual has complaints (lasting several years) of various physical problems for which no physical cause can be found (Box 35-20).[13] The condition is more common in women than men. It sometimes results in unnecessary surgery and other treatments. These patients most often complain of neurological symptoms (double vision, seizure, weakness), gynecological symptoms (painful menstruation, painful intercourse), and gastrointestinal symptoms (abdominal pain, nausea).

CONVERSION DISORDER

Conversion disorder is a mental illness in which painful emotions are repressed and unconsciously converted into physical symptoms (Box 35-21).[13] A loss of sensory or motor capabilities or of special senses may occur. For example, the person suddenly may not be able to speak, hear, see, or feel, or an arm or a leg may be paralyzed. In many cases the areas of the body affected do not correspond to the actual arrangement of neural pathways. The symptoms also may be intermittent or may appear at different times and in different areas of the body.

MANAGEMENT

Paramedics should manage symptoms of somatoform disorders as if they are real, because differentiating these disorders from an organic ailment may be difficult. The paramedic should recognize that these patients are not "faking"; they believe their illness or loss of function to be factual. These patients require evaluation by a physician.

Factitious Disorders

Factitious disorders are a group of disorders in which symptoms mimic a true illness. However, the symptoms have actually been invented. The symptoms are under the control of the patient, who is attempting to gain attention. The most common disorder in this group is **Munchausen syndrome.** With this disorder, the patient makes routine pleas for treatment and hospitalization for a symptomatic, but imaginary, acute illness. Other complaints that may be associated with factitious disorders include bereavement, Cushing syndrome, dental problems, infection with the human immunodeficiency virus (HIV), hypoglycemia, and stroke. **Munchausen syndrome by proxy** is a form of this disorder in which a person injures or induces illness in others (usually children) in order to gain sympathy. Munchausen syndrome by proxy is often considered to be a form of child abuse.

The symptoms of a factitious disorder are often dramatic but plausible. They usually resolve with treatment. After the treatment, the person seeks treatment for another invented disease. Once the factitious disorder is diagnosed, treatment is aimed at protecting these people from unnecessary surgeries and other treatments they do not need.

Dissociative Disorders

Dissociative disorders are a group of psychological illnesses. In these illnesses, a particular mental function is separated (dissociated) from the mind as a whole. These disorders include the following:

- *Dissociative amnesia:* A disorder characterized by the blocking out of critical personal information, usually of a traumatic or stressful nature. Dissociative amnesia, unlike other types of amnesia, does not result from other medical trauma.
- *Dissociative fugue:* A rare disorder in which an individual suddenly and unexpectedly takes physical leave of the surroundings.

BOX 35-20 Facts About Somatization Disorders

- The lifetime prevalence rate for somatization disorder is 0.2% to 2% of the U.S. population.
- Somatization disorders are rare in men.
- Somatization disorders tend to run in families. They occur in 10% to 20% of the primary female relatives of somatization disorder patients.
- Most somatization disorders begin in adolescence or early adulthood. Most are chronic in nature.
- The symptoms sometimes increase and decrease in severity over time. Usually, though, the individual has a few symptom-free episodes.
- Anxiety and depression often accompany the disorder.
- Suicide threats are common in these patients, but suicide is rarely carried out.

BOX 35-21 Facts About Conversion Disorder

- True conversion disorder is rare in the United States.
- The disorder is seen more often in lower socioeconomic groups. It may be more common in military personnel exposed to combat.
- Conversion disorder may appear at any age. However, it is rare before age 10 or after age 35.
- In pediatric patients, the incidence of conversion disorder is higher after physical or sexual abuse. The incidence also rises among children whose parents are very ill or have chronic pain.
- About 64% of adult patients with conversion disorder have evidence of organic brain disorder.

- *Dissociative identity disorder:* A disorder that has been called "multiple personality disorder."
- *Depersonalization disorder:* A condition marked by a feeling of detachment or distance from one's own experience, body, or self.

Dissociative disorders usually are associated with emotional conflicts. These conflicts are so repressed that a split in the personality occurs. This results in an altered state of consciousness or confusion in identity. The condition also may be caused by an inability to cope with severe stress or conflict. Dissociation can occur soon after a catastrophic event, such as the traumatic death of a child or spouse. People with dissociative disorders often are unable to remember their names or personal histories. However, they can still speak, read, and learn new material. Treatment may include antianxiety medications, hypnosis, and psychotherapy.

Eating Disorders

The two most common eating disorders considered to be forms of psychiatric illness are anorexia nervosa and bulimia nervosa (Box 35-22).[22] Both of these eating disorders can lead to serious dehydration, starvation, and electrolyte imbalances. They also may cause critical illness or death. The disorders are best managed with supervision and regulation of eating habits, psychotherapy, and, sometimes, antidepressants. Most patients require hospitalization.

ANOREXIA NERVOSA

Anorexia nervosa is an eating disorder characterized by an intense fear of being obese, severe weight loss, malnutrition, and, eventually, amenorrhea (absence of menstrual bleeding). A patient feels intensely hungry, even though hunger pains are denied. Signs and symptoms include weight loss, obsession with exercise, fatigue, binge eating, induced vomiting, and use of laxatives to promote weight loss. The condition mainly is seen in adolescents, mostly girls. It usually is associated with emotional stress or conflict. It often is difficult to identify an exact underlying cause for this disease.

BOX 35-22 Facts About Eating Disorders

- More than 5 million Americans suffer from eating disorders.
- Anorexia, bulimia, and binge-eating disorders are diseases that affect the mind and body at the same time.
- Three percent of adolescent and adult women have an eating disorder. One percent of men have an eating disorder.
- A young woman with anorexia is 12 times more likely to die than another woman her age without anorexia.
- Fifteen percent of young women have substantially poor eating attitudes and behaviors.

BULIMIA NERVOSA

Bulimia nervosa is sometimes considered a form of anorexia. It is an insatiable craving for food. This craving often results in episodes of binge eating followed by purging (through self-induced vomiting or use of laxatives), depression, and self-deprivation. Like anorexia, bulimia is most common in adolescent girls and young women. Anorexic and bulimic patients often worry about their compulsive behavior. As a result, they may become depressed and suicidal.

NOTE

Binge-eating disorder is similar to anorexia and bulimia, but with slightly different characteristics. It involves recurrent binge-eating episodes during which a person feels loss of control over eating. Unlike bulimia, binge-eating episodes are not followed by purging, excessive exercise, or fasting. As a result, people with binge-eating disorder often are overweight or obese. They also experience guilt, shame, and/or distress about the binge eating, which can lead to more binge eating. Obese people with binge-eating disorder often have coexisting psychological illnesses including anxiety, depression, and personality disorders. In addition, links between obesity and cardiovascular disease and hypertension are well documented.[23]

Impulse Control Disorders

Impulse-control disorders are a group of psychiatric conditions. They are characterized by the inability to resist an impulse or a temptation to perform some act that is unlawful, socially unacceptable, or self-harmful. Disorders in this category include the following:

- *Intermittent explosive disorder:* A condition marked by frequent and often unpredictable episodes of extreme anger or physical outbursts. Between episodes there is usually no evidence of violence or physical threat.
- *Kleptomania:* The failure to resist impulses to steal things that are not needed either for personal use or for their monetary value.
- *Pathological gambling:* A persistent and maladaptive pattern of gambling that causes difficulties with interpersonal, financial, and vocational functioning.
- *Pyromania:* Deliberate and purposeful fire-setting for nonmonetary gain. This condition typically is associated with tension or heightened arousal before the act and with gratification or relief afterward.
- *Trichotillomania:* The recurrent pulling out of one's own hair, which results in significant hair loss.

Impulse-control disorders often are difficult to treat. Most are managed with behavior modification and drug therapy. Failure to control these disorders may result in violent behavior or unlawful activities (e.g., road rage). Incarceration is common.

PERSONALITY DISORDERS

Personality disorders are a large group of conditions distinguished by a failure to learn from experience or to adapt appropriately to changes. This failure results in personal distress and impairment of social functioning. These disorders may have an environmental component. They also may be genetic. Personality disorders become especially obvious during times of stress.

The symptoms of a personality disorder usually are first recognized in early adolescence. They continue throughout the person's life. The symptoms may vary in frequency and intensity. Generally, however, they are relatively constant. They usually affect most aspects of a patient's life. This includes thoughts, emotions, relationships and interpersonal skills, and impulse control. Personality disorders have been classified in a number of ways. However, the following are three common disorders:

- *Antisocial personality disorder:* A long-standing pattern (after the age of 15) of disregard for the rights of others. It often is associated with irresponsible behavior and a lack of remorse for wrongdoing.
- *Borderline personality disorder:* A pattern of unstable relationships, poor or negative self-image, mood swings, and poor impulse control. It may be associated with destructive and self-harming behaviors (e.g., suicide attempts, self-mutilation), an intense fear of abandonment, and displays of sudden anger.
- *Narcissistic personality disorder:* A pattern of grandiosity, need for admiration, and sense of entitlement. It often is associated with exaggerated achievements and fantasies about unlimited success, power, love, or beauty.

Many factors are associated with the development of a personality disorder. These may include unstable relationships during childhood, family violence, and childhood abuse or neglect (see Chapter 50). Treatment involves behavior modification techniques, counseling, drug therapy, and individual psychotherapy.

SPECIAL CONSIDERATIONS FOR PATIENTS WITH BEHAVIORAL PROBLEMS

In addition to caring for the immediate needs of patients with behavioral problems, paramedics may have to deal with complications arising from the situation or other factors affecting the patient. Among these factors are the patient's age and the possibility of violent behavior. This section presents special considerations for pediatric patients, elderly patients, and the potentially violent patient.

CRITICAL THINKING

When responding to a behavioral emergency that involves a child or an adolescent, do you use the same safety guidelines that you use with an adult?

Behavioral Problems in Children

Young children who are victims of emotional crisis need to be managed with techniques that are different from those used to care for older children and adults. The following suggestions may be helpful to the paramedic in dealing with some children:

1. Gain the child's trust and try to convince the child that you are a friend who can help.
2. Make it clear that you are strong enough to be in control but will not hurt the child.
3. Keep the interview questions brief; the child's attention span may be extremely short.
4. Never lie; be honest.
5. Use all available resources to communicate (e.g., drawing pictures, telling stories).
6. Involve parents or caregivers in the interview or examination if appropriate.
7. Take any threat of violence seriously.

If the child's behavior or physical condition makes restraint necessary, the paramedic should use only humane and reasonable force (the minimum force necessary to ensure the patient's safety and the safety of the EMS crew). Sufficient manpower should be available. Calming measures may fail to work. If so, wrapping the child in a full body blanket secured to the stretcher with straps often is sufficient during transport for evaluation by a physician. As with any method of restraint, the paramedic should monitor the child's airway and circulation and ensure that they are not compromised. Documentation should be thorough and complete.

Behavioral Problems in Elderly Patients

An estimated 15% to 25% of elderly people in the United States suffer from significant symptoms of mental illness. More than 6.5 million elderly individuals are clinically depressed.[24] Most of these disorders can be diagnosed and treated successfully. However, many of these people do not seek care. Problem behavior in an elderly patient can be a sign of a long-standing psychiatric disorder, a newly emerging psychiatric problem, a medical illness, substance abuse, drug noncompliance or drug interactions, and other factors (see Chapter 49). The following suggestions may be helpful to the paramedic in communicating with some elderly patients:

1. Identify yourself and speak at eye level to make sure the patient can see you.
2. Address the patient by surname (e.g., "Mr. Jones" or "Miss [or Mrs.] Smith") unless directed otherwise.
3. Speak slowly, distinctly, and respectfully.
4. Ask one question at a time and allow time for complete answers.
5. Listen closely.
6. Explain what you are doing and why.
7. Provide reassuring physical touch.
8. Be patient.

9. Permit family members and caregivers to remain with the patient if appropriate.
10. Preserve the patient's dignity.

Assessing the Potentially Violent Patient

Only a small number of people with mental health problems are potentially violent. Nonetheless, assessment and management of the potentially violent patient should be part of an EMS protocol. The following four factors may help the paramedic determine the potential for a violent episode[25]:

1. *Past history:* Has the patient previously shown hostile, aggressive, or violent behavior?
2. *Posture:* Is the patient sitting or standing? Does the patient appear to be tense or rigid?
3. *Vocal activity:* Loud, obscene, and erratic speech indicates emotional distress.
4. *Physical activity:* Is the patient pacing or agitated or protecting his or her physical boundaries?

If any of these signs of potentially violent behavior are present, efforts should be taken to reduce the effect of the stress while avoiding confrontation. Paramedics should prepare a way to cope with the crisis that reduces the potential for a life-threatening incident. It also should reduce the chance for psychologically damaging consequences.

NOTE

Paramedics should retreat from the scene if they anticipate violence that would threaten their personal safety or the safety of the crew. They should wait for law enforcement personnel to ensure that the scene is safe.

CONTROLLING VIOLENT SITUATIONS

Severely disturbed patients who pose a threat to themselves or others may need to be restrained, transported, and hospitalized against their will. Each state has a law establishing the criteria for involuntary commitment. The paramedic should be familiar with all relevant laws. The premise on which most state laws are based suggests that one person may restrain another to protect life or prevent injury.

When a psychiatric patient refuses care, EMS personnel should consult with medical direction. The decision to restrain, treat, or release the patient is a medical direction decision. If violent behavior must be contained, "reasonable force" should be used to restrain the patient. It should be used as humanely as possible and with respect for the patient's dignity. In most cases the restraint duty (if needed) should be given to law enforcement personnel. As in all other aspects of health care, details of the incident should be carefully documented for future reference. When dealing with a patient who may require restraint, the paramedic should do the following:

1. Provide a safe environment.
2. Gather a significant medical and psychiatric history.
3. Attempt to gain the patient's cooperation.
4. Be confident but not confrontational.

CRITICAL THINKING

Have you ever seen an EMS crew member or a police officer lose control of his or her own behavior when dealing with a violent patient? How did it affect the patient's physical or psychological state?

DID YOU KNOW?

Tasers

Tasers (stun guns) are electronic-control devices designed for self-defense and to subdue unruly or violent individuals. Tasers are used by many law enforcement, military, and security personnel. In most states, the devices are legal for civilian use (though some states or municipalities restrict or ban them). Tasers deliver a high-voltage, low-amperage electrical charge (about 3 milliampere [mA] or 0.3 joule [J]). The charge is delivered through two small dartlike electrodes tethered to the device by conductive wires. The electrodes in most devices can be quickly launched about 15 feet. The darts are pointed to penetrate clothing and barbed to prevent removal once in place. (Other styles of taser devices are available and use different methods.) The delivered current disrupts the voluntary control of muscles and produces neuromuscular incapacitation. Once the electricity stops flowing (preset time sequences up to 30 seconds in each cycle), the subject regains immediate control of all muscular activity. The use of tasers is considered highly controversial by some in the medical community and other groups.

RESTRAINT GUIDELINES

The following guidelines can help paramedics to use restraint appropriately:

- If the patient is homicidal, do not attempt restraint without assistance from law enforcement personnel. If the patient is armed, move everyone out of range and retreat from the scene. Wait for law enforcement personnel.
- Remember that the patient may not be responsible for his or her actions.
- When planning the restraining action, include a backup plan in case the initial attempt fails.
- Make sure that adequate help is available. This means that at least four capable people should be available to help restrain an adult patient.
- Keep in mind that the potential for personal injury and legal liability is always present.

SHOW ME THE EVIDENCE

This descriptive study evaluated a sample of 39 cases of taser-related deaths between 2001 and 2005. All were male and 54.1% had cardiovascular disease on autopsy. Medical examiners diagnosed 75.5% with excited delirium and 78% tested positive for illegal substances. Law enforcement restraint was documented in 78.4% of cases. The type of restraint was not specified in 32.4% of cases. Types of restraint documented were handcuffs, hobble or hog-tied, choke hold, or beanbag gun. Although this research was not designed to establish cause, the authors feel it contributed to an understanding of risk factors associated with taser-related deaths. They reiterate the need for paramedics to carefully monitor restrained patients.

From Strote J, Hutson R: Taser use in restraint-related deaths, *PEC* 10(4):447-450, 2006.

RESTRAINT METHODS

A number of restraint methods can be used to manage a violent patient. A gentle, nonthreatening, low-profile technique should be attempted first. The approach should move to more direct intervention as needed. The options of physical restraint should always be explained to the patient before force is applied. If still unwilling to cooperate, the patient should be informed that restraint is required to protect against injury and to ensure the safety of others.

Before approaching a violent patient, the paramedic should be aware of the patient's surroundings. Seemingly harmless items should be noted, such as ashtrays, lighted cigarettes, hot coffee, letter openers, soda bottles, cans, and furniture. No attempt should be made to enter the patient's physical space until the other members involved in the restraint action are ready to proceed. (The patient's physical space usually is considered to be one arm's length.)

The patient's muscle groups and potential range of motion should be considered before restraint is initiated. The paramedic should plan to position the patient in a way that limits strength and range of motion. Each member of the restraint team should be assigned a specific body part or responsibility before the actual restraint procedure begins.

FIGURE 35-3 Restraint devices.

Paramedics must be familiar with the restraint devices available and should be able to improvise if the need arises. The preferred method is to use commercially manufactured wrist/waist/ankle padded leather or Velcro straps, or full jacket restraints (Figure 35-3). Effective restraints also may be improvised using common materials such as the following:

- Small towels that can be wrapped around the patient's wrists and ankles and secured with tape to the stretcher
- Cravats
- Webbed straps ordinarily used to secure patients to spine boards
- Roller bandage
- Blanket roll

Regardless of the types used, restraints should be strong enough to achieve the desired effect. However, they should not compromise circulatory or respiratory status.

SEQUENCE OF RESTRAINT ACTIONS

Trained personnel can use many restraint techniques. The following sequence is an example of a restraint action that may be used to contain violent behavior.

1. The paramedic offers the patient one final chance to cooperate.
2. If the patient does not respond, at least four rescuers move swiftly toward the person. They position themselves close to and slightly behind the patient. Two rescuers should then position an inside leg in front of the patient's leg to force the patient to the ground if necessary (Figure 35-4). Swift movement by several rescuers minimizes the patient's ability to focus on restraint actions. It also reduces the accuracy of kicks or blows. During the restraint procedure, the patient should be continually reassured by a rescuer not involved in the physical maneuver.

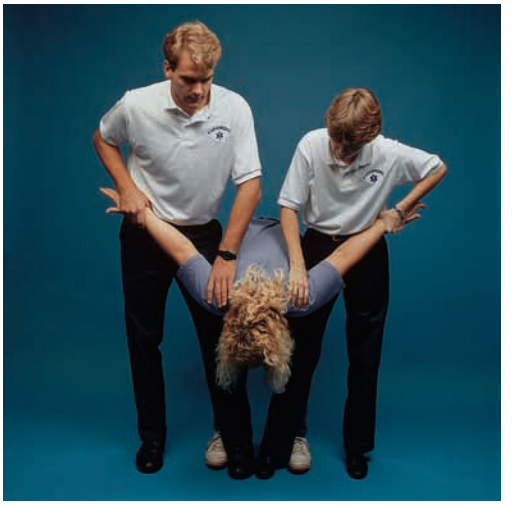

FIGURE 35-4 Control position. Rescuers face the same direction. The rescuers' inside legs are placed in front of the patient. The rescuers' outside hands hold the patient's wrists. The rescuers' inside hands form a C on the patient's shoulders.

FIGURE 35-5 Patient restrained in supine position.

3. If the patient calms and agrees to be transported without restraints, the paramedic positions the patient lateral or supine on a stretcher (if not contraindicated by the mechanism of injury or medical condition). The paramedic secures the patient with straps to limit range of motion (Figure 35-5). If the patient becomes dangerous en route to the hospital, restraints should be used.
4. Once applied, restraints should not be removed until the patient is delivered to the emergency department or there are adequate resources to control the situation. The patient's respiratory and circulatory status should be assessed frequently and documented. This ensures that the restraint action has not compromised vital functions. If a change in the restraints is required, additional manpower must be available for assistance. Also, only one limb should be repositioned at a time.

Restraint procedures should be fully documented on the patient care report. Any attempts at negotiation and a description of the patient's behavior before restraint should be clearly described. Paramedics should document that circulatory evaluation and continued monitoring of the patient were performed after restraint. Again, physical restraint is advised only when all verbal and nonverbal techniques have been exhausted and only when a person presents a danger to self or others.

PERSONAL SAFETY

Paramedics' personal safety should be considered in any emergency response. However, behavioral emergencies are more likely to require that paramedics protect themselves and the crew from hostile injury. The following measures for preventing personal injury should be considered:

- When possible, remain a safe distance from the patient.
- Do not allow the patient to block the exit.
- Keep large furniture between you and the patient. Do not allow a single paramedic to remain alone with the patient.
- Do not make statements that the patient might perceive as threatening.
- Use folded blankets or cushions to absorb the impact of thrown objects.

Various training programs have been developed to provide safety and security to the rescuer and the violent patient. Paramedics should learn nonviolent personal protection maneuvers. They also should practice these maneuvers under the supervision of a qualified instructor.

CHEMICAL RESTRAINT

The term **chemical restraint** refers to the use of drugs to control behavior. Drug treatment varies. However, it generally is intended to provide sedation. Two groups of drugs that are effective for chemical restraint are benzodiazepines and antipsychotics (see Chapter 13).

Benzodiazepines bind to specific receptors in the cerebral cortex and limbic system (a major integrating system that governs emotional behavior). These drugs are popular because of their very high therapeutic index. They have four main actions: anxiety reducing, sedative-hypnotic, muscle relaxing, and anticonvulsant. Benzodiazepines commonly used for chemical restraint include ***diazepam, midazolam,*** and ***lorazepam.***

Antipsychotics block dopamine receptors in specific areas of the central nervous system. These drugs are primarily used to treat schizophrenia. They also are used to treat other conditions that produce disturbed behavior (e.g., Tourette's syndrome and senile dementia associated with Alzheimer's disease). A well-known antipsychotic used for chemical restraint is ***haloperidol.*** The benzodiazepine ***lorazepam*** is also administered for this purpose. Short-term use of antipsychotics rarely produces extrapyramidal reactions. However, if such reactions occur, administration of ***diphenhydramine*** may reverse these side effects.

Benzodiazepines and antipsychotics can be very effective at controlling hostile or combative patients. As with all other restraint methods, paramedics should consult with medical direction, follow protocol, and carefully document the event.

NOTE

As described in Chapter 13, extrapyramidal reactions are neuromuscular effects that can be caused by some antipsychotic medications. These effects include Parkinson-like symptoms (e.g., tremor, muscle rigidity, pill-rolling motion, shuffling gait), akathisia (abnormal restlessness, agitation), dystonias (abnormal muscle tone or posturing), and tardive dyskinesia (involuntary, repetitious movement). The occurrence and severity of extrapyramidal reactions frequently are dose-related. They often subside when the dose is reduced or the drug is discontinued. However, in some patients tardive dyskinesia persists even after drug therapy is stopped. (This is especially the case for patients prescribed long-term drug therapy.) These rhythmical, involuntary movements are most evident in the tongue, face, mouth, or jaw. They are characterized by protrusion of the tongue, puffing of the cheeks, puckering of the mouth, chewing movements, and sometimes involuntary movements of the extremities.

SUMMARY

- A behavioral emergency is a change in mood or behavior. This change cannot be tolerated by the involved person or others. It calls for immediate attention.
- Physical or biochemical disturbances can result in significant changes in behavior. Psychosocial mental illness is often the result of childhood trauma, parental deprivation, or a dysfunctional family structure.
- Changes in behavior caused by interpersonal or situational stress are often linked to specific incidents, such as environmental violence, death of a loved one, economic or employment problems, or prejudice and discrimination.
- When dealing with behavioral emergencies, the paramedic should contain the crisis. It begins by establishing a rapport with the patient. He or she should provide the proper emergency care as well. Also, the paramedic should transport the patient to an appropriate health care facility.
- During the patient assessment, an attempt should be made to determine the patient's mental state, name and age, significant medical history, medications (and compliance), and past psychiatric problems, as well as the precipitating situation or problem.
- Effective interviewing techniques include active listening, being supportive and empathetic, limiting interruptions, and respecting the patient's personal space.
- A mental status exam includes assessment of appearance and behavior; speech and language; cognitive abilities; and emotional stability.
- All cognitive disorders result in a disturbance in thinking that may manifest as delirium or dementia.
- Schizophrenia is characterized by recurrent episodes of psychotic behavior. This behavior may include abnormalities of thought process, thought content, perception, and judgment.
- Anxiety disorders may cause a panic attack. Anxiety disorders include phobias, obsessive-compulsive disorders, and posttraumatic syndrome.
- Depression is a mood disorder. A person with depression may have feelings of hopelessness, loss of appetite, decreased libido, and feelings of worthlessness and guilt.
- Bipolar disorder is a manic-depressive illness. In this illness, depressive and manic episodes alternate.
- Suicide threats or attempts indicate the patient has a serious crisis. Certain factors increase the risk of suicide. Patients who express the wish to harm or kill themselves should be transported.
- Somatoform disorders are conditions in which there are physical symptoms for which no physical cause can be found. The cause is thought to be psychological. These include somatization disorder and conversion disorder.
- Factitious disorders are disorders in which symptoms mimic a true illness. However, the symptoms have been invented. They are under the control of the patient.
- Dissociative disorders are a group of psychological illnesses. In these disorders, a particular mental function is separated from the mind as a whole.
- The most common eating disorders considered to be forms of psychiatric illness are anorexia nervosa and bulimia nervosa.
- Impulse control disorders are characterized by the inability to resist an impulse or temptation to perform an act that is unlawful, socially unacceptable, or self-harmful.
- Personality disorders are conditions characterized by failing to learn from experience or adapt appropriately to changes. This results in personal distress and impairment of social functioning.
- A threat of suicide is an indication that a patient has a serious crisis. This crisis requires immediate intervention.
- Questions that determine the patient's ideation, plan, intent, and means to commit suicide should be asked.
- After ensuring scene safety, the first priority in patient management after a suicide attempt is medical care. If the patient is conscious, developing rapport as soon as possible is crucial.
- Assessment of a potentially violent patient should include history of violence, posture, vocal activity, and physical activity.
- When trying to defuse a situation involving a potentially violent patient, the paramedic should ensure a safe environment, gather the patient's history, try to gain the patient's cooperation, avoid threats, and explain the paramedic's role in providing care.
- Severely disturbed patients who pose a threat to themselves or others may need to be restrained.
- Reasonable force to restrain a patient should be used as humanely as possible. An adequate number of personnel is needed. This will ensure patient and rescuer safety during restraint. The risk of personal injury and legal liability is always present.
- Personal safety measures while responding to a behavioral emergency should include not allowing the patient to block the exit, keeping large furniture between you and the patient, working as a team, avoiding threatening statements, and using soft objects to absorb the impact of thrown objects.
- When caring for children with behavioral emergencies, the paramedic should attempt to gain the child's trust, tell the child he or she will not be hurt, keep questions brief, be honest, involve parents (if appropriate), and take threats of violence seriously.

PART EIGHT

Shock and Resuscitation

Chapter 36: Shock

CHAPTER

36 Shock

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Define shock.
2. Outline the factors necessary to achieve adequate tissue oxygenation.
3. Describe how the diameter of resistance vessels influences preload.
4. Calculate mean arterial pressure when given a blood pressure.
5. Outline the changes in the microcirculation during the progression of shock.
6. List the causes of hypovolemic, cardiogenic, neurogenic, anaphylactic, and septic shock.
7. Describe pathophysiology as a basis for signs and symptoms associated with the progression through the stages of shock.
8. Describe key assessment findings that distinguish the etiology of the shock state.
9. Outline the prehospital management of the patient in shock based on knowledge of the pathophysiology associated with each type of shock.
10. Discuss how to integrate the assessment and management of the patient in shock.
11. Describe principles of fluid administration in shock.

KEY TERMS

anaphylactic shock Shock that occurs when the body is exposed to a substance that produces a severe allergic reaction.

cardiac output The volume of blood pumped each minute by the ventricle.

cardiogenic shock Shock that results when cardiac action is unable to deliver sufficient circulating blood volume for tissue perfusion.

colloid solutions Solutions that contain molecules (usually protein) that are too large to pass through the capillary membrane.

compensated shock A stage of shock associated with some decreased blood flow and perfusion to the tissues.

crystalloid solutions Solutions created by dissolving crystals such as salts and sugars in water.

disseminated intravascular coagulation A grave coagulopathy that results from the overstimulation of the clotting and anticlotting processes in response to disease or injury.

distributive shock Shock that occurs when peripheral vasodilation causes a decrease in systemic vascular resistance.

hemodilution Diluting the blood of elements.

hemostasis The cessation of bleeding by mechanical or chemical means or by substances that arrest the blood flow.

hypertonic solutions Solutions that have higher osmotic pressure than that of body cells.

hypoperfusion Severely inadequate circulation that results in insufficient delivery of oxygen and nutrients necessary for normal tissue and cellular function. Also known as *shock*.

hypovolemic shock A form of shock most frequently caused by hemorrhage but also caused by dehydration.

irreversible shock A stage of shock that results in cellular ischemia and necrosis and subsequent organ death, even with oxygenation and perfusion restored.

leaky capillary syndrome A syndrome that occurs when the capillary lining permits protein-containing fluid to leak into the interstitial spaces.

mean arterial pressure The arithmetic mean of the blood pressure in the arterial portion of the circulation.

microcirculation Refers to circulation of blood from the heart to the arteries, capillaries, and veins.

microinfarcts A small infarct caused by obstruction of circulation in capillaries, arterioles, or small arteries.

neurogenic shock Shock resulting from vasomotor paralysis below the level of injury; also known as *spinal cord shock*.

obstructive shock Shock that results from obstruction to blood flow.

perfusion The circulation of blood to the tissues.

peripheral vascular resistance The total resistance against which blood must be pumped; also known as *afterload*.

pneumatic antishock garment A garment used to manage some forms of hypovolemia and to stabilize some fractures.

pulse pressure The difference between the systolic and diastolic blood pressures.

refractory shock A stage of shock that is resistant to treatment, but still reversible.

relative hypovolemia Inadequate preload as a result of vasodilation.

rouleaux formation An aggregation of red cells in what looks like a stack of coins or checkers.

septic shock A form of shock that most often results from a serious systemic bacterial infection.

shock An abnormal condition of inadequate blood flow to the body's peripheral tissues that is associated with life-threatening cellular dysfunction; also known as *hypoperfusion*.

uncompensated shock A stage of shock that occurs when the body is no longer able to maintain systemic blood pressure.

viscosity The physical property of a liquid. It is characterized by the degree of friction between its component molecules.

Severe illnesses and injury can threaten the normal internal environment of the body. During such events, the protective systems of the body try to compensate. They work to maintain cellular oxygenation. The paramedic must be able to integrate pathophysiological principles and assessment findings to form a field impression and to implement a treatment plan for the patient in shock.

(Courtesy Ray Kemp, St. Charles, Mo.)

SHOCK

Shock was defined by Gross in 1850 as a "rude unhinging of the machinery of life"[1] and since has been redefined by many others. Robert M. Hardaway, professor of surgery at Texas Tech University School of Medicine in El Paso, Texas, defines shock this way[2]:

> I believe that the best definition of shock is inadequate capillary perfusion. As a corollary of this broad definition, almost anyone who dies, except one who is instantly destroyed, must go through a stage of shock—a momentary pause in the act of death.

Shock is not a single event. It does not have one specific cause and treatment. Rather, it is a complex group of physiological abnormalities. It can result from a variety of disease states and injuries[3] (Box 36-1). There are many complexities involved in shock. Thus, it is not adequately defined by pulse rate, blood pressure, or cardiac function. Moreover, it cannot be reduced to loss of circulating blood or loss of pressure in the vascular system. Shock may affect the entire body, or it may occur at a tissue or cellular level, even with normal hemodynamics. An understanding of cellular physiology is needed to recognize the subtle aspects of shock. This also will aid in properly assessing the severity of various stages of shock.

TISSUE OXYGENATION

The adequate oxygenation of tissue cells is known as **perfusion.** To achieve adequate oxygenation, three distinct components of the cardiovascular system must work properly. These components are the heart, vasculature, and lungs. When any one of these malfunctions, a decrease in cellular oxygenation can occur. This is known as **hypoperfusion.**

BOX 36-1 Possible Causes of Shock

Healthy Patient (Adult)
Coronary syndromes
Respiratory arrest
Anaphylaxis
Drowning
Traumatic hemorrhage
Spinal cord injury
Electrocution
Hypothermia
Toxic exposures
Pulmonary embolus

Unhealthy Patient (Adult)
Congestive heart failure
Renal failure
Uncontrolled hypertension
Uncontrolled diabetes
Obesity
Electrolyte imbalance
Drug toxicity
Stroke

Pediatric Patient
Trauma
Chest wall injury
Fluid loss
Spinal cord injury
Anaphylaxis
Heart disease

Heart

The pumping action of the heart produces pressure changes that circulate blood through the body. This repetitive pumping action is known as the *cardiac cycle*. **Cardiac output** (described in Chapter 22) is a crucial determinant of organ perfusion. Cardiac output depends on several factors, including strength of contraction, rate of contraction, and amount of venous return available to the ventricle (preload). The formula to determine cardiac output is as follows:

$$\text{Cardiac output (CO)} = \text{Heart rate (HR)} \times \text{Stroke volume (SV)}$$

LOOK AGAIN

See Chapter 22: Cardiology, pp. 578-580.

PRELOAD, AFTERLOAD, AND MAP

Important terms in understanding cardiac physiology and shock are *preload, afterload,* and *mean arterial pressure (MAP)*. To review, **preload** is the amount of venous return to the ventricle (the ventricular volume at the end of diastole). It is the "load" that must be given to the left ventricle before contraction. **Afterload** is the total resistance against which blood must be pumped. It is the "load" that must be given to the heart to overcome the resistance to ventricular ejection. Total peripheral vascular resistance is determined by the volume of blood in the vascular system and by the diameter of the vessel walls (described below).

Mean arterial pressure (MAP) is a function of total cardiac output and total peripheral resistance. MAP represents the average pressure in the vascular system that perfuses the tissues. Because more time is spent in diastole than in systole, MAP is not the average of diastolic and systolic pressure. Rather, MAP reflects the relative time spent in each portion of the cardiac cycle.[4] MAP can be calculated in several ways. A common formula used in prehospital care uses the diastolic pressure and the pulse pressure (the difference between the systolic and diastolic pressures)[5]:

$$\text{MAP} = \text{diastolic pressure} + \frac{1}{3}\,\text{pulse pressure}$$

Example

Patient with blood pressure of 120/80 mm Hg

$$\text{MAP} = 80 + ([120 - 80]/3)$$
$$= 80 + (40/3)$$
$$= 80 + 13.3$$
$$= 93.3, \text{ rounded down to } 93$$

A systolic pressure of 80 to 90 mm Hg (MAP of 60 to 65 mm Hg) is needed to maintain adequate tissue perfusion. MAP is further discussed later in this chapter and in Chapter 40.

Vasculature

The entire vascular system is lined with smooth, low-friction endothelial cells. All vessels larger than capillaries have layers of tissue surrounding the endothelium. These layers of tissue are known as *tunicae*. They provide supporting connective tissue to counter the pressure of blood contained in the vascular system. The layers have elastic properties to dampen pressure pulsations and minimize flow variations throughout the cardiac cycle. The layers also have muscle fibers to control the vessel diameter. The vascular system maintains blood flow by changes in pressure and peripheral vascular resistance.

PERIPHERAL VASCULAR RESISTANCE

As stated previously, peripheral vascular resistance (afterload) is the total resistance against which blood must be pumped. It is determined primarily by a change in the diameter of the arterioles: arteriolar constriction raises mean arterial pressure by preventing the free flow of blood into the capillaries. Dilation has the opposite effect. Reflex control of vasoconstriction and vasodilation is mediated by the sympathetic nervous system.[6]

Peripheral vascular resistance is a measure of friction between the vessel walls and fluid, and between the molecules of the fluid themselves, both of which oppose flow. When the resistance to flow increases, blood pressure must increase for the flow to remain constant. Resistance to blood flow increases with increased fluid viscosity or vessel length and decreased vessel diameter.

Viscosity is the physical property of a liquid. It is characterized by the degree of friction between its component molecules (e.g., between the blood cells and between the plasma proteins). Viscosity normally plays a minor role in blood flow regulation because it remains fairly constant in healthy persons. Vessel length in the human body also remains fairly constant. Vessel diameter is the main factor affecting the resistance to blood flow.

CRITICAL THINKING

How do firefighters use these principles of viscosity and vessel diameter when fighting a fire?

Major arteries are large. They offer little resistance to flow unless they have an abnormal narrowing (stenosis). Arterioles have a much smaller diameter than arteries. They offer the major resistance to blood flow. The smooth muscle in the arteriole walls can relax or contract, changing the diameter of the inside of the arteriole as much as fivefold. Thus the vasoconstriction or vasodilation of these vessels primarily regulates arterial blood pressure.

Fluid flows through a tube in response to pressure gradients between the two ends of the tube. The difference in

pressure between the two ends determines flow, not the absolute pressure in the tube. In many animals and human beings the two ends are the aorta and the venae cavae.

Systemic pressure (left-sided pressure) and pulmonic pressure (right-sided pressure) are the measurements of pressure in the vascular system. Systemic pressure, like pulmonic pressure, has two phases: systolic and diastolic. As described earlier, the difference between these two pressures is the **pulse pressure.** Pulse pressure reflects the tone of the arterial system. This pressure is greatest at its origin (the heart) and is least at its terminating point (the venae cavae). Pulse pressure is more sensitive to changes in perfusion than the systolic or diastolic pressures alone.

SHOW ME THE EVIDENCE

This retrospective look at trauma registry data evaluated prehospital systolic blood pressure (PSBP) and patient injury severity and mortality to determine if a threshold for trauma triage greater than the current 90 mm Hg should be considered. The authors reviewed 32,266 trauma patients seen at a level I trauma center from 1995 to 2003. Their findings suggest that mortality risk increased when the PSBP dropped below 110 mm Hg. The risk of death increased substantially when the PSBP was less than 100 mm Hg. They recommend further study to determine if the systolic blood pressure threshold for trauma triage should be altered based on these data.

MICROCIRCULATION

Microcirculation refers to circulation of blood from the heart to the arteries, capillaries, and veins. The microcirculation of the body is divided into *pulmonary microcirculation* and *peripheral microcirculation*. Separate pumps, the right side and left side of the heart, respectively, produce pressure in each of these divisions.

At any given moment, about 5% of the total circulating blood is flowing through the capillaries.[7] This 5% is exchanging nutrients and picking up the waste from cellular metabolism. The muscular arterioles are the major resistance vessels. They regulate regional blood flow to the capillary beds. The venules and veins serve as collecting channels and storage vessels. These are known as *capacitance vessels.* Capacitance vessels normally contain about 70% of the blood volume. The mechanisms that control blood flow to the tissues were described in Chapter 11 and include the following:

- Local control of blood flow by the tissues
- Nervous control of blood flow
- Baroreceptor reflexes
- Chemoreceptor reflexes
- Central nervous system ischemia response
- Hormonal mechanisms
- Adrenal-medullary mechanism
- Renin-angiotensin-aldosterone mechanism
- Vasopressin mechanism
- Reabsorption of tissue fluid

LOOK AGAIN

See Chapter 11: General Principles of Pathophysiology, pp. 238-240.

Lungs

Tissue cells require adequate oxygen to function. Adequate oxygen must be available to the red blood cells as they pass through the capillary membranes in the lungs. The high partial pressure of oxygen in inspired air, adequate depth and rate of ventilation, and matching of pulmonary ventilation and perfusion make adequate oxygenation possible.

CRITICAL THINKING

What might impair each of these components of adequate oxygenation?

THE BODY AS A CONTAINER

The healthy body can be viewed as a smooth-flowing fluid delivery system inside a container. The container must be filled to achieve adequate preload and tissue oxygenation. The external size of the container of any human body is relatively constant, yet the volume of the vascular component in the container is related directly to the diameter of the resistance vessels. This diameter can change rapidly. Any change in the diameter of the vessels changes the volume of fluid that the container holds. Thus this affects preload.

An example of this principle is a 5-L container. This is the normal container size for a 70-kg adult male (Figure 36-1). If the fluid volume is 5 L, preload is adequate. With a strong heart, cardiac output and perfusion also are adequate. If 2 L of this fluid has been lost, externally or internally, the 3 L that remain are inadequate to supply an effective preload. Because cardiac output depends on preload, a decrease in preload notably decreases cardiac output.

If the patient is hypovolemic and the 5-L container has remained the same size despite the 3-L volume, the patient becomes hypotensive or loses pressure in the container because of decreased cardiac output. However, if the container is reduced to 3 L by compensatory mechanisms (e.g., vasoconstriction), the 3-L container can provide adequate preload to the heart with the 3 L of available fluid. This is at the expense of certain tissues that are not perfused in this constricted state.

If fluid is adequate for a 5-L container but the container size has been enlarged to 7 L by illness or injury that results in vasodilation, the 5 L of fluid does not provide adequate preload for the container (**relative hypovolemia**). Factors that occasionally are responsible for vasodilation include cardiac and blood pressure medications,

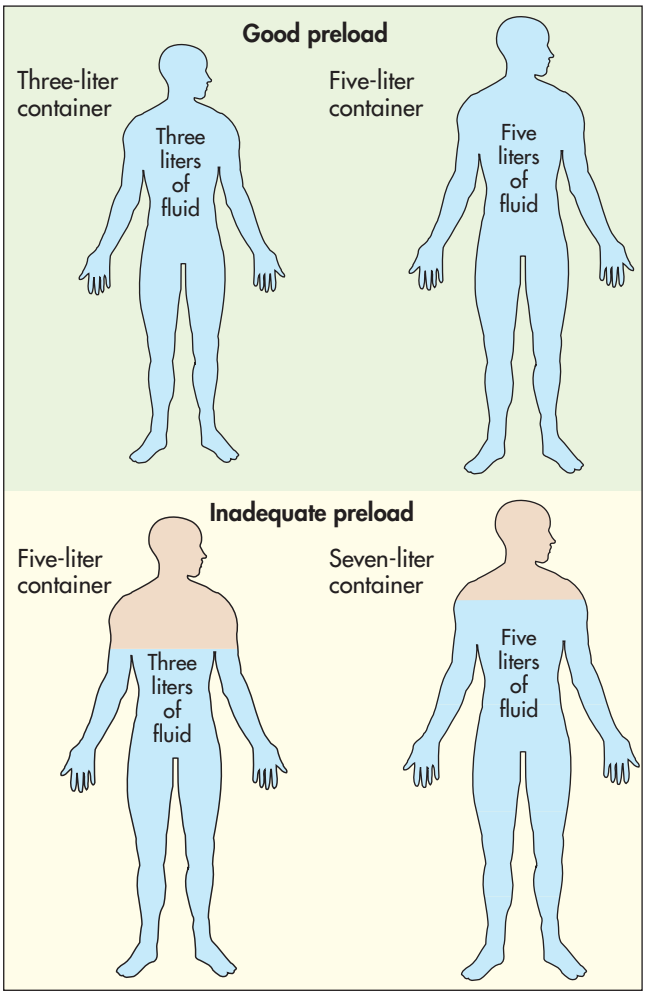

FIGURE 36-1 Fluid volume versus container volume.

allergic reaction, heat- and cold-related injuries, and alcohol or other drug use.

CAPILLARY-CELLULAR RELATIONSHIP IN SHOCK

The progression of shock in the microcirculation follows a sequence of stages related to changes in capillary perfusion and cellular necrosis (Figure 36-2).[1]

Stage 1: Vasoconstriction

In response to intravascular volume depletion (hypovolemia), the precapillary arterioles and postcapillary venules constrict. This constriction helps to maintain systemic blood pressure. Because of the narrowing of the entrance to the microcirculation, the velocity of blood passing through it increases. This leads to an increase in hydrostatic pressure in the capillaries and allows fluid to be reabsorbed into the circulation. Fluid is reabsorbed as it shifts from the extravascular space (*transcapillary refill*). As shock progresses, oxygen and nutrient delivery to the cells supplied by these capillaries decreases; anaerobic metabolism replaces aerobic metabolism; and production of hydrogen ions and lactate increases. Shortly thereafter, the lining of the capillaries can begin to lose the ability to hold large molecules within the capillary. Thus the capillary lining permits protein-containing fluid to leak into the interstitial spaces. This is known as the **leaky capillary syndrome.**

CRITICAL THINKING
If this leak persists, what effect will it have on preload and cardiac output?

Arteriovenous (AV) shunts open, particularly in the skin, kidneys, and gastrointestinal tract. The shunts cause less flow to the arterioles and thus less flow through the capillaries. Sympathetic stimulation produces pale, sweaty skin; a rapid, thready pulse (caused by hypovolemia and vasoconstriction); and an elevation in blood glucose level. The release of epinephrine dilates coronary, cerebral, and skeletal muscle arterioles and constricts other arterioles. As a result, blood is shunted to the heart, brain, and skeletal muscle. Moreover, capillary flow to the kidneys and abdominal organs decreases. The vasoconstriction stage of shock must be treated by prompt restoration of circulatory fluid volume. Otherwise, shock progresses to the next stage.

NOTE
Stage 1 of hypovolemic shock occurs when intravascular blood volume is decreased by about 15%. Blood pressure and heart rate usually are normal at this stage of compensation. This stage is reversible if the hemorrhage is controlled.

Stage 2: Capillary and Venule Opening

As shock progresses, the precapillary sphincter relaxes. This results in some expansion of the vascular space. Postcapillary sphincters resist the relaxation effects. Thus they remain closed. This causes blood to pool or stagnate in the capillary system. The capillaries become engorged with fluid. Arterial hypotension, secondary arteriolar vasoconstriction, and opening of arteriovenous shunts result in less blood flow through arterioles. These conditions also contribute to the stagnation of blood flow in the capillaries.

The vascular space expands greatly as increasing hypoxemia and acidosis lead to the opening of more venules and capillaries. When this occurs, even normal blood volume may be inadequate to fill the container. The capillary and venule capacity can increase to the point that the volume of available blood returning to the great veins and venae cavae is reduced. This in turn results in decreased venous return and a drop in cardiac output. In addition, the viscera (lungs, liver, kidneys, and gastrointestinal mucosa) can become congested with fluid. The low arterial blood pressure, extremely constricted arterioles, presence of

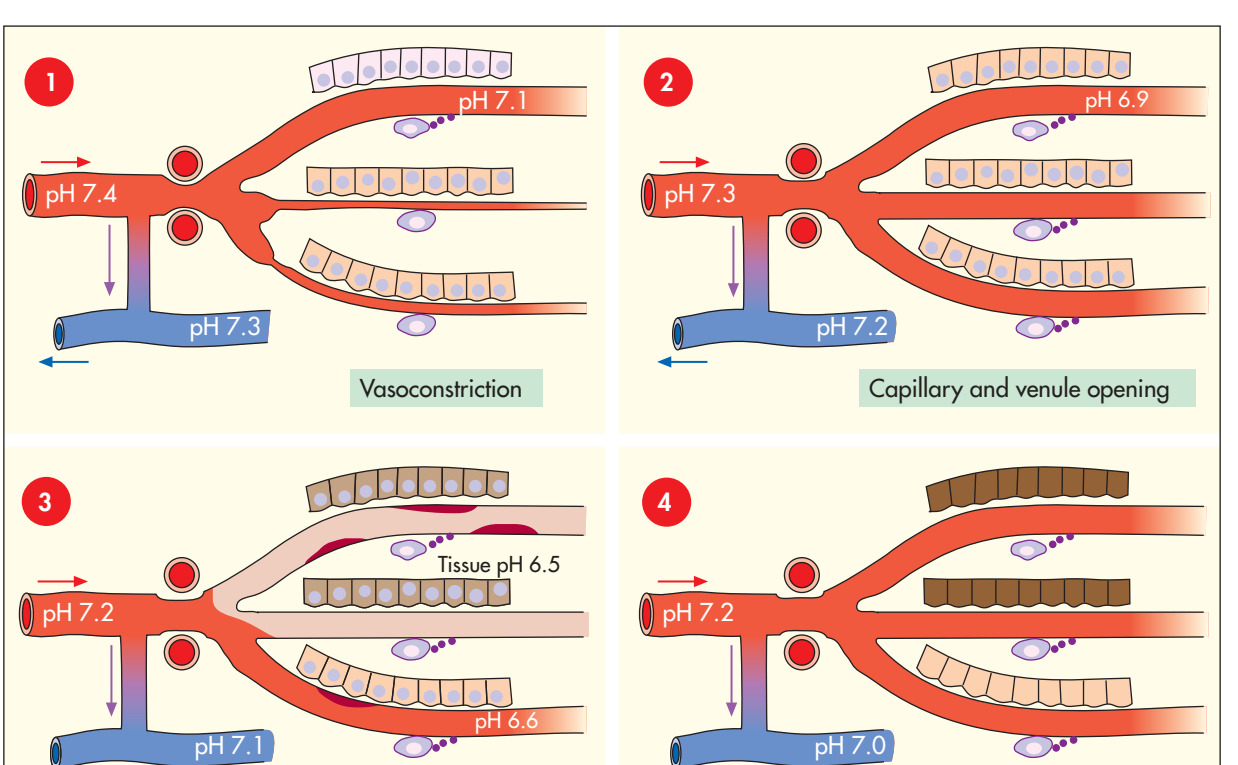

FIGURE 36-2 Diagram of the microcirculation in shock, progressing from (*1*) vasoconstriction, (*2*) capillary and venule opening, (*3*) disseminated intravascular coagulation, and (*4*) multiple organ failure. (Adapted from Hardaway R, editor: *Shock: the reversible stage of dying*, Littleton, Mass, 1988, PSG Publishing.)

arteriovenous shunts, and many open capillaries result in stagnant capillary flow.

CRITICAL THINKING
What happens to the function of the heart as acidosis increases?

Sluggish blood flow and a decrease in the amount of oxygen delivered to the cell result in cell metabolism occurring without oxygen (anaerobic metabolism). As described in Chapter 11, when tissue hypoxia is present, pyruvate oxidation decreases, lactate production increases, and adenosine triphosphate (ATP) formation continues via glycolysis. This results in metabolic acidosis. The respiratory system attempts to compensate for the acidosis by increasing ventilation to release carbon dioxide. This produces a partially compensated metabolic acidosis. As the acidosis increases and the pH decreases, the red blood cells may cluster. (This is known as *rouleaux formation*.) **Rouleaux formation** halts perfusion in the vital organ capillaries. In turn, this affects nutritional flow and prevents the removal of waste products of metabolism. Clotting mechanisms also are affected; this leads to hypercoagulability. This stage of shock often advances to the third stage if fluid resuscitation is inadequate or delayed. This stage also may progress if the shock state is complicated by trauma or infection (sepsis).

LOOK AGAIN
See Chapter 11: General Principles of Pathophysiology, pp. 227-230.

NOTE
Stage 2 of hypovolemic shock occurs with a 15% to 25% decrease in intravascular blood volume. Heart rate, respiratory rate, and capillary refill time are increased, and pulse pressure is decreased at this stage. Blood pressure readings may still be normal.

Stage 3: Disseminated Intravascular Coagulation

Stage 3 of shock is resistant to treatment. (This is **refractory shock**.) However, stage 3 shock is still reversible early on with fluid replacement and support of vital functions. Blood begins to coagulate in the microcirculation, clogging

capillaries. This is referred to as **disseminated intravascular coagulation.** Clumps of red blood cells may occlude the capillaries. This occlusion decreases capillary perfusion, prevents delivery of oxygenated substrates such as glucose, and prevents removal of metabolites. As a result, distal tissue cells switch to anaerobic metabolism, and lactic acid production increases.

As stage 3 of shock continues, lactic acid accumulates around the cell. The cell no longer has the energy needed to maintain homeostasis, or the balance to function normally. Water and sodium leak into the cell through the cellular membrane. Potassium leaks out. Lastly, the cells swell and die (also known as the *washout phase*). **Microinfarcts** (small areas of dead cells) develop in the organs. Microthrombi produce capillary congestion, fluid leakage, cell rupture, and hemorrhage. The pulmonary capillaries become permeable to fluid, which leads to pulmonary edema. The edema decreases the absorption of oxygen and results in possible alterations in carbon dioxide elimination. This can lead to acute respiratory failure or acute respiratory distress syndrome (described in Chapter 24). If shock and disseminated intravascular coagulation continue, the patient progresses to multiple organ failure.

NOTE
Stage 3 of hypovolemic shock occurs with a 25% to 35% decrease in intravascular blood volume. At this stage, hypotension occurs. This stage of shock usually requires blood replacement.

Stage 4: Multiple Organ Failure

The amount of cellular necrosis (death) required to produce organ failure varies with each organ. Cellular necrosis also depends on the underlying condition of the organ. Usually hepatic failure occurs first, followed by renal failure and heart failure. But if any given area of capillary occlusion persists for more than 1 to 2 hours, the cells nourished by that capillary undergo changes that rapidly become irreversible. In this stage of shock, blood pressure falls dramatically (to levels of 60 mm Hg or less). Even if blood pressure is returned to normal after a couple of hours, the ability of the cell to obtain energy through aerobic metabolism fails. Thus the cell dies from inadequate capillary perfusion. Inadequate tissue perfusion and cell death are the results of irreversible shock.

If cellular necrosis damages a critical amount of a vital organ, the organ soon fails. Failure of the liver and kidneys is common and often presents early in this stage. Capillary blockage can cause heart failure. Gastrointestinal bleeding and sepsis can result from gastrointestinal mucosal necrosis. In addition, pancreatic necrosis can lead to further clotting disorders and severe pancreatitis. Pulmonary thrombosis can produce hemorrhage and fluid loss into the alveoli. This can lead to death from respiratory failure.

NOTE
Stage 4 of hypovolemic shock occurs when intravascular blood volume is decreased by 35% to 40%.

CLASSIFICATIONS OF SHOCK

Many types of shock have been discussed in the medical literature. In emergency care, shock commonly is classified based on the initiating cause. (For example, the cause may be hypovolemia.) Although these classifications are separate and distinct, two or more types often are combined. For example, hypovolemia may occur in septic shock. Elements of cardiogenic shock may occur in hypovolemic shock. Regardless of the classification, the underlying defect is inadequate tissue perfusion. The following discussion is a brief overview of common classifications of shock. *Note:* A more detailed discussion can be found throughout this chapter by subject matter.

Hypovolemic Shock

In the United States, **hypovolemic shock** (shock that occurs from fluid loss) most often is caused by hemorrhage. Hypovolemic shock also can result from dehydration (commonly seen with severe diarrhea and vomiting). In either case, a loss of circulating volume occurs. Illnesses and injuries that can lead to hypovolemic shock include hemorrhage, burns, severe or prolonged diarrhea, vomiting, endocrine disorders, and internal third-space loss, as in peritonitis. In addition to loss of circulating volume, tissue injury resulting from trauma can worsen shock. Tissue injury causes microemboli and further activates the inflammatory and coagulation responses (Figure 36-3).

NOTE
Most patients with shock have hypovolemia. Thus shock is assumed to be hypovolemic in origin until it is proved otherwise. The paramedic should first manage the patient in shock by administering normal saline or lactated Ringer's solution (per protocol)[8] to stabilize blood pressure. This is the case unless the lungs are wet (identified by crackles). Crackles on physical examination indicate cardiogenic shock.

Cardiogenic Shock

Cardiogenic shock (described in Chapter 22) results when the cardiac pump cannot deliver adequate circulating blood volume for tissue perfusion. Cardiogenic shock can result from inadequate filling of the heart, poor contractility of the heart, and obstruction of blood flow from the heart to central circulation (Figure 36-4). The patient in cardiogenic shock usually suffers from an acute myocardial infarction, a serious cardiac rhythm disturbance, cardiac tamponade, tension pneumothorax, cardiac contusion, severe valvular heart disease, cardiomyopathy, pulmonary embolism, or dissecting aortic aneurysm. Cardiogenic shock occurs in 5% to 10% of patients hospitalized for myocardial infarction. The associated mortality rate in these patients approaches 80%.[9]

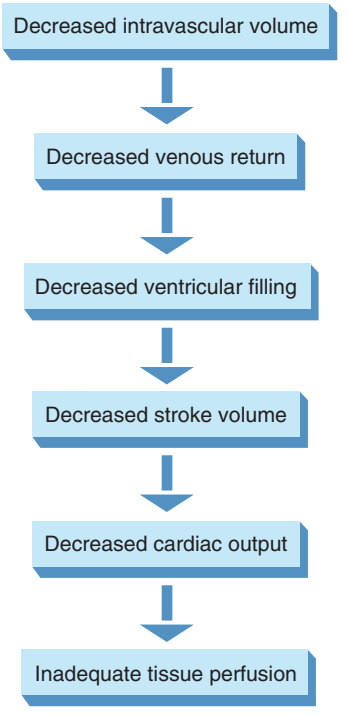

FIGURE 36-3 Pathophysiology of hypovolemic shock.

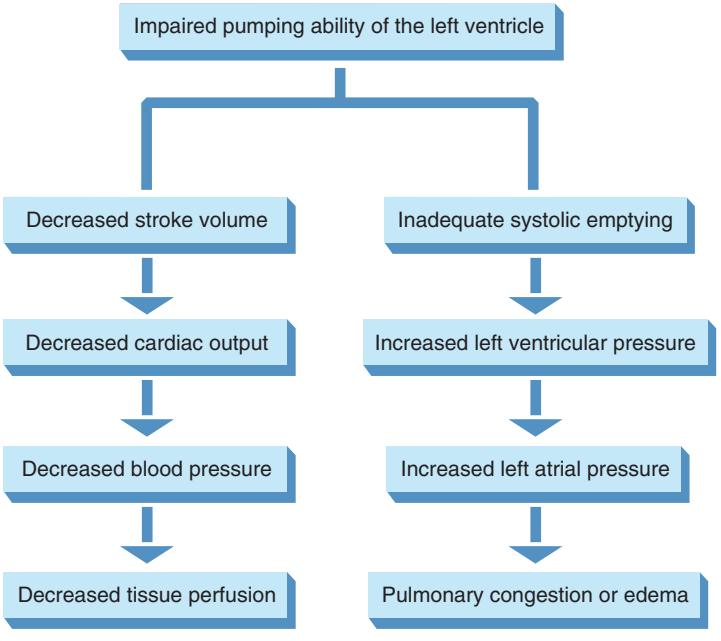

FIGURE 36-4 Cardiogenic shock.

NOTE

Cardiogenic shock that develops from extrinsic causes, such as cardiac tamponade, tension pneumothorax, or pulmonary embolism, is known as **obstructive shock.** This term is used because the common pathophysiology in these conditions is obstruction to blood flow. **Distributive shock** occurs when peripheral vasodilation causes a fall in systemic vascular resistance. The most common causes of distributive shock are septic shock, anaphylactic shock, and neurogenic shock.

CRITICAL THINKING

Why does cardiogenic shock develop in a patient who has had a severe myocardial infarction?

Neurogenic Shock

Neurogenic shock is also known as *spinal cord, distributive*, or *vasogenic shock*. Neurogenic shock results from vasomotor paralysis below the level of injury. Normal vasomotor tone through sympathetic nervous system control is lost. This results in a decrease in peripheral vascular resistance. The loss of sympathetic impulses causes vasodilation and increases the size of the container (so to speak) (Figure 36-5). Therefore, even normal intravascular volume is inadequate to fill the enlarged vascular compartment and perfuse the tissues. Because of the mechanism of injuries responsible for this syndrome, respiratory insufficiency, head injury, or both also may be present.

NOTE

Fainting may be due to mild, readily reversible vasogenic shock. This shock can occur in the absence of injury. This shock results from a temporary bradycardia and vasodilation that produce a drop in cardiac output.

Anaphylactic Shock

Anaphylactic shock (described in Chapter 27) occurs when the body is exposed to an antigen that produces a severe allergic reaction. To review, common causes include antibiotic agents (especially penicillins), venoms, and insect stings. The body responds to the release of histamine and other mediators. Histamine and other mediators act on receptors in the systemic and pulmonary microcirculation. They also produce an effect on bronchial smooth muscle. Histamine causes arterioles and capillaries to dilate and increases capillary membrane permeability. Intravascular fluid leaks into the interstitial space and results in a decrease in intravascular volume (Figure 36-6). In addition, many of the mediators released cause constriction of the upper and lower airways. This creates the potential for complete airway obstruction.

Septic Shock

Septic shock most often results from a serious systemic bacterial infection. Septic shock is thought to be caused by toxins that are a part of the microorganism (endotoxin: gram-negative sepsis) or are released by the organism (exotoxin: gram-positive shock). These toxins stimulate the release of complex vasoactive agents. The agents affect arterioles, capillaries, and venules. They alter pressure in the microcirculation and increase capillary permeability (Figure 36-7). Septic shock can result from staphylococcal and streptococcal infections, pneumonia, postoperative

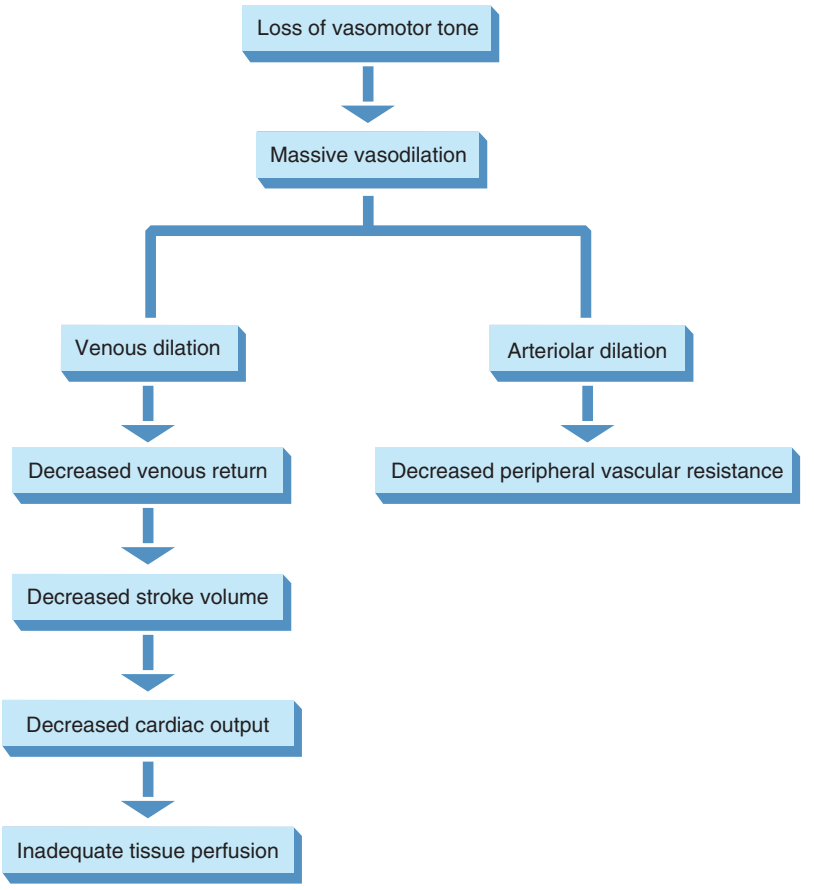

FIGURE 36-5 Pathophysiology of neurogenic shock.

infections, and infections from indwelling urinary catheters. Between 40,000 and 100,000 persons develop septic shock each year; septic shock is the leading cause of death in intensive care units.[10] Septic shock most often occurs in older adults (particularly nursing home residents), alcoholics, neonates, and patients who are immunosuppressed (e.g., patients with cancer, human immunodeficiency virus [HIV] infection, or sickle cell disease).

STAGES OF SHOCK

The degree of hypoperfusion and anaerobic metabolism can be categorized by stages of the response of the body to the shock syndrome. The three stages are (1) compensated shock, (2) uncompensated (or decompensated) shock, and (3) irreversible shock.[3] Table 36-1 lists the stages of shock and the signs and symptoms of each.

Compensated Shock

Compensated shock (Figure 36-8) is associated with some decreased blood flow and perfusion to the tissues. However, the compensatory responses of the body can overcome a decrease in available fluid. An increase in catecholamine production maintains cardiac output and a normal systolic blood pressure.

The decrease in perfusion and subsequent increase in acidosis lead to a chemoreceptor response. This response increases the rate and depth of ventilation. (This helps correct the acidosis by decreasing P_{CO_2}.) Sympathetic stimulation increases heart rate and contractility. In addition, it causes bronchodilation, leads to increases in peripheral vascular resistance, and decreases capillary flow in some capillary beds, such as the gastrointestinal tract. The patient may exhibit delayed capillary refill and cool skin as the blood is shunted from the skin to the vital organs. In spite of maintaining normal blood pressure and urinary output, some patients may show signs of decreased central nervous system (CNS) perfusion (lethargy, confusion, combativeness), even at this stage. If the underlying cause of shock is untreated, the compensatory mechanisms collapse.

Uncompensated Shock

Uncompensated shock (Figure 36-9) occurs when the body is no longer able to maintain systemic blood pressure. The systolic pressure usually drops before the diastolic pressure because the systolic pressure depends more on blood volume. Diastolic pressure may rise at first because of vasoconstriction. The decrease in systolic pressure, along with maintained or increased diastolic pressure, can lead to a

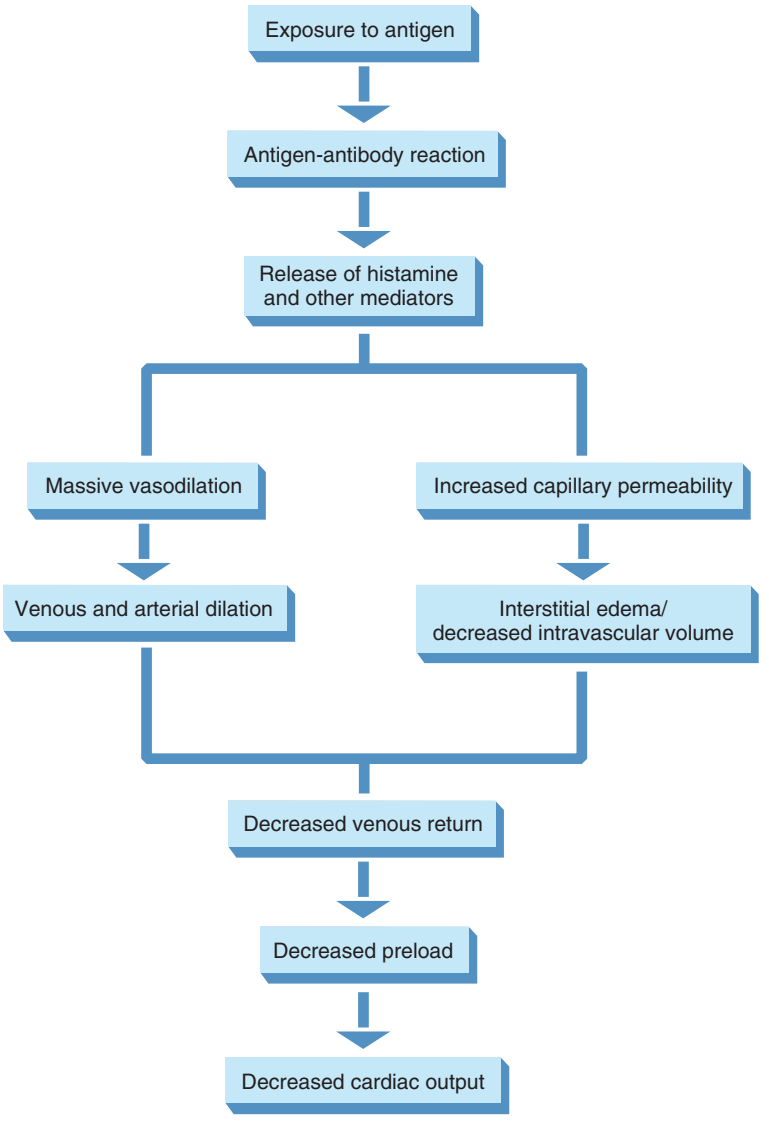

FIGURE 36-6 Pathophysiology of anaphylactic shock.

TABLE 36-1 Stages of Shock

	SIGNS AND SYMPTOMS		
Vital Signs	**Compensated Shock**	**Uncompensated Shock**	**Irreversible Shock**
Heart rate	Mild tachycardia	Moderate tachycardia	Bradycardia, severe dysrhythmias
Level of consciousness	Lethargy, confusion, combativeness	Confusion, unconsciousness	Coma
Skin	Delayed capillary refill, cool skin	Delayed capillary refill, cold extremities, cyanosis	Pale, cold, clammy skin
Blood pressure	Normal or slightly elevated measurement	Decreased systolic and diastolic pressure	Frank hypotension

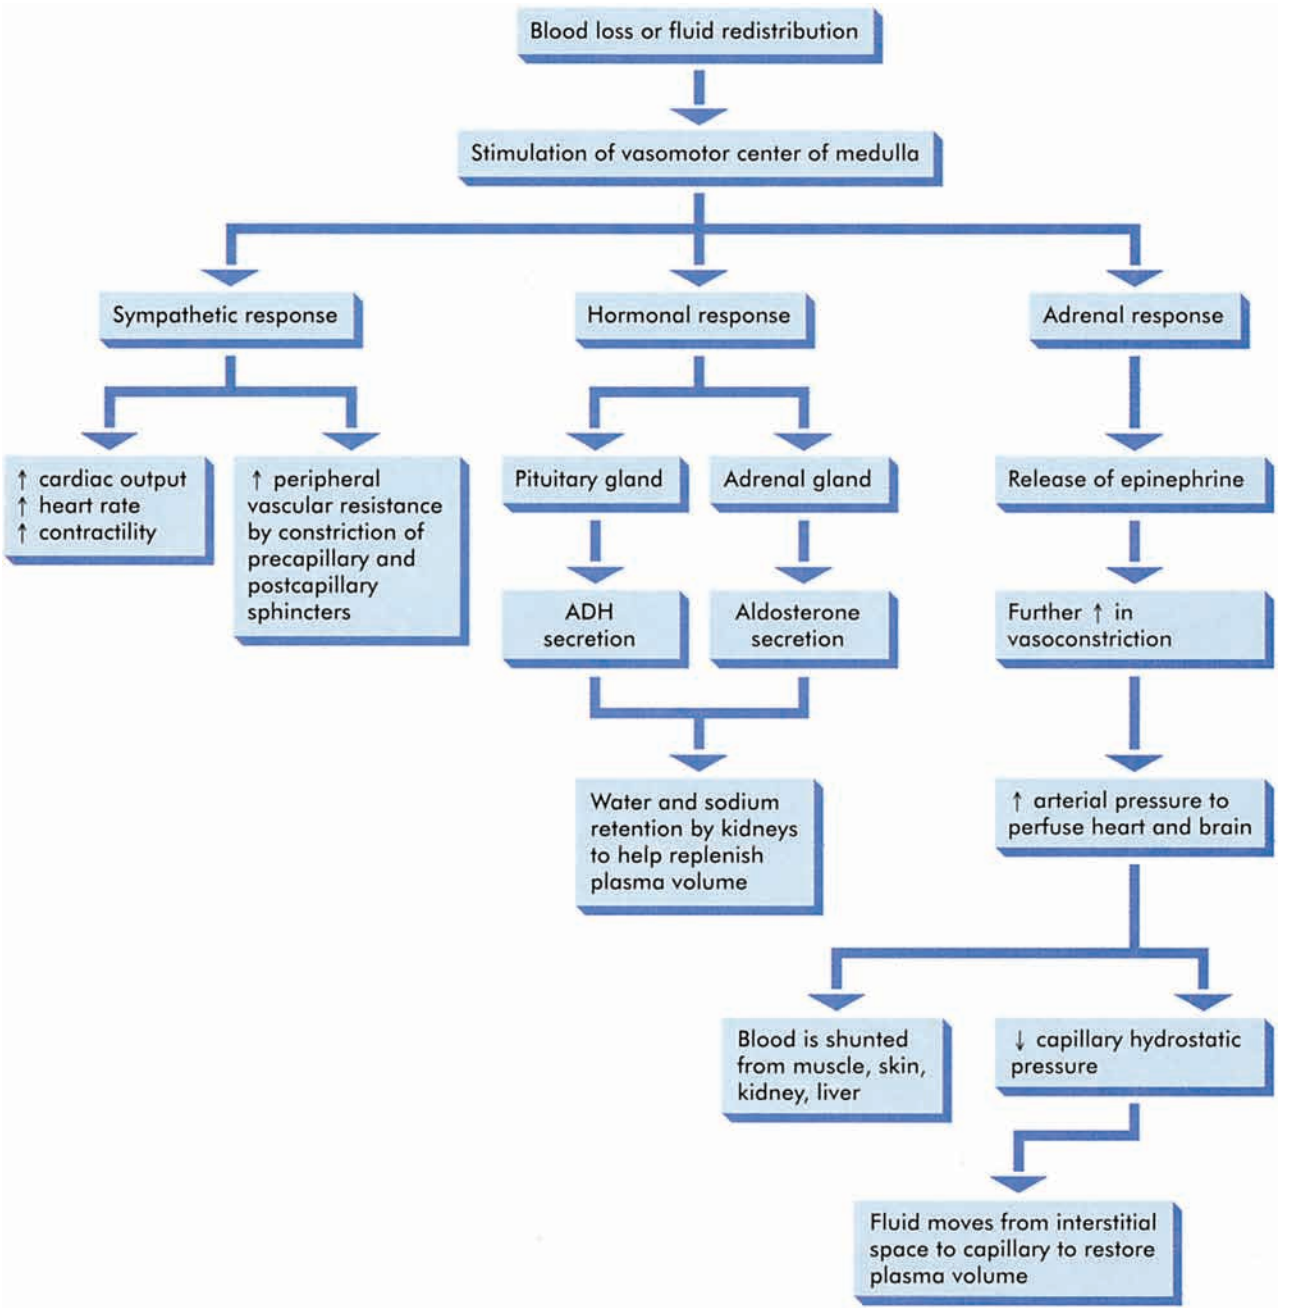

FIGURE 36-8 Compensated shock. This stage of shock is reversible.

narrow pulse pressure. The pulse pressure can be narrowed to such an extent that it is not detectable with a blood pressure cuff.

As the compensatory mechanisms of the body begin to fail, systolic and diastolic pressures drop and cerebral blood flow decreases. P_{O_2} may drop; however, P_{CO_2} usually remains normal or low unless the patient has a head or chest injury that leads to hypoventilation. The clinical signs of uncompensated shock include hypotension, tachycardia, tachypnea, delayed capillary refill, and decreased urinary output. Shunting of blood and tissue hypoxia may cause the patient to have cold extremities and cyanosis. Effects on the cardiovascular system include a decreased preload and an increased rate of contraction caused by catecholamine stimulation. Myocardial contractions initially can be stronger as a result of catecholamine release. However, in the latter phases of uncompensated shock, myocardial strength may decrease as a result of the following factors:

1. Ischemia can result from a reduction of circulating red blood cells, a lower oxygen saturation pressure (P_{O_2}), and decreased coronary perfusion because of hypotension (especially diastolic hypotension).

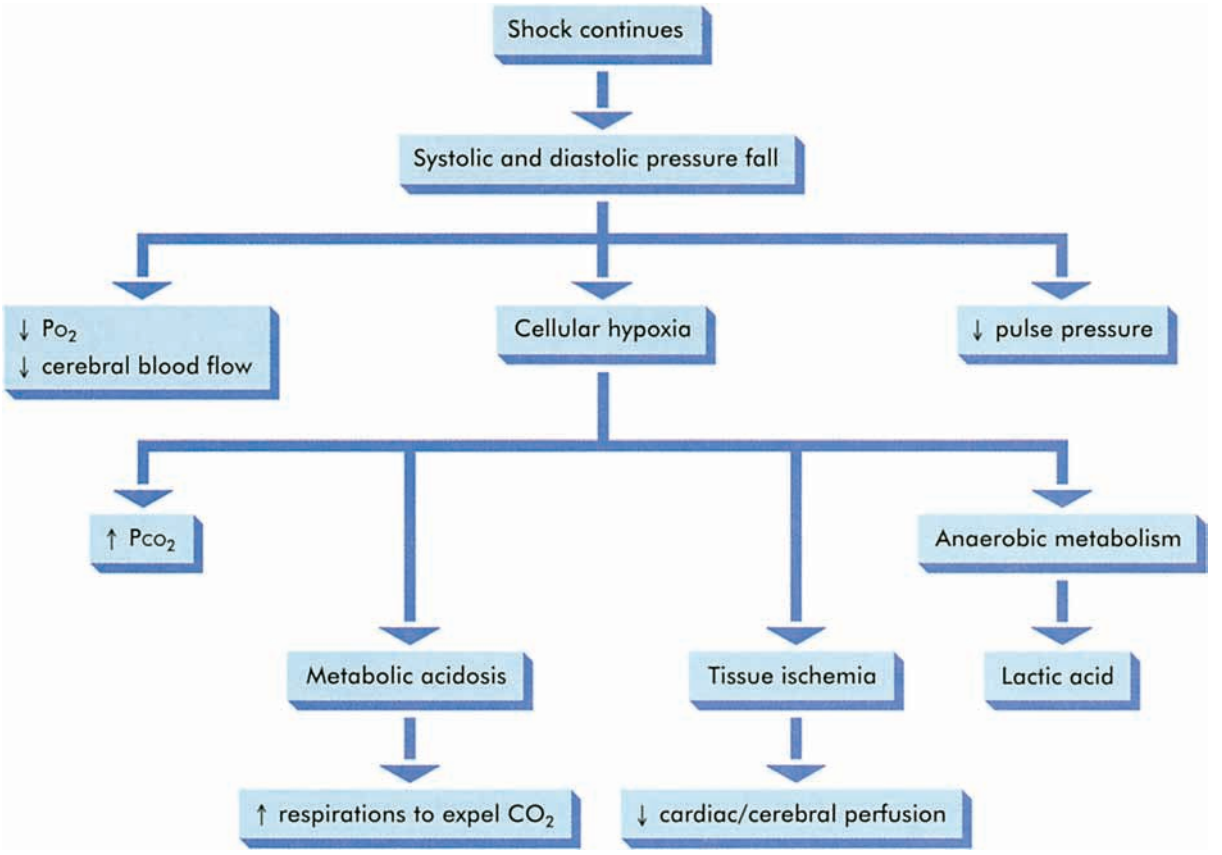

FIGURE 36-9 Uncompensated shock. This stage of shock is reversible.

2. Cardiodepressant substances (e.g., myocardial toxin released from the ischemic pancreas) can depress heart function in late shock.
3. Necrosis of myocardium (essentially simulating myocardial infarction) can result from associated ischemia.
4. Decreased preload can lead to decreased contractility.
5. Acidosis can lead to decreased contractility.
6. Cardiac rhythm disturbances can result from hypoxia.

Irreversible Shock

The progression of cellular ischemia and necrosis and subsequent organ death, even with oxygenation and perfusion restored, indicate **irreversible shock** (the third stage of shock) (Figure 36-10). Despite a return to normal perfusion, patients with irreversible shock as a result of massive cellular damage do not survive. Cells and the vital organs begin to die from the lack of energy. The membrane pumps fail. The various organelles in the cells sequentially break down. Thus necrosis is inevitable even if cell perfusion is restored.

Decompensation may occur suddenly or may be delayed from 1 day to 3 weeks after the onset of shock. The clinical signs of irreversible shock include bradycardia; serious dysrhythmias; frank hypotension; evidence of multiple organ failure; and pale, cold, and clammy skin. Cardiopulmonary collapse usually is imminent in these patients.

NOTE

During the prehospital management of shock, it is impossible to distinguish between uncompensated and irreversible shock. Therefore management of the shock victim should always focus on resuscitation. This is especially true because irreversible shock usually occurs over a longer period of time. Rapid resuscitation and transportation to an appropriate medical facility can prevent the development of irreversible shock. Fluid resuscitation in these patients should be guided by medical direction and established protocol.

Variations in Physiological Response to Shock

Many variations in physiological response occur among patients who are in shock. Determining factors include the following:

- Age
  - Older adults are less able to compensate
  - Children compensate longer but deteriorate faster
- General health
  - Preexisting disease
  - Other injuries
- Ability to activate compensatory mechanisms
- Medications, some of which can interfere with compensatory mechanisms
- Specific organ system(s) affected

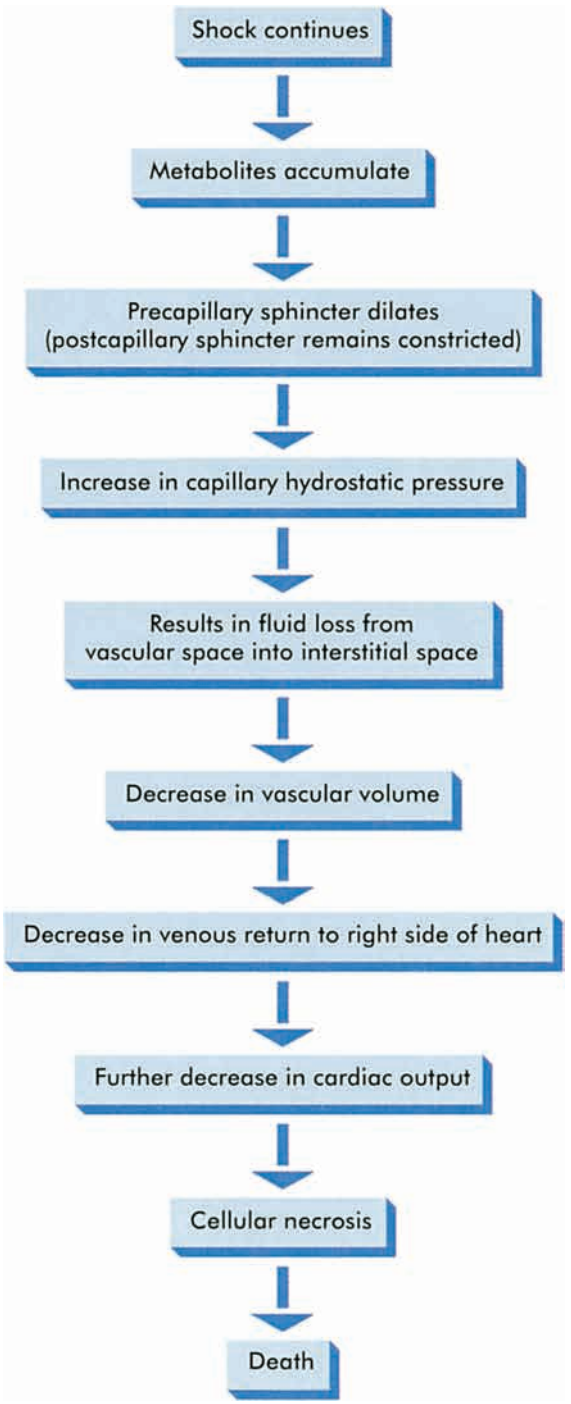

FIGURE 36-10 Irreversible shock.

CRITICAL THINKING
What diseases can influence a patient's response to shock?

MANAGEMENT AND TREATMENT PLAN FOR THE PATIENT IN SHOCK

The management and treatment plan for the patient in shock focuses on assessment of oxygenation and perfusion of the body organs. The goals of the treatment plan are to ensure a patent airway, to provide adequate oxygenation and ventilation, and to restore perfusion.

Primary Survey

The primary survey can help to identify whether cell perfusion is adequate. The following five-step description of the primary survey focuses on evaluating the shock victim, but the paramedic should be aware of common objectives in evaluating any patient with other types of serious illness or injury:

1. *Airway*. The airway must be opened and patency must be maintained to ensure adequate air movement.
2. *Breathing*. The respiratory pattern often reflects the adequacy of ventilation. Respiration can offer clues to the presence of shock. For example, if the patient is acidotic, the rate and depth of ventilation increase in an attempt to reduce carbon dioxide content of the blood and compensate for the metabolic acidosis. Pulse oximetry should be closely monitored.
3. *Circulation*. The paramedic should assess the patient's circulatory status. The first step is to check the patient for any uncontrolled arterial bleeding. In cases of external hemorrhage, applying direct pressure almost always helps to control bleeding. If direct pressure does not immediately control vigorous bleeding in an extremity, a tourniquet should be applied. (See Chapter 38 for methods to control external bleeding.) This usually will control external hemorrhage until the patient can be taken to the emergency department for definitive care. Pressure dressings can be applied to maintain control of hemorrhage. (Examples of such are bandages or a pneumatic antishock garment [PASG], per protocol.) If the paramedic suspects internal bleeding, after securing the airway and ensuring adequate ventilation, rapid transport to a proper facility is the highest priority. Internal bleeding should be suspected in any trauma patient with signs of shock, especially trauma patients without evidence of external blood loss. Treatment for internal hemorrhage must be directed at definitive care to stop the bleeding. Thus rapid transport to a proper facility is critical. Intravenous fluid therapy, if initiated in the field, should be performed en route to avoid a delay of definitive care.

CRITICAL THINKING
Consider a patient with early signs and symptoms of shock. However, the patient's SaO_2 reading is normal. Should you administer oxygen?

The paramedic should evaluate the rate, character, and location of the patient's pulse as part of the circulatory assessment. Pulse rates increase fairly early in shock. The increase helps to maintain an adequate cardiac output. The strength of contraction also may increase. However, both of these attempts to maintain cardiac output may be negated by the decrease in preload. Tachycardia usually will

not occur until the patient has suffered a 10% to 15% volume depletion (relative to container size) as a result of blood loss or an increase in container size. The character of the pulse can be strong or weak. The strength of the pulse provides an estimate of the filling volume of the artery being palpated and an indirect measurement of systolic pressure.

Tissue perfusion sometimes can be estimated by evaluating the color, moisture, and temperature of the skin. These guidelines, however, can be unreliable in older patients and in those who have been exposed to extremes of temperature. They also can be unreliable in those suffering from septicemia and shock caused by neurological injury. An evaluation of the fingers and toes (the most distal points of circulation) is crucial. These areas can be the first to show signs of inadequate tissue perfusion (cyanosis, cool skin). If ambient temperatures are moderate and tissue perfusion is adequate, these areas will be pink, warm, and dry.

The capillary refill test (described in Chapter 19) can offer useful details on the pediatric patient's tissue perfusion. These measurements should be used only as a guide. The accuracy of this test can be affected by the environment and by the patient's general health, age, and gender.

LOOK AGAIN

See Chapter 19: Primary Assessment, pp. 508-509.

4. *Disability*. The evaluation of the patient's level of consciousness is crucial in assessing cerebral oxygenation. The patient can become restless, agitated, and confused as cerebral ischemia develops. In addition to shock, cerebral edema and intracranial hemorrhage from head injury can compromise cerebral perfusion. Any significant change in the patient's sensorium should be considered an indicator of a critical perfusion deficit. This is true whether the decrease in cerebral circulation is from shock or from an increase in intracranial pressure. The paramedic can measure the patient's level of consciousness with the AVPU scale or other evaluation methods (see Chapter 40).

NOTE

Some authorities believe that the level of consciousness and other indicators of adequate brain functions are the best way to determine appropriate blood pressure for the trauma patient. They contend that the brain is the organ most sensitive to changes in physiological state. The goals of this patient-focused method of shock management are to ensure that systolic pressure is at least 90 mm Hg and that the patient has positive peripheral pulses and is awake or responsive to stimuli.[8]

5. *Exposure of the body surfaces*. The paramedic should expose the body surfaces in the primary survey as indicated by scenario or mechanism of injury. A visual inspection can reveal conditions that may be life threatening. These conditions can be hidden by clothing.

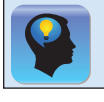
Differential Shock Assessment Findings

Shock is assumed to be hypovolemic until it is proved otherwise. However, assessment findings that can help the paramedic to differentiate between hypovolemic shock and other causes of shock include the following (Figure 36-11):

1. *Cardiogenic shock*. The patient often has a chief complaint of chest pain, dyspnea, or extreme heart rates (tachycardia, bradycardia, and other dysrhythmias). Some patients also show signs of congestive heart failure such as jugular vein distention (described in Chapter 22 and 42).
2. *Distributive shock* (neurogenic shock, anaphylactic shock, septic shock). The patient's history or scene assessment may reveal a mechanism that suggests vasodilation as the cause of the shock state. Signs and symptoms of distributive shock that are unusual in the presence of hypovolemic shock include warm, flushed skin (especially in dependent areas). Those of neurogenic shock include a normal pulse rate (*relative bradycardia*).
3. *Obstructive shock* (caused by obstruction to blood flow). These patients often are the victims of a major chest injury (usually a penetrating type of injury). Or they have a history that is consistent with pulmonary embolism. (For example, they have had a recent surgery or long bone fracture.) Patients with cardiac tamponade or tension pneumothorax often have jugular vein distention. Also, patients with tension pneumothorax almost always have decreased breath sounds on the affected side (see Chapter 42).

Detailed Physical Examination

As discussed, the first action is the primary survey and management of any life-threatening conditions. Then the paramedic should evaluate the patient further. A systematic approach offers a way to evaluate potentially life-threatening conditions and allows the paramedic to further assess the patient's perfusion status. This assessment should begin with baseline measurements of the patient's vital signs and evaluation of the patient's electrocardiogram.



CRITICAL THINKING

Can blood donation cause a fluid deficit large enough to cause shock? If so, how is that fluid deficit managed?

The paramedic should expect the pulse rate to increase above normal limits after fluid volume drops 10% to 15%. Some patients continue to have normal pulse rates even though a volume deficit of this extent exists. Thus the patient's pulse rate should be only one factor in evaluating the patient's level of perfusion.

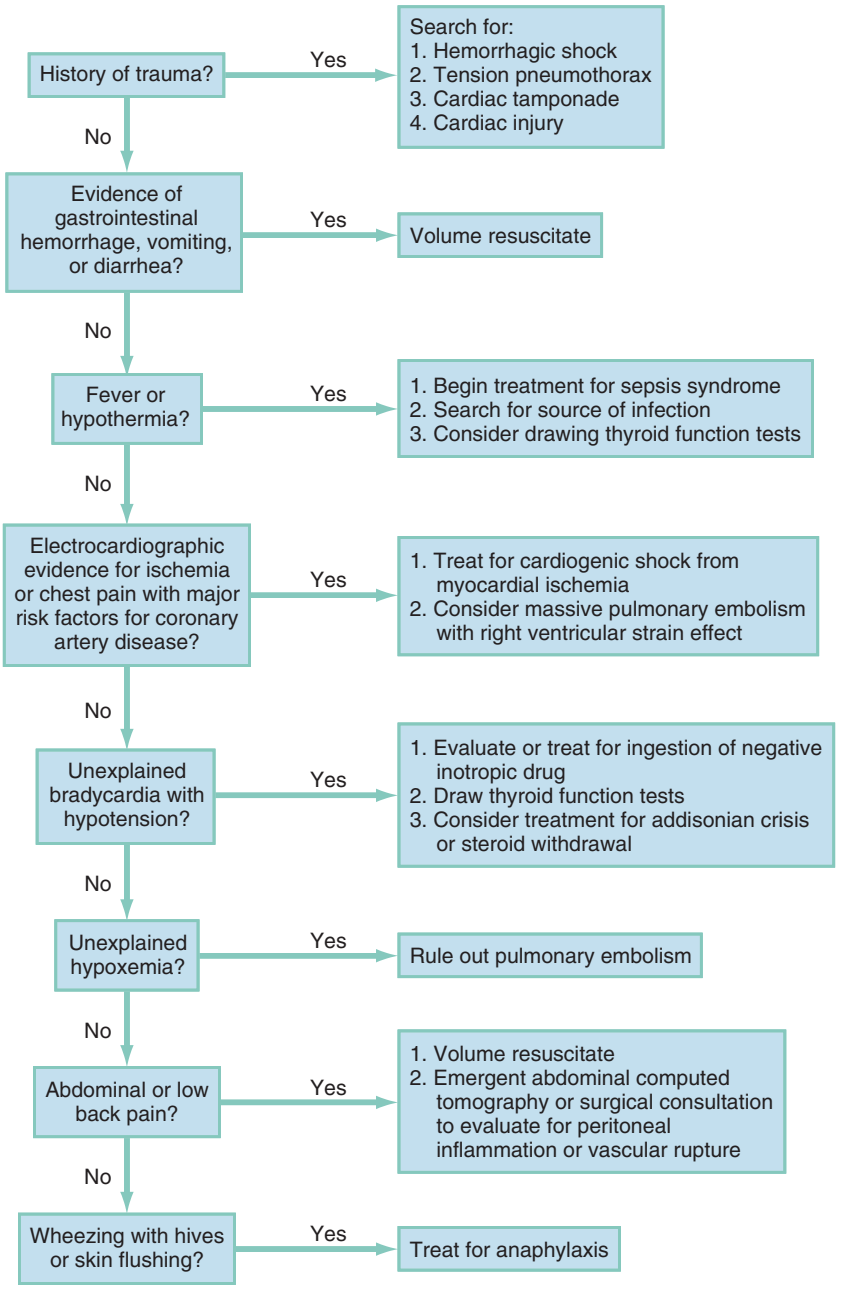


FIGURE 36-11 Flow diagram to classify undifferentiated shock. (From Marx J, et al: *Rosen's emergency medicine: concepts and clinical practice*, ed 6, St Louis, 2006, Mosby.)

Bradycardia, which can result from hypoxemia, existing neurological injury, increased vagal tone, preexisting illness, or prior medication use, also can indicate severe myocardial ischemia (a primary cause of cardiogenic shock). Bradycardic rhythms often occur just before cardiac arrest. If the rhythm is bradycardic, the paramedic should optimize oxygenation by increasing the fraction of inspired oxygen (FiO_2) and by assisting ventilations if needed.

The diastolic pressure at first rises as peripheral vascular resistance increases with increased vascular tone. These changes decrease the container size. Blood also is shunted away selectively from certain portions of the body. When the heart can no longer pump blood to keep the container full on the arterial side, the diastolic pressure begins to drop. The paramedic should expect this when blood loss is greater than 20% to 25% of normal circulating blood volume.

The systolic pressure falls when the heart can no longer pump enough blood to fill the container at the end of cardiac contraction. Systolic pressure usually is more sensitive to volume depletion than is diastolic pressure. Therefore systolic pressure drops first. However, as the fluid deficit approaches 25%, systolic and diastolic pressures both begin to drop.

The paramedic should consider evaluation of orthostatic vital signs in conscious patients suspected of having lost circulating blood volume. This evaluation should only be performed in the absence of suspected spinal injury or another condition that precludes this assessment. As discussed in Chapter 20, a change from a recumbent position to a sitting or standing position that is associated with a decrease in systolic pressure (after 1 minute) of 10 to 15 mm Hg or a concurrent rise in pulse rate (after 1 minute) of 10 to 15 beats per minute indicates a significant (at least 10%) volume depletion (postural hypotension) and a decrease in perfusion status.

A fluid deficit still can exist even after the systolic pressure returns to normal following fluid replacement. However, continuing IV fluids after indicators of adequate tissue perfusion are present (e.g., improved skin color, capillary refill time of less than 2 seconds in pediatric patients, and normal pulse oximetry readings) is controversial. Aggressive fluid resuscitation can result in **hemodilution** (diluting the blood of elements), the disruption of clots, and renewed hemorrhage.[8] As a rule, patients who have suspected internal hemorrhage in their chest, abdomen, or pelvis should have fluids titrated to maintain a systolic blood pressure of 90 mm Hg (MAP of 60 to 65 mm Hg). This *permissive hypotension* can be protective and may prevent further blood loss. The paramedic should follow local protocol established by medical direction.

RESUSCITATION

Resuscitation of the shock victim is aimed at restoring adequate peripheral tissue oxygenation as quickly as possible. As previously stated, this is accomplished by ensuring adequate oxygenation, maintaining an effective ratio of volume to container size, and rapidly transporting the victim to an appropriate medical facility.

FIGURE 36-12 Jobst Gladiator shock suit. (Courtesy Jobst Institute, Inc., Toledo, Ohio.)

NOTE
The over-resuscitation of trauma patients can occur. In patients with closed head injury or pulmonary or cardiac contusion, one must avoid fluid overload. As stated before, medical direction and protocol should guide fluid resuscitation for the shock patient.

Red Blood Cell Oxygenation

Adequate oxygenation of red blood cells is required for adequate tissue oxygenation. For red blood cell oxygenation to be adequate, the patient must have a patent airway. Ventilation also must be supported with a high fraction of inspired oxygen. If needed, the paramedic can assist ventilation with positive pressure. Any abnormality that interferes with adequate ventilation should be corrected if possible. Examples include obstructed airway, pneumothorax, hemothorax, open chest wound, and an unstable chest wall (see Chapter 42).

Ratio of Volume to Container Size

The second component necessary to maintain adequate oxygen-carrying capacity requires that the container be full of fluid. The paramedic can achieve this by decreasing the size of the container. This is especially the case in shock states not associated with hemorrhage. In addition, in some cases of distributive shock, vasoconstricting drugs can be used to manage the shock when reduction of container size is the main concern. Volume replacement also may be necessary in these patients. One should note that vasoconstricting drugs are not recommended to treat patients in hypovolemic shock until fluid volume replacement is complete. Complete volume replacement rarely occurs in the prehospital setting.

Pneumatic Antishock Garment

The **pneumatic antishock garment** (PASG) (Figure 36-12) is thought by some to be effective in managing shock. The theory is that when the PASG is applied to the legs and abdomen, pressure is transmitted directly through the skin, fat, muscle, and other soft tissues to the blood vessels themselves. Hemorrhage is then controlled in a similar fashion as any other compression device or bandage.[8] The PASG device may be useful in managing hemorrhagic shock with hypotension (a systolic blood pressure <90 mm Hg) in cases of:

- Suspected pelvic fracture
- Suspected intraperitoneal hemorrhage
- Suspected retroperitoneal hemorrhage

Decisions to use the PASG are left to local protocol and medical direction. However, penetrating thoracic trauma, evisceration of abdominal organs, impaled objects in the abdomen, pregnancy, traumatic arrest, and coexisting medical conditions (congestive heart failure, pulmonary edema) generally are considered contraindications for the PASG.[8] The PASG is also not recommended as a splinting device for isolated lower extremity fractures in the absence of shock.[8]

GENERAL PNEUMATIC ANTISHOCK GARMENT GUIDELINES

The paramedic should apply the PASG when indicated after the lower extremities and abdomen have been inspected for major wounds. The garment must always be positioned below the level of the patient's lowest rib. The patient's blood pressure and lung sounds should be monitored before, during, and after inflation. Inflation is stopped when an adequate blood pressure has been obtained. The compartments are inflated before or with the abdominal compartment. *The paramedic should never inflate the abdominal section before inflating the leg sections*. Doing so can cause the abdominal compartment to act as a constrictive band that reduces venous return from the legs.

CRITICAL THINKING

Consider that the abdominal compartment of the pneumatic antishock garment is inflated mistakenly before the leg segments. What effect can this have on cardiac output?

After PASG inflation the garment should seldom if ever be deflated in the prehospital setting and only with a physician's direction. The abdominal section is deflated before the leg sections. The patient should be monitored closely during the deflation process. Removal of the garment before fluid replacement commonly results in a rapid fall of blood pressure and cardiac output, which can lead to cardiac arrest.

Changes in temperature and atmospheric pressure can cause a notable change in the pressure within the PASG. The paramedic should monitor the patient constantly when the patient is moved from a cold environment to a warm one or when transported by air. The relationship among temperature, atmospheric pressure, and pressure within the PASG is as follows:

- A rise in temperature raises the pressure within the PASG; a fall in temperature decreases the pressure.
- A fall in atmospheric pressure causes an increase in PASG pressure; a rise in atmospheric pressure produces a decrease in garment pressure.

The PASG is not without complications even with appropriate use. Sustained inflation of the garment for more than 1 to 2 hours can lead to decreased tissue perfusion, ischemia of the underlying tissues, and loss of the limb, even without underlying fracture.

Fluid Resuscitation in Shock

Almost every shock victim, except for patients in cardiogenic shock, requires volume expanders as part of resuscitation. The selection of intravenous (IV) fluids for initial volume replacement varies according to medical direction. In prehospital care, the most common emergency requiring fluid replacement is loss of volume caused by hemorrhage or dehydration. The type of fluid replacement needed depends on the nature and extent of the volume loss. The two main categories of fluids used in resuscitation are crystalloids and colloids. The paramedic should follow the recommendations for fluid resuscitation provided by medical direction.

CRYSTALLOIDS

Crystalloid solutions are created by dissolving crystals such as salts and sugars in water. These solutions do not have as much osmotic pressure as colloid solutions. They can be expected to equilibrate more quickly between the vascular and extravascular spaces. Two thirds of the infused crystalloid fluid leaves the vascular space within 1 hour. So 3 mL of a crystalloid solution is needed to replace 1 mL of blood. Examples of crystalloid solutions are lactated Ringer's solution, normal saline, and glucose solutions in water.

Hypertonic solutions have higher osmotic pressure than that of body cells. They include 5% dextrose in 0.9% sodium chloride, 7.5% saline, and 5% dextrose in 0.45% sodium chloride. Hypotonic solutions have a lower osmotic pressure than that of body cells (e.g., distilled water and 0.45% sodium chloride).

Lactated Ringer's solution is the fluid of choice for resuscitating patients in shock.[8] The solution is well balanced and contains many of the chemicals found in human blood. Lactated Ringer's solution contains sodium chloride, small amounts of potassium and calcium, and 28 mEq of lactate, which can act as a buffer to neutralize acidity when metabolized by the liver. One third of the infused solution remains in the vascular space after 1 hour.

Normal saline contains 154 mEq/L of sodium. Normal saline has no buffering capabilities. Although preferred by some physicians, the higher chloride content of normal saline is less desirable than the more balanced lactated Ringer's solution. As in lactated Ringer's solution, nearly one third of the infused normal saline remains in the vascular space after 1 hour. This makes it an equally effective volume expander. Paramedic should follow local protocol when choosing IV fluids.

Glucose-containing solutions (e.g., 5% dextrose in water) have immediate volume expansion effects. However, the glucose leaves the intravascular compartment rapidly with a resultant free water increase. The volume-replacement benefits of glucose solutions only last 5 to 10 minutes while the glucose is metabolized. Thus 5% dextrose in water should not be used to replace a volume deficit. Glucose solutions most often are used to maintain vascular access for administration of IV medications.

NOTE

Five percent dextrose in water is an isotonic solution. When administered, however, the dextrose molecules leave the circulation so rapidly that its effect is that of a hypotonic solution.

COLLOIDS

Colloid solutions contain molecules (usually protein) that are too large to pass through the capillary membrane. These solutions exhibit osmotic pressure. They remain within the vascular compartment for a considerable time. Examples of colloid solutions are whole blood, packed red blood cells, blood plasma, and plasma substitutes. Colloids generally are reserved for in-hospital use and are not recommended for prehospital management of shock.[8]

Whole blood replacement is rarely given in the United States for management of shock and is usually unavailable in the emergency department. Rather, packed red cells are transfused, and other blood components are transfused as necessary. (Packed red blood cells have a volume of hemoglobin per unit that is almost twice that of whole blood.) In addition, because there is no plasma in packed red cells, circulatory overload is less likely and transfusion reactions are less frequent.

A type and crossmatch should be obtained when possible before a patient is given blood products to determine the patient's ABO group and Rh type (described in Chapter 11). Typing and crossmatching also will determine whether other antibodies are present that may cause a transfusion reaction. Type-specific blood should be used for resuscitation when the patient's condition and time permit. However, uncrossmatched blood is usually given immediately for patients with hypotension and uncontrolled hemorrhage.[11] Group O universal donor blood does not have A or B antigens on their surface; they are not agglutinated by anti-A or anti-B antibodies. O-negative blood is used for women of childbearing age who are at risk for Rh complications with future pregnancies. O-positive blood is used in all other patients.

LOOK AGAIN

See Chapter 11: General Principles of Pathophysiology, pp. 245-246.

NOTE

Several types of blood transfusion reactions may occur during or up to 96 hours after infusion. Symptoms may range from mild fever to life-threatening shock. If a reaction is suspected (e.g., during an interhospital transfer), the paramedic should stop the transfusion and contact medical direction. The blood bag or tubing should not be discarded.

Blood plasma may be given without concern for ABO compatibility. Blood plasma contains fibrinogen, albumin, gamma globulins, *hemagglutinins* (an agglutinin that clumps red blood corpuscles), prothrombin (a chemical that is part of the clotting cascade, further described in Chapter 38), other clotting factors, sugar, and salts. Blood plasma sometimes is used to restore effective blood volume in circulatory failure associated with burns, traumatic shock, and hemorrhage. Blood plasma more commonly is used to correct clotting deficiencies. It is often supplied as *fresh frozen plasma*.

Plasma substitutes do not increase oxygen-carrying capacity by replacing red blood cells. They also do not improve clotting by the addition of plasma protein. Yet at times they are used to restore circulating blood volume as an emergency treatment for hypovolemia caused by blood loss. Plasma substitutes such as dextran and hetastarch have osmotic properties similar to those of plasma. Thus they stay in the intravascular space longer than crystalloid solution. Plasma substitutes do not carry the human immunodeficiency virus or hepatitis viruses. They also do not require typing and crossmatching before administration. They are readily available as well. Plasma substitutes do have some adverse effects, including increased bleeding tendencies and immune suppression. Emergency vehicles can carry plasma substitutes, but expense and storage issues make them impractical for general use in the prehospital setting.

NOTE

Oxygen-carrying blood substitutes (e.g., PolyHeme) are being studied. They may have future application in prehospital care for severely injured patients. These solutions contain hemoglobin from red blood cells (treated to destroy viruses). In addition, they are compatible with all blood types. They do not require refrigeration and can be stored up to several months.

Theory of Fluid Flow

The flow of fluid through a catheter is related directly to its diameter (to the fourth power) and inversely related to its length. Therefore, a catheter with a large diameter has a much greater flow rate than a catheter with a small diameter. This also means that short catheters provide faster flow rates than longer catheters of equal diameter. Other factors that affect the flow of fluid include the diameter and length of the tubing, the size of the vein, the height of the fluid bag, and the viscosity and temperature of the IV fluid. (Temperature affects viscosity; warm fluids generally flow better than cold ones.) Pressure bags are available that pressurize the IV system to 300 mm Hg to maximize the rate of fluid administration. Table 36-2 lists the maximum rate of fluid flow for various gauges of 2-inch Medicut catheters without pressure on the bag at a height of 1 m above the patient.[12] When aggressive fluid resuscitation is indicated, the paramedic should do the following:

- Use short, large-diameter catheters.
- Use warm fluids of low viscosity (if possible).
- Keep the tubing short, and pressurize the IV system.

CRITICAL THINKING

Aside from improved flow, what other benefits do warmed fluids offer for the patient in shock who needs a large-volume fluid bolus?

TABLE 36-2 Needle Gauges and Maximum Fluid Flow

Needle Gauge*	Maximum Fluid Flow
18 gauge	4.81 L/hr or 80 mL/min
16 gauge	7.45 L/hr or 124 mL/min
14 gauge	9.67 L/hr or 161 mL/min

*Inside diameter.

Key Principles in Managing Shock

The paramedic should follow these key principles as part of the plan for managing shock (Figure 36-13):

1. Establish and maintain an open airway.
2. Administer high-concentration oxygen. Assist ventilation as needed.
3. Control external bleeding (if present).
4. By order of medical direction or per protocol, initiate IV fluid replacement if appropriate. Two large-bore IV lines of a volume-expanding fluid commonly are established in cases of hypovolemia. *The IV administration of fluids in the prehospital setting should not delay patient transportation because crystalloid solutions cannot restore the oxygen-carrying capacity of blood.* Generally, the patient is best served by rapid assessment, airway stabilization, immobilization, and rapid transportation to an appropriate medical facility. Many emergency medical services authorities recommend that IV therapy for shock resuscitation be initiated en route to the hospital.
5. Consider the use of a PASG (per protocol).
6. Maintain the patient's normal body temperature. Patients in shock often are unable to conserve body heat. They can become hypothermic easily.
7. Transport the patient in the supine position, immobilized on a long spine board.
8. Monitor cardiac rhythm and oxygen saturation.
9. Frequently reassess vital signs en route to the emergency department.

MANAGEMENT OF SPECIFIC FORMS OF SHOCK

In addition to the general management appropriate for all shock victims, certain management guidelines are specific to each shock classification (Box 36-2).

Hypovolemic Shock

The management of hypovolemic shock is not considered complete until the volume is replaced and the cause or causes of shock are corrected. This includes crystalloid fluid replacement in cases of simple dehydration or volume replacement because of hemorrhage, definitive surgery, critical care support, and postoperative rehabilitation. The amount of fluid replaced in trauma is controversial and should be guided by medical direction.

Trauma patients who are stable should not receive aggressive fluid resuscitation.[8] The volume of fluid that should be given to trauma patients will depend on the type of trauma and the patient's condition. Large volumes of fluid to maintain a systolic blood pressure ≥90 mm Hg (MAP 60 to 65 mm Hg) should only be given to patients with isolated head or extremity injuries. As stated earlier, aggressive fluid resuscitation may increase blood loss and can delay arrival to surgical care at a trauma center.

Cardiogenic Shock

The management of cardiogenic shock focuses on improving the pumping action of the heart and on managing cardiac rhythm irregularities. The paramedic should initiate fluid resuscitation in the adult with 100 to 200 mL of a volume-expanding fluid. Fluid resuscitation should be initiated as long as the patient has no crackles in the lung fields that would indicate pulmonary edema. If the patient improves, fluid therapy should be continued cautiously. Fluid therapy should continue until the blood pressure stabilizes and the pulse rate decreases. The paramedic should assess lung sounds often. If the patient shows signs of increased lung congestion, the paramedic should adjust the rate of infusion to keep the vein open.

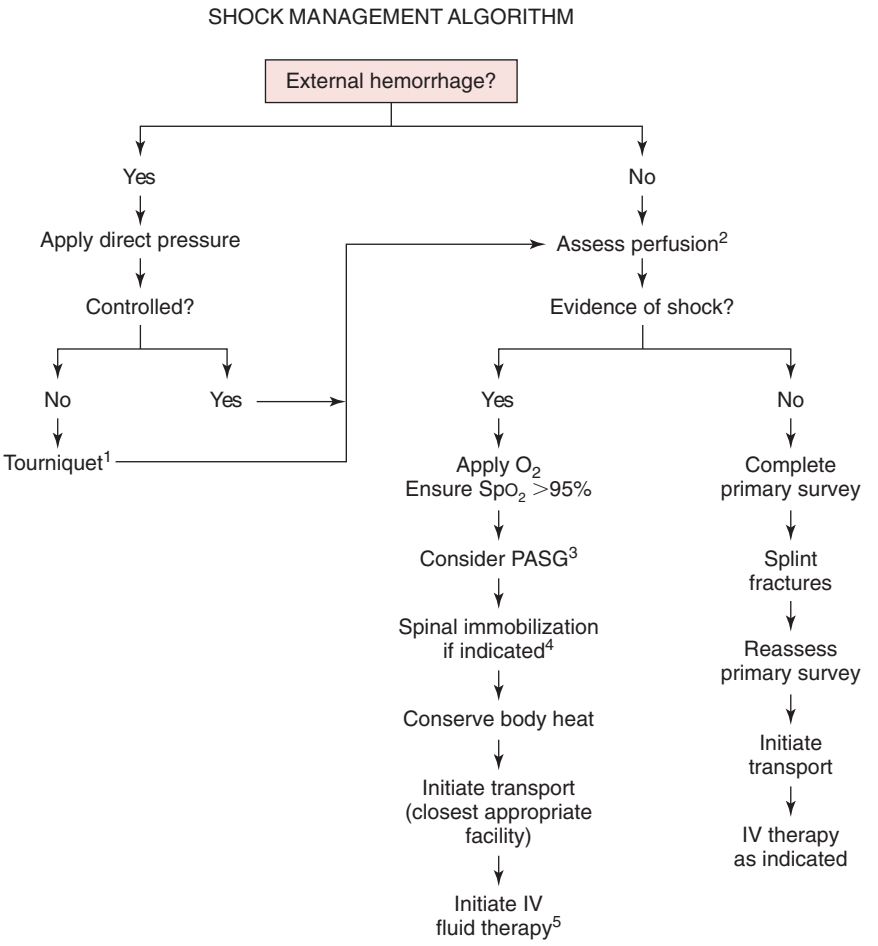
Drug therapy for cardiogenic shock varies according to cause. Drug therapy can include vasopressors, vasodilators, inotropic drugs, and antidysrhythmics (usually after fluid infusion) (see Chapter 22). Patients with cardiogenic shock caused by myocardial ischemia or infarction require reperfusion strategies (clot-busting drugs or surgery) and possible circulatory support. The paramedic must manage obstructive causes of cardiogenic shock immediately, including tension pneumothorax and cardiac tamponade (see Chapter 42).

Neurogenic Shock

The management of neurogenic shock is similar to the management for hypovolemia. However, the paramedic must take care during fluid therapy to avoid circulatory overload. Throughout the resuscitation phase, the paramedic should monitor the patient's lung sounds closely for signs of pulmonary congestion. In addition, patients in neurogenic shock may respond to the administration of vasopressors (e.g., ***dopamine***).

Anaphylactic Shock

As described in Chapter 27, intramuscular administration of ***epinephrine*** is the treatment of choice in acute anaphylactic reactions. Depending on the severity of reaction, other treatment modalities can include IV or intramuscular administration of antihistamines such as ***diphenhydramine.*** The paramedic can administer bronchodilators to treat



Notes:
[1]A manufactured tourniquet, blood pressure cuff, or cravat should be placed just proximal to the bleeding site and tightened until bleeding stops. The application time is marked on the tourniquet.

[2]Assessment of perfusion includes, presence, quality, and location of pulses; skin color, temperature, and moisture; and capillary refilling time.

[3]PASG should be considered for decompensated shock (SBP <90 mm Hg), and suspected pelvic, intraperitoneal, or retroperitoneal hemorrhage, and in patients with profound hypotension (SBP <60 mm Hg). PASG is contraindicated in penetrating thoracic trauma, abdominal evisceration, pregnancy, impaled object in the abdomen, and traumatic cardiopulmonary arrest, or for splinting the lower extremity fractures.

[4]See Indications for Spinal Immobilization algorithm (p. 235)

[5]Initiate two large-bore (14- or 16-guage) IV catheters en route. See Managing Volume Resuscitation algorithm (p. 188).

FIGURE 36-13 Shock management algorithm. (Courtesy Jobst Institute, Inc., Toledo, Ohio.)

bronchospasm that persists after administration of ***epinephrine.*** Steroids can be used to reduce the inflammatory response.

Crystalloid volume replacement also is indicated. Crystalloids may compensate for the increased container size caused by vasodilation resulting from histamine release during an anaphylactic reaction. Administration of 1 to 3 L of normal saline may be indicated in patients who have signs of shock after administration of ***epinephrine.*** Paramedics should anticipate the need for aggressive airway management in any allergic reaction (see Chapter 27).

Septic Shock

The management of septic shock in the prehospital setting can include the management of hypovolemia (if present) and the correction of metabolic acid-base imbalance. Depending on the patient's response to the infection,

BOX 36-2 Categories of Shock According to Primary Treatment

Causes That Require Primarily the Infusion of Volume

Hemorrhagic shock
Traumatic
Gastrointestinal
Body cavity
Hypovolemia
Gastrointestinal losses
Dehydration from insensible losses
Third-space sequestration from inflammation

Causes That Require Improvement in Pump Function by Either Infusion of Inotropic Support or Reversal of the Cause of Pump Dysfunction

Myocardial ischemia
Coronary artery thrombosis
Arterial hypotension with hypoxemia
Cardiomyopathy
Acute myocarditis
Chronic diseases of heart muscle (ischemic, diabetic, infiltrative, endocrinological, congenital)
Cardiac rhythm disturbances
Atrial fibrillation with rapid ventricular response
Ventricular tachycardia
Supraventricular tachycardia
Hypodynamic septic shock (late sepsis)
Overdose of negative inotropic drug
Beta blocker
Calcium channel antagonist overdose (e.g., verapamil)
Structural cardiac damage
Traumatic (e.g., flail mitral valve)
Ventriculoseptal rupture
Papillary muscle rupture

Causes That Require Volume Support and Vasopressor Support

Hyperdynamic sepsis syndrome (early sepsis)
Anaphylactic shock
Central neurogenic shock
Drug overdose (dihydropyridines, α_1-antagonists)

Problems That Require Immediate Relief From Obstruction to Cardiac Output

Pulmonary embolism
Cardiac tamponade
Pneumothorax
Valvular dysfunction
Acute thrombosis of prosthetic valve
Critical aortic stenosis
Congenital heart defects in newborn (e.g., closure of patent ductus arteriosus with critical aortic coarctation)
Critical idiopathic subaortic stenosis

Cellular Poisons That Require Specific Antidotes

Carbon monoxide
Methemoglobinemia
Hydrogen sulfide
Cyanide

From Marx J, et al: *Rosen's emergency medicine: concepts and clinical practice*, ed 6, St Louis, 2006, Mosby.

prehospital care may involve fluid resuscitation, respiratory support, and the administration of vasopressors to improve cardiac output. If possible, the paramedic should obtain a thorough patient history to help identify the cause of sepsis. Any immunocompromised group of patients has an increased risk of septic shock. Examples of such groups include those with human immunodeficiency virus infection, some cancer patients receiving chemotherapy, and patients with indwelling urinary or vascular catheters.

BOX 36-3 Complications of Shock

Acute renal failure
Acute adult respiratory distress syndrome
Hematologic failure
Multiple organ dysfunction syndrome (MODS)
Sepsis
Acute respiratory distress syndrome
Death of organs
Death of organism
Disseminated intravascular coagulation (DIC)

INTEGRATION OF PATIENT ASSESSMENT AND THE TREATMENT PLAN

Complications of shock are many[3] (Box 36-3). The goals of prehospital care for the patient with severe hemorrhage or shock include rapid recognition of the event, initiation of treatment, prevention of additional injury, rapid transport to an appropriate medical facility by ground or air ambulance, and advanced notification of the receiving facility. The paramedic should follow guidelines established by local protocol and medical direction in determining the appropriate prehospital level of care for patients and in identifying the appropriate medical facility for patient transport.

SUMMARY

- Shock is inadequate tissue perfusion. It is not a single event but rather the culmination of a complex group of physiological abnormalities.
- Perfusion is the adequate oxygenation of tissue cells. The heart, lungs, and blood vessels (and blood volume) must all be working effectively to achieve normal perfusion.
- The blood vessels form the body's container. This container must be able to shrink and grow and must be filled with an adequate volume to achieve normal tissue perfusion.
- Uncorrected shock progresses through a series of stages. These are vasoconstriction, capillary and venous opening, disseminated intravascular coagulation, and multiple organ failure.
- Shock can be categorized using many methods. Hypovolemic shock occurs when excess blood or body fluid is lost.
- Cardiogenic shock results from pump failure related to a heart muscle, valve, or rhythm problem.
- Neurogenic shock occurs when there is vasomotor paralysis high on the spinal cord.
- Anaphylactic shock is a type of severe allergic reaction that causes impaired vasomotor tone, fluid volume loss, airway obstruction, and bronchospasm.
- Septic shock occurs as a result of a systemic infection. Chemical toxins released from the infectious agent cause a cascade of events that impair cardiac output.
- The three stages of shock are compensated, uncompensated, and irreversible shock.
- Treatment of the patient in shock aims to ensure a patent airway, provide adequate oxygenation, and restore perfusion. The means to achieve each of those objectives varies according to the type of shock and the condition of the patient.
- Fluid resuscitation in shock varies according to the cause. If the patient has uncorrected internal hemorrhage isotonic crystalloid solution should be infused to maintain a systolic blood pressure of 90 mm Hg.
- Treatment of cardiogenic shock is aimed at normalizing heart rate and improving pumping action of the heart.
- During neurogenic shock fluids should be administered cautiously with frequent monitoring of lung sounds.
- Anaphylactic shock is treated with epinephrine, diphenhydramine, and fluid bolus.
- Treatment for patients with septic shock will include fluid resuscitation and possibly administration of vasopressors.

CHAPTER

37 Trauma Overview and Mechanism of Injury

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the incidence and scope of traumatic injuries and deaths.
2. Identify the role of each component of the trauma system.
3. Predict injury patterns based on knowledge of the laws of physics related to forces involved in trauma.
4. Describe injury patterns that should be suspected when injury occurs related to a specific type of blunt trauma.
5. Describe the role of restraints in injury prevention and injury patterns.
6. Discuss how organ motion can contribute to injury in each body region depending on the forces applied.
7. Identify selected injury patterns associated with motorcycle and all-terrain vehicle collisions.
8. Describe injury patterns associated with pedestrian collisions.
9. Identify injury patterns associated with sports injuries, blast injuries, and vertical falls.
10. Describe factors that influence tissue damage related to penetrating injury.

KEY TERMS

acceleration An increase in the velocity of a moving object.

blunt trauma An injury produced by the wounding forces of compression and change of speed, both of which can disrupt tissue.

cavitation A temporary or permanent opening produced by a force that pushes body tissues laterally away from the track of a projectile.

deceleration A decrease in the velocity of a moving object.

incident phase The phase of trauma that refers to the trauma event.

kinematics The process of predicting injury patterns that can result from the forces and motions of energy.

penetrating trauma An injury produced by crushing and stretching forces of a penetrating object that results in some form of tissue disruption.

postincident phase The phase of trauma where emergency care is delivered to injured patients.

preincident phase The phase of trauma that refers to the prevention of intentional and unintentional trauma deaths.

trauma center A specialized hospital distinguished by the immediate availability of specialized personnel, equipment, and services to treat most severe and critical injuries.

Trauma is a major cause of morbidity (nonfatal injury), mortality (death), and years of life lost from normal life expectancy. The paramedic must have an appreciation of trauma systems and how they impact patient care. The paramedic also must be able to recognize how mechanisms of injury predict injury patterns and severity. With these two abilities, the paramedic will be able to enhance patient assessment and emergency care. The purpose of this chapter is to provide an overview of trauma. Care considerations are addressed in later chapters by subject matter.

EPIDEMIOLOGY OF TRAUMA

Unintentional injury is a devastating medical and social problem. Unintentional injury is the leading cause of death among persons 1 to 44 years of age and the fifth leading cause of death among all Americans.[1] Trauma deaths in 2006 were exceeded only by deaths attributable to heart disease, cancer, stroke, and chronic lower respiratory tract diseases. In 2006, about 120,000 unintentional injury deaths occurred in the United States. The National Safety Council estimates that the total number of unintentional injuries in the United States approaches 61 million annually. Of these injuries, 9 million are disabling, 350,000 result in permanent impairment, and 8.4 million result in permanent disabilities. The economic effect of unintentional injuries in the United States exceeds $700 billion each year.

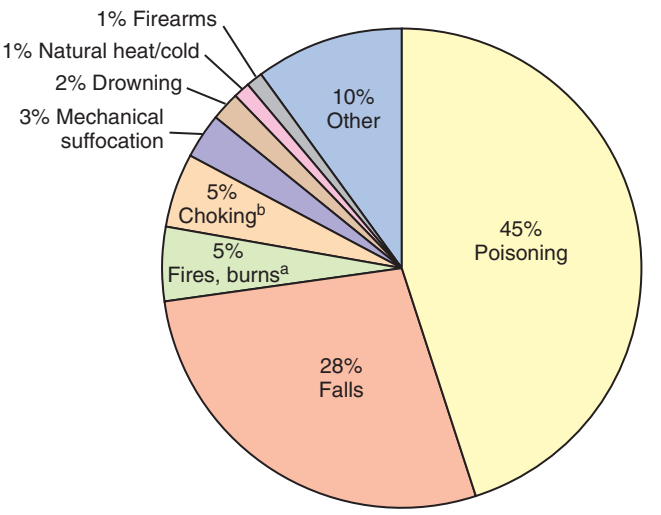

FIGURE 37-1 Deaths from unintentional injury by event. [a]Includes deaths resulting from conflagration, regardless of nature of injury. [b]Inhalation and indigestion of food or other object that obstructs breathing. (From National Safety Council: *Injury facts 2010 Edition.*)

NOTE
In any given 10-minute period in the United States, 2 persons are killed. In that same time period, about 490 persons suffer a disabling injury. Costs in these 10-minute periods amount to more than $13.3 million.[1]

Trends in Trauma Deaths

Deaths from unintentional injury are increasing yearly. However, most deaths from trauma can be prevented. The increase in deaths points to the need for increased safety and health efforts to reverse the trend. After motor vehicle crashes, poisoning by solids and liquids, falls, fire and flames, drowning, and choking have been the top five causes of trauma deaths since 1970[1] (Fig. 37-1) (Box 37-1).[2]

NOTE
More than 3000 deaths resulted from the terrorist attacks of September 11, 2001. These deaths are not included in these statistics.

BOX 37-1 Classifications of Deaths Attributable to Trauma in the United States[2]

All external causes of mortality
Motor vehicle crashes
Pedestrian injury
Motorcycle crashes
Falls
Mechanical forces (struck by object or machinery)
Drowning
Electrical current
Intentional self-harm
Assaults (firearms)

Phases of Trauma Care

Trauma care is divided into three phases. The three phases are preincident, incident, and postincident.[3] The **preincident phase** refers to the prevention of intentional and unintentional trauma deaths. Paramedics and other health care professionals play a key role in this phase. A part of this phase includes participating in public education. (For example, paramedics may educate the public on the use of personal restraint systems, motorcycle helmets, and the proper use of 9-1-1.) Paramedics also promote legislation that supports injury prevention programs (see Chapter 3).

LOOK AGAIN
See Chapter 3: Injury Prevention and Public Health, pp. 56-58.

The **incident phase** is the trauma event. The paramedic can prevent many of these events through education and by practicing personal safety. Thus the paramedic's role in this phase is to "practice what you preach" and to teach by example. The paramedic can achieve this by driving safely and by using personal restraint systems while on and off duty. During the incident phase, the application of active (e.g., seat belts) and passive (e.g., air bags) systems can alter the outcome of a trauma event significantly.

The **postincident phase** is when the paramedic uses his or her expertise and skills. (This is the delivery of emergency care to injured patients.) Important responsibilities for the paramedic in this phase include the following:

BOX 37-2 The Golden Hour

The first hour after severe injury is known as the golden hour and is a critical period. In this period, surgical intervention for the trauma patient can enhance survival and reduce complications. The paramedic must recognize patients who are in this group. The paramedic also must ensure that prehospital care does not delay patient transportation. The paramedic can best serve these patients through rapid assessment, stabilization of life-threatening injuries, and rapid transportation to an appropriate medical facility for definitive care.

- Performing lifesaving maneuvers
- Properly preparing the patient for transportation to an appropriate medical facility
- Promptly transporting the patient to the appropriate medical facility (Box 37-2)

The factor most critical to any severely injured patient's survival is the length of time that elapses between the incident and definitive care[3,4] (Box 37-3).

Trauma Systems

A comprehensive trauma system consists of many different components. These components are integrated and coordinated to provide cost-effective services for injury prevention and patient care. At the center of this system is the continuum of care, which includes injury prevention, prehospital care, acute care facilities, and posthospital care.[5] The following is a sampling of these components:

1. Injury prevention
2. Prehospital care, including management, transportation, and trauma triage guidelines
3. Emergency department care
4. Interfacility transportation if needed
5. Definitive care
6. Trauma critical care
7. Rehabilitation
8. Data collection and trauma registry

CRITICAL THINKING

How can you learn more about the components of the trauma system during your career as a paramedic?

The paramedic plays a crucial role in the trauma system. One aspect of this role is being involved in injury prevention programs. Another aspect includes entering appropriate patients into the trauma care system while providing appropriate patient care. Lastly, the paramedic fulfills this role by taking part in data collection and research. As described in Chapter 3: Injury Prevention and Public Health, this research can influence health care improvements in caring for injured patients (Box 37-4).

Trauma Centers

As described in Chapter 1, the U.S. Department of Health and Human Services released the *Position Paper on Trauma Center Designation* in 1980. Since then, states have developed comprehensive trauma systems. As of 2010, 225 hospitals have a designated specialty in trauma.[6]

The American Medical Association recommended categorization of hospital emergency services in the early 1970s.[7] In 1990 (revised in 1999) the Task Force of the American College of Surgeons (ACS) Committee on Trauma published *Resources for Optimal Care of the Injured Patient*. The paper described three levels of trauma centers. These levels are based on resources (essential and desired), admissions, staff, research, and education involvement.

A level I trauma center has a full range of specialists and equipment available 24 hours a day and admits a minimum required annual volume of severely injured patients.

BOX 37-3 Prevention of Trauma Deaths

Deaths from trauma occur in three periods: immediate, early, and late. Each period presents its own unique problems.[4]

Immediate

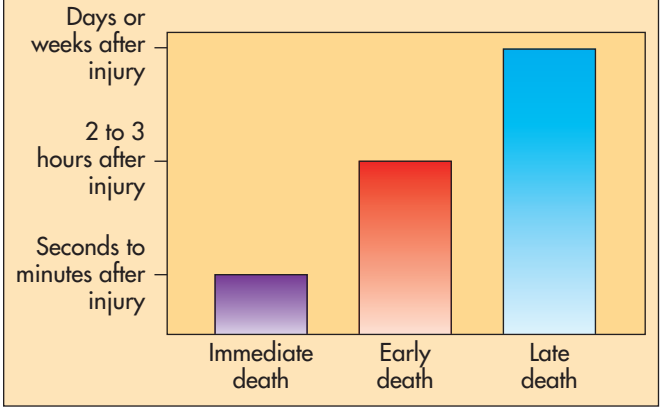
Immediate death occurs within seconds or minutes of the injury. Lacerations of the brain, brainstem, upper spinal cord, heart, aorta, or other large vessels usually cause these deaths. Few if any patients in this category can be saved. Effective injury prevention programs are the only way to reduce the number of these deaths.

Early

The second peak of death occurs within the first 2 to 3 hours after injury. The causes of these deaths usually are major head injury, hemopneumothorax, ruptured spleen, lacerated liver, pelvic fracture, or multiple injuries associated with significant blood loss. Most of these injuries can be treated with available techniques. However, the time lapse between injury and definitive care is critical.

Late

The third peak of death occurs days or weeks after the injury. These deaths most often result from sepsis, infection, or multiple organ failure. Prehospital emergency care focused on early recognition and management of life-threatening injuries is critical to the prevention of late deaths from trauma.



BOX 37-4 Trauma Registries

Trauma registries allow for the collection of injury data by individual hospitals or groups of hospitals on a local, regional, or state level. The American College of Surgeons funded these registries and the data collection software programs. (An example of a registry is the National Trauma Data Bank. An example of a software program is NATIONAL TRACS.) The registries and programs are meant to provide online data management. They also are intended to provide national exchange of injury data for a variety of commercial registry programs. Trauma registries generate periodic standard reports. These reports offer statistical data. The data allow facilities to compare the trends and to compare other key details regarding trauma care.

Additionally, a level I center has a program of research, is a leader in trauma education and injury prevention, and is a referral resource for communities in neighboring regions through community outreach. The level I trauma center must have a program for substance abuse screening and provide brief intervention to patients as appropriate.[6] A level I trauma center can provide total care for every aspect of injury. The level I center is followed by level II and III facilities. (A level IV trauma center exists in some states where the resources do not exist for a level III trauma centers [Box 37-5].) The assignment of category to a trauma center also enables emergency medical services personnel to transport patients rapidly to the most appropriate facility. Other specialized care facilities—such as pediatric trauma centers, burn centers, hyperbaric centers, and poison treatment centers—provide care for critically ill or injured patients with special needs. The ACS Committee on Trauma also established guidelines for field triage, interhospital triage to specialized care facilities, and mass casualty triage. These criteria are based on the patient's condition, mechanism of injury, injury severity indexes, and available patient care resources (Figure 37-2).

CRITICAL THINKING

Where can you find the trauma triage criteria for your area?

Transportation Considerations

Determining the proper level of care and hospital destination is based on the patient's needs and condition, and sometimes the advice of medical direction. (The Centers for Disease Control and Prevention along with key experts in trauma care have developed guidelines to assist EMS personnel in identifying patients who need trauma center care. Other methods of triage will be addressed in Chapter 54.) Once the paramedic determines the level of care needed and the destination facility, decisions can be made about the mode of transportation. (For example, the paramedic chooses between ground or air ambulance.)

BOX 37-5 Trauma Centers

A trauma center is a specialized hospital distinguished by the *immediate* availability of *specialized* personnel, equipment, and services to *treat* most severe and critical injuries. This includes ready-to-go teams that perform immediate surgery and other necessary procedures for people with serious or life-threatening injuries, for example, due to a car crash, a long fall, or gunshot wounds. The mission of a trauma center is to ensure continuity and quality of care for injured patients from the scene of injury through treatment at the trauma center and ultimately physical rehabilitation. Currently, less than 10% of hospitals have a trauma center.

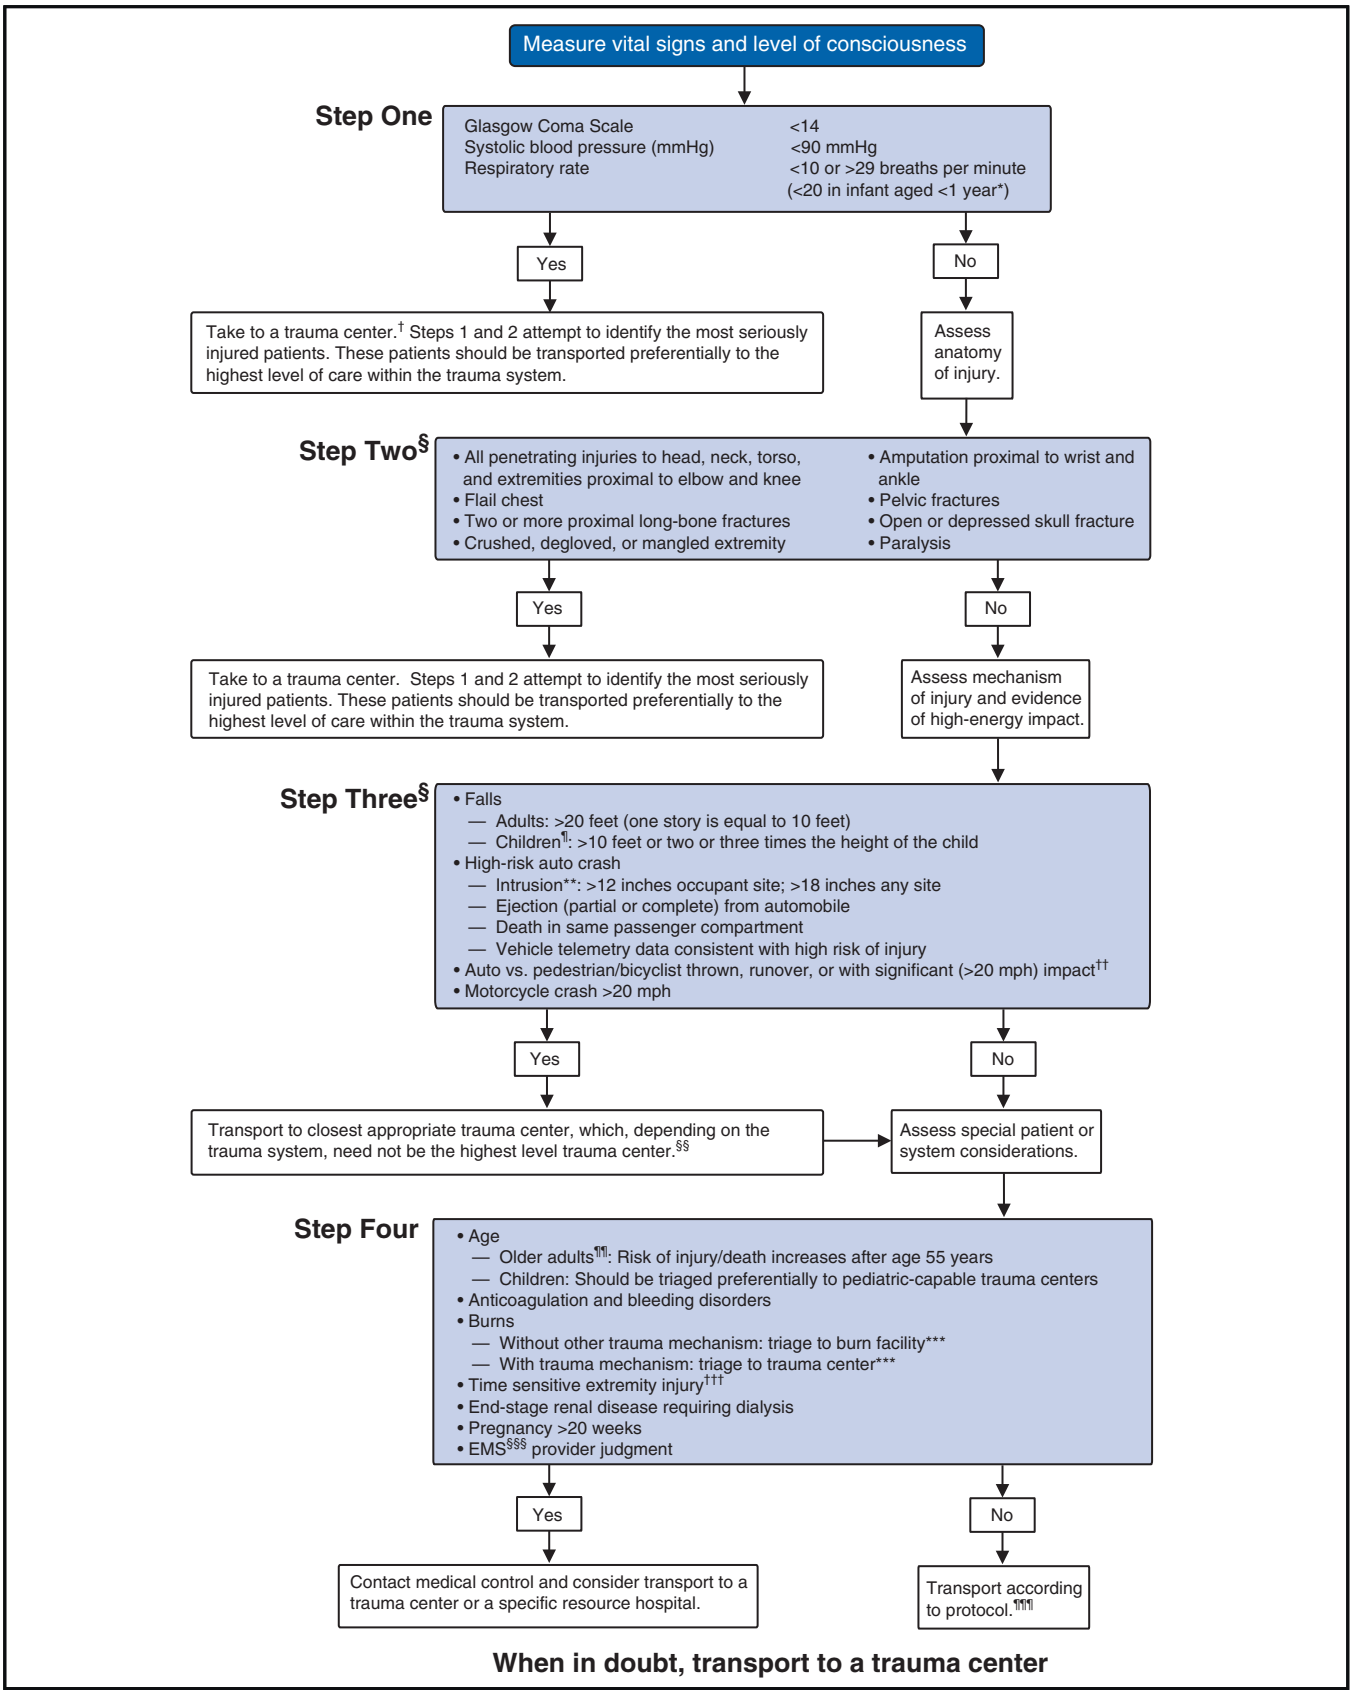
Trauma centers are classified by levels dependent upon the amount of equipment, staff, and care provided[8]:

- *Level I*. Has a full range of specialists and equipment available 24 hours a day. Admits a minimum required annual volume of severely injured patients. Has a research program. Is a leader in trauma education and injury prevention, and is a referral resource for communities in neighboring regions. Has a required program for substance abuse screening and provides brief intervention to patients.
- *Level II*. Usually works in collaboration with a level I center but may be the only resource in a rural state. Provides comprehensive trauma care and supplements the clinical expertise of a level I institution. Provides 24-hour availability of all essential specialties, personnel, and equipment. Has no minimum volume requirements. Provides an injury prevention program and also conducts substance screening, but is not required to have an ongoing program of research or a surgical residency program.
- *Level III*. Has resources for the emergency resuscitation, stabilization, emergent surgery, and intensive care of most trauma patients. Has transfer agreements with level I and/or level II trauma centers to ensure back-up resources for the care of patients with severe injuries. Has an injury prevention program. Does not have the full availability of specialists, except surgery and orthopedics, in most states.
- *Level IV*. Provides initial evaluation, emergency resuscitation, and stabilization of trauma patients, but most patients will require transfer to higher level trauma centers. Has 24-hour emergency coverage by a physician.

SHOW ME THE EVIDENCE

Researchers reviewed previously collected data on selected trauma patients 16 years of age and older with a physiological abnormality. Patients were included if they had any of the following conditions: systolic blood pressure (SBP) ≤90 mm Hg; respiratory rate (RR) ≤10 or ≥29 breaths/min, Glasgow Coma Scale score (GCS) ≤12, or advanced airway intervention. The researchers examined the correlation between field times and patient deaths. Of their sample 22% died. The analyses found no significant association between time and mortality for any EMS interval (activation, response, on-scene, transport, or total EMS time).

From Newgard CD, Schmicker RH, Hedges JR, et al: Emergency medical services intervals and survival in trauma: assessment of the "Golden Hour" in a North American prospective cohort, *Ann Emerg Med* 55(3):235-246, 2010.



Measure vital signs and level of consciousness
Step One
Glasgow Coma Scale <14
Systolic blood pressure (mmHg) <90 mmHg
Respiratory rate <10 or >29 breaths per minute (<20 in infant aged <1 year*)
Yes
No
Take to a trauma center.† Steps 1 and 2 attempt to identify the most seriously injured patients. These patients should be transported preferentially to the highest level of care within the trauma system.
Assess anatomy of injury.
Step Two§
• All penetrating injuries to head, neck, torso, and extremities proximal to elbow and knee
• Flail chest
• Two or more proximal long-bone fractures
• Crushed, degloved, or mangled extremity
• Amputation proximal to wrist and ankle
• Pelvic fractures
• Open or depressed skull fracture
• Paralysis
Yes
No
Take to a trauma center. Steps 1 and 2 attempt to identify the most seriously injured patients. These patients should be transported preferentially to the highest level of care within the trauma system.
Assess mechanism of injury and evidence of high-energy impact.
Step Three§
• Falls
— Adults: >20 feet (one story is equal to 10 feet)
— Children¶: >10 feet or two or three times the height of the child
• High-risk auto crash
— Intrusion**: >12 inches occupant site; >18 inches any site
— Ejection (partial or complete) from automobile
— Death in same passenger compartment
— Vehicle telemetry data consistent with high risk of injury
• Auto vs. pedestrian/bicyclist thrown, runover, or with significant (>20 mph) impact††
• Motorcycle crash >20 mph
Yes
No
Transport to closest appropriate trauma center, which, depending on the trauma system, need not be the highest level trauma center.§§
Assess special patient or system considerations.
Step Four
• Age
— Older adults¶¶: Risk of injury/death increases after age 55 years
— Children: Should be triaged preferentially to pediatric-capable trauma centers
• Anticoagulation and bleeding disorders
• Burns
— Without other trauma mechanism: triage to burn facility***
— With trauma mechanism: triage to trauma center***
• Time sensitive extremity injury†††
• End-stage renal disease requiring dialysis
• Pregnancy >20 weeks
• EMS§§§ provider judgment
Yes
No
Contact medical control and consider transport to a trauma center or a specific resource hospital.
Transport according to protocol.¶¶¶
When in doubt, transport to a trauma center

Figure 37-2 Field Triage Decision Scheme—United States, 2006. *The upper limit of respiratory rate in infants is >29 breaths per minute to maintain a higher level of overtriage for infants. †Trauma centers are designated level I to IV, with level I representing the highest level of trauma care available. §Any injury noted in steps 2 and 3 triggers a "yes" response. ¶Age <15 years. **Intrusion refers to interior compartment intrusion, as opposed to deformation, which refers to exterior damage. ††Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact >20 mph with a motor vehicle. §§Local or regional protocols should be used to determine the most appropriate level of trauma center; appropriate center need not be level I. ¶¶Age >55 years. ***Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center. †††Injuries such as an open fracture or fracture with neurovascular compromise. §§§Emergency medical services. ¶¶¶Patients who do not meet any of the triage criteria in steps 1 to 4 should be transported to the most appropriate medical facility as outlined in local EMS. (Adapted from American College of Surgeons: *Resources for the optimal care of the injured patient,* Chicago, Ill, 2006, Author. Footnotes have been added to enhance understanding of field triage by persons outside the acute injury care field.) (From CDC (2009): Guidelines for field triage of injured patients: Recommendations of the National Expert Panel on Field Triage, Jan. 29, 2009, V. 58 # RR-1.)

GROUND TRANSPORTATION

As a rule the paramedic should use ground transportation by ambulance if the appropriate facility can be reached within a "reasonable time." Reasonable time is defined by national standards (e.g., definitive care within 60 minutes after the injury for severe trauma) and local protocol. Factors that affect the decision to use ground or air transportation include geographical location, topographical area, population, weather, availability of resources, traffic conditions, and time of day.

AEROMEDICAL TRANSPORTATION

The availability and use of aeromedical services vary throughout the United States. Aeromedical services can provide rapid response time, high-quality medical care, and rapid transportation to appropriate care facilities. Helicopters also can provide aerial surveillance and transportation of additional personnel and equipment to the emergency scene. Paramedic crews should consult with medical direction and follow local protocol regarding the use of aeromedical services. (Use of aeromedical services is addressed further in Chapter 53.) The paramedic should consider air transportation in the following situations:

- The time needed to transport a patient by ground to an appropriate facility poses a threat to the patient's survival and recovery.
- Weather, road, or traffic conditions would seriously delay the patient's access to definitive care.
- Critical care personnel and equipment are needed to adequately care for the patient during transportation.

SECTION ONE
Kinematics

ENERGY

A transfer of energy from an external source to the human body causes injuries. The extent of injury is determined by (1) the type and amount of energy applied, (2) the speed with which energy is applied, and (3) the part of the body to which energy is applied.

Physical Laws

Knowledge of four basic laws of physics is required to understand the wounding forces of trauma:

1. *Newton's first law of motion*. An object, whether at rest or in motion, remains in that state unless acted upon by an outside force.
2. *Conservation of energy law*. Energy cannot be created or destroyed; it can only change form. (Energy can take mechanical, thermal, electrical, chemical, and nuclear forms.)
3. *Newton's second law of motion*. Force (F) equals mass (M) multiplied by acceleration (a) or deceleration (d):

$$F = M \times a \textit{ or } F = M \times d$$

4. *Kinetic energy*. Kinetic energy (KE) equals half the mass (M) multiplied by the velocity squared (V^2).

$$KE = \frac{1}{2} m \times V^2$$

As the kinetic energy formula shows, velocity is much more critical than mass in determining total kinetic energy. For example, a car and its unrestrained 150-lb driver are traveling 60 miles per hour. According to Newton's first law of motion, the car remains in motion until acted upon by an outside force. If the driver gradually applies the brakes, the friction of the brakes slowly converts the mechanical energy of the car to thermal energy (conservation of energy law); the energy transfer occurs gradually through the slow deceleration. If the car strikes a tree, though, and is stopped instantly, the tree absorbs the mechanical energy, the car, and the driver. When the front of the car has stopped, the rear of the car continues forward until all of the energy of its motion is absorbed. The driver is traveling in the same direction and at the same speed as the car before impact. So, like the rear of the car, the driver continues forward. The driver suffers injuries in areas of the body that strike the vehicle.

In this sequence the tree stops the motion of the front of the car. The steering column continues forward and stops against the dashboard. The driver's sternum stops

against the steering column. The driver's chest cavity and its contents hit the sternum and are crushed from behind by the posterior thorax, deforming the entire chest. The kinetic energy in this example is calculated as follows:

KE = one half of the mass times the velocity squared,

$$\text{or } KE = \frac{1}{2} m \times V^2$$

$$KE = \frac{150}{2} \times 60^2$$

KE = 270,000 units of energy

As shown in this calculation, the 150-lb driver traveling 60 miles per hour must change 270,000 units of kinetic energy (known as *foot-pounds,* calculated as pounds multiplied by miles per hour) into another form of energy when he or she stops. In addition, recall that force equals mass multiplied by acceleration (Newton's second law of motion). Thus the 150-lb driver is moving forward in the car with about 9000 ft-lb of force when stopped by the steering column. The energy of the motion of the body causes tissue destruction as this energy is absorbed into the body cells when the body stops. This example illustrates the principle. However, the actual total force also is determined by the true rate of deceleration, or "g" force, and several other factors. Lap and shoulder restraints and air bags increase the distance over which the body stops its movement. This can decrease the deceleration force a great deal. New car construction is also designed to absorb some of this energy and lessen the force applied to the vehicle occupants.

CRITICAL THINKING

Can you apply these same four laws of physics to another traumatic situation, such as a fall onto concrete? What force is applied? What factors influence the kinetic energy?

Kinematics

Kinematics is the process of predicting injury patterns. Specific types and patterns of injuries are associated with certain mechanisms. In addition to individual factors (such as age) and protective factors (such as restraint systems, helmets, and air bags), the paramedic should consider the following when evaluating the trauma patient:

- Mechanism of injury
- Force of energy applied
- Anatomy
- Energy (for example, mass; velocity; distance; and thermal, electrical, and chemical forms)

SECTION TWO
Blunt Trauma

BLUNT TRAUMA

Blunt trauma is an injury produced by the wounding forces of compression and change of speed (usually deceleration). These forces can disrupt tissue. Direct compression is the pressure on a structure and is the most common type of force applied in blunt trauma. The amount of injury depends on the length of time of compression, the force of compression, and the area compressed. For example, compression of the thorax can lead to rib fracture or pneumothorax. Other compression injuries include contusions and lacerations of solid organs and rupture of hollow (air-filled) organs.

Acceleration is an increase in the velocity of a moving object. **Deceleration** is a decrease in the velocity of a moving object. Both can produce major injury. For example, consider a car that comes to a stop abruptly. The occupant's body continues its constant velocity after the impact until it decelerates as a result of striking the steering wheel, restraint system, or dashboard. The external aspect of the body is stopped forcibly. However, the contents of the cranial, thoracic, and peritoneal cavities remain in motion because of inertia. As a result, tissues can be stretched, crushed, ruptured, lacerated, or sheared from their points of attachment. Examples of injuries caused by a change of speed include concussion, cardiac or pulmonary contusion, organ laceration, and aortic tear.

Motor Vehicle Collision

The various injuries produced by blunt trauma are illustrated best through examination of vehicle collisions. Forces that cause blunt trauma, however, can result from a variety of impacts. As described in the previous example, a vehicle collision involves three separate impacts as the energy is transferred. In the first impact, the vehicle strikes an object. In the second, the occupant collides with the inside of the car. In the third, the internal organs collide inside the body. The injuries that result depend on the type of collision and the position of the occupant inside the vehicle. The injuries also depend on the use or nonuse of active or passive restraint systems.

NOTE

Inattention to driving is a contributing factor in 78% of motor vehicle crashes and in 65% of near-crashes, according to data from observational studies by NHTSA.[9] Distracted driving includes being fatigued, glancing at a rear-view mirror, eating, smoking, and talking and listening on a wireless device. At any given time, about 5% of all drivers use a hand-held cell phone; 0.6% use headsets; and 0.4% manipulate a hand-held device.

FIGURE 37-3 Down-and-under pathway. (From NAEMT: *Prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

A vehicle collision is classified by the type of impact: head-on, lateral, rear-end, rotational, and rollover. The forces of compression and change of speed produce predictable injury patterns in each type of collision.

HEAD-ON (FRONTAL) IMPACT

Head-on collisions result when forward motion stops abruptly. (For example, one vehicle collides with another one traveling in the opposite direction.) The first collision occurs when the vehicle hits the second vehicle, resulting in damage to the front of the car. As the vehicle abruptly stops, the occupant continues to move at the speed of the vehicle before impact. The front seat occupant continues forward into the restraint system, steering column, or dashboard. This results in the second collision. The occupant who is not restrained usually travels in one of two pathways in relationship to the dashboard. The two pathways are down-and-under or up-and-over. The precise course of this pathway determines how the organs collide inside the body and the extent of tissue damaged.

In the down-and-under pathway the occupant travels downward into the vehicle seat and forward into the dashboard or steering column (Figure 37-3). The knees become the leading part of the body, striking the dashboard. The upper legs absorb most of the impact. Predictable injuries include knee dislocation, patellar fracture, femoral fracture, fracture or posterior dislocation of the hip, fracture of the acetabulum, vascular injury, and hemorrhage. After the initial impact of the knees into the dashboard, the body rotates forward. As the chest wall hits the steering column or dashboard, the head and torso absorb energy as indicated in the description of the up-and-over pathway.

CRITICAL THINKING
How does the use of lap and shoulder restraints influence the patterns of injury described here?

FIGURE 37-4 Up-and-over pathway. (From NAEMT: *Prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

In the up-and-over pathway the body in forward motion strikes the steering wheel. As this occurs, the ribs and underlying structures absorb the momentum of the thorax (Figure 37-4). Predictable injuries from this transfer of energy include rib fracture, ruptured diaphragm, hemopneumothorax, pulmonary contusion, cardiac contusion, myocardial rupture, and vascular disruption (most notably aortic rupture).

If the abdomen is the point of impact, compression injuries can occur to the hollow abdominal organs, solid organs, and lumbar vertebrae. The kidneys, liver, and spleen are subject to vascular tears from supporting tissue. Such injuries may include the tearing of renal vessels from their points of attachment to the inferior vena cava and descending aorta. Predictable injuries include liver laceration, spleen rupture, internal hemorrhage, and abdominal organ incursion into the thorax (ruptured diaphragm).

If the head absorbs most of the impact, the cervical vertebrae absorb the continued momentum of the body. Cervical flexion, axial loading, and hyperextension (further described in Chapter 41) can result in fracture or dislocation of the cervical vertebrae. In addition, severe angulation of the cervical vertebrae can damage the soft tissues of the neck. This may cause spinal cord injury and spinal instability, even without fracture. Other predictable injuries include trauma to the brain (e.g., concussion, contusion, shearing injury, and edema) and disruption of vessels inside the head (intracranial vascular disruption), resulting in subdural or epidural hematoma (see Chapter 40).

LATERAL IMPACT

Lateral impact occurs when a vehicle is struck from the side. Injury patterns depend on whether the damaged vehicle remains in place or moves away from the point of impact. The external shell of a vehicle that remains in place after impact usually intrudes into the passenger compartment and usually directs force at the lateral aspect of the person's body. Predictable injuries result from compression to the

torso, pelvis, and extremities. Examples of these injuries include fractured ribs, pulmonary contusion, ruptured liver or spleen (depending on the side involved), fractured clavicle, fractured pelvis, and head and neck injury. Vehicles that have side-impact air bags can guard against injury in some lateral impacts.

If the damaged vehicle moves away from the point of impact, the occupant accelerates away from the point of impact. The occupant moves laterally with the car. The effects of inertia on the head, neck, and thorax produce lateral flexion and rotation of the cervical spine. This movement can result in neurological injury. Such movement also can result in tears or strains of the lateral ligaments and supporting structures of the neck. Injuries also can occur on the side of the passenger opposite the impact as the occupant is propelled toward the other side of the car. If other occupants are in the vehicle, secondary collision with other passengers is likely.

REAR-END IMPACT

A vehicle that is struck from behind rapidly accelerates, causing it to move forward under the occupant. The greater the difference in the forward speed of the two vehicles, the greater the force and damaging energy of the initial impact. For example, consider a vehicle that is traveling 50 mph and hits a stationary vehicle. The damaging energy is greater than that of a vehicle traveling 50 mph that hits another vehicle going 30 mph. Thus in forward collisions, the sum of the speeds of both vehicles is the velocity that produces damage. In rear-end collisions the difference between the two speeds is the damaging velocity.

Predictable injuries in rear-end collisions include back and neck injuries and cervical strain or fracture caused by hyperextension. The cervical portion of the spine is susceptible to secondary hyperextension caused by the rapid forward acceleration of the vehicle and subsequent relative rearward movement of the occupant. If the vehicle collides with an object in front of it, the paramedic should suspect injuries associated with frontal impact.

ROTATIONAL IMPACT

Rotational impacts occur when an off-center portion of the vehicle (usually the front quarter) strikes an immovable object or one that is moving more slowly or in the opposite direction. The part of the vehicle striking the object stops during impact. The rest of the vehicle continues in forward motion until the energy is transformed completely. The occupant moves inside the vehicle with the forward motion. The occupant usually is struck by the side of the car as the vehicle rotates around the point of impact. A rotational impact results in injuries common to those found in head-on and lateral collisions.

ROLLOVER CRASHES

In rollover crashes or collisions the person tumbles inside the vehicle. The occupant is injured wherever his or her body strikes the vehicle. The various impacts occur at many different angles, which can cause multiple-system injuries. Predicting injury patterns from rollover collisions is difficult. These crashes can produce any of the injury patterns that are associated with other types of collisions.

RESTRAINTS

In recent years, public awareness programs and various state laws have increased the use of personal restraints. According to the National Safety Council, among passenger vehicle occupants more than 4 years of age, safety belts saved an estimated 15,383 lives in 2006.[1] Another 5541 lives could have been saved if *all* passengers older than 4 years of age had worn safety belts. At this time, all states and the District of Columbia have child safety seat laws. Forty-nine states and the District of Columbia have mandatory belt use laws in effect (the one exception is New Hampshire).

A serious hazard to unrestrained occupants is ejection from the vehicle after impact. Among crashes in which a fatality occurred in 2005, only 1% of restrained passenger car occupants were ejected, compared with 31% of those who were unrestrained.[1] In addition, 1 of every 13 ejection victims suffers a spinal fracture, and ejected victims are killed 6 times more often than those who are not ejected.[3] The mortality rate among ejected victims is high. This results in part from the occupant being subjected to a second impact as the body strikes the ground or another object outside the vehicle.

CRITICAL THINKING

How can you apply this knowledge about ejection statistics to your practice in each of the phases of trauma care (preincident, incident, and postincident)?

Four restraining systems are available in the United States. These are lap belts, diagonal shoulder straps, air bags, and child safety seats. All of these restraints significantly reduce injuries. If they are used inappropriately, however, these protective devices also can produce injuries.

Lap Belts

The lap belt, used alone or with a shoulder strap, is the most commonly used active restraint system. A person should direct the lap belt at a 45-degree angle to the floor between the anterior-superior iliac spine and the femur (Figure 37-5). A lap belt worn tightly enough to stay in this position absorbs energy forces. The belt protects the abdominal cavity by transferring energy to the strong, bony pelvis.

However, the lap belt often is worn incorrectly. If the lap belt is worn above the anterior iliac spine, the forward motion of the body during impact is absorbed by vertebrae T12, L1, and L2. As the thorax is propelled forward, the abdominal organs are compressed between the vertebral column and the lap belt. This compression can cause injury to the liver, spleen, duodenum, and pancreas. A sign of

FIGURE 37-5 Properly positioned seat belt. (From NAEMT: *Prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

these abdominal injuries is abrasions or a lap belt imprint over the abdomen.

Major injury can result even when a person uses a lap belt correctly. These injuries occur from angulation of the lumbar spine, pelvis, thorax, and head around the restraint system. Injuries also occur from failure of the restraint system to decrease the impact forces. Injuries that can occur during high-speed impacts include sternal fractures, chest wall injuries, lumbar vertebral fractures, head injuries, and maxillofacial trauma.

Diagonal Shoulder Straps

Use of a shoulder strap helps absorb the forward motion of the thorax after impact. When a person wears the shoulder strap with the lap belt, the shoulder strap prevents the thorax, face, and head from striking the dashboard, windshield, or steering column. Clavicular fracture can result from the position of the shoulder strap. Organ collision inside the body with resultant internal organ injury, cervical fracture, and spinal cord injury still can occur during high-speed impacts, even when personal restraint systems are used.

Air Bags

Some vehicles are equipped with side-impact air bags, curtain air bags, knee air bags, safety belt air bags, and rear-curtain air bags to protect against impacts. However, the more common air bag is a frontal air bag that inflates from the center of the steering wheel and from the dashboard during frontal impact. These devices cushion the forward motion of the occupant when used with a lap and shoulder belt. Frontal air bags deflate rapidly. They are effective only with initial frontal and near-frontal collisions. They are ineffective in multiple collisions, rear-impact collisions, and lateral or rollover impacts. These systems do not prevent movement in the down-and-under pathway. Thus the occupant's knees still may be the point of impact. This may result in leg, pelvis, and abdominal injuries.

An air bag can produce significant injury if it is deployed in proximity (10 inches or closer) to the occupant. Deployment in these situations can produce spinal fractures, hand and eye injury, and facial and forearm abrasions. The following groups are at higher risk of injury from air bag deployment[10]:

- Infants and children less than 12 years of age
- Adults of short stature (less than 5 feet 2 inches)
- Older adults
- Persons with special medical conditions

Most air bag injuries are minor cuts, bruises, or abrasions. Most of these injuries are far less serious than the head, neck, and chest injuries that air bags prevent. According to the National Highway Traffic Safety Administration, frontal air bags saved more than 28,000 lives in 2009.[11] Although deaths do sometimes occur from air bag deployment, most are a result of the occupant being too close to the air bag when it deployed. This problem occurred more commonly from the child not being restrained adequately with lap/shoulder devices or child safety seats during pre-crash braking. To protect against injury from air bag deployment, the driver of the vehicle should be positioned at least 10 inches from the air bag cover; the front seat passenger should be positioned at least 18 inches away from the air bag cover; and children under 12 years of age should always ride in the back seat and be in the proper restraint device for their size.

Child Safety Seats

The leading cause of death in children younger than 4 years of age is injuries sustained in motor vehicle crashes. For each of these deaths, the U.S. Department of Health, Education, and Welfare estimates that thousands more suffer debilitating injury. The National Center for Statistics and Analysis reports that an estimated 4877 lives were saved by child restraints between 1975 and 1998, and 425 lives were saved by child restraints in 2006 alone.[12]

Child safety seats are available in several shapes and sizes. This variety accommodates the different stages of physical development. These seats include infant carriers, booster seats, and toddler seats. Child safety seats use a combination of lap belts, shoulder belts, full-body harnesses, and harness-and-shield apparatus to protect the child during vehicle collision. Predictable injuries likely to occur even with the appropriate use of child safety seats include blunt abdominal trauma, change-of-speed injuries from deceleration forces, and neck and spinal injury. A large amount of misuse of child safety seats occurs. (For example, common issues include location, installation, and strapping.) Public education on the correct use of child safety seats is a key prevention measure. For information on transporting children in an ambulance, see Box 37-6.

BOX 37-6 Transportation of Children in an Ambulance

Although no formal regulations have been established, it is recommended that child safety seats be available in emergency vehicles. In addition to practicing safe driving in all patient transports, the paramedic should observe the following guidelines.*

The method or device used to secure children during transport must provide effective restraint without compromising the safety of others on board.

Younger children and infants who do not require spinal immobilization should be transported in child safety seats appropriate for their size. If an appropriate safety seat is not available, the paramedic should ask to borrow one from family members (preferably one that has not been in a motor vehicle collision).

Any time a child is secured to a device such as a safety seat or spine board, the paramedic must ensure that the device is secured to the stretcher.

For any patient where medically appropriate, position the patient on the stretcher with the back of the stretcher placed upright at least at a 45-degree angle. This angle optimizes transportation safety in the event of an impact or deceleration.

If the child is secured in a safety seat, the seat should be secured to the stretcher using at least two belts placed at a 90-degree angle to each other; that is, one strap is oriented vertically and the other strap is oriented horizontally to secure the child seat to the upright stretcher. A child safety seat secured to the stretcher with the stretcher back in the upright position has performed well in the crash testing conducted to date.

Restraint systems applied to a flat stretcher are less secure in a crash. If a suboptimal restraint technique such as this must be used, the paramedic should notify the driver to exert additional caution during transport to minimize the risk.

Older children who do not require special positioning should be secured on a stretcher that has had the back elevated to an angle of at least 45 degrees.

The paramedic should use shoulder harnesses to restrain patients who must be immobilized in the supine position on a backboard and therefore cannot have the back of the stretcher elevated for protection. The paramedic should *never* secure the parent and child together on the stretcher. The paramedic also should *never* allow infants or young children to ride in the arms or lap of a parent or rescuer.

*The Center for Pediatric Emergency Medicine: *Teaching resource for instructors in prehospital pediatrics for paramedics: safe transport of children,* www.cpem.org/trippals/38TRANSP.PDF, accessed 3-15-10.

ORGAN COLLISION INJURIES

Organs can be injured as a result of movement caused by deceleration and compression forces. The paramedic must maintain a high degree of suspicion regarding injuries to organs based on the principles of kinematics. (In-depth discussions of these injuries are presented in later chapters by subject matter.)

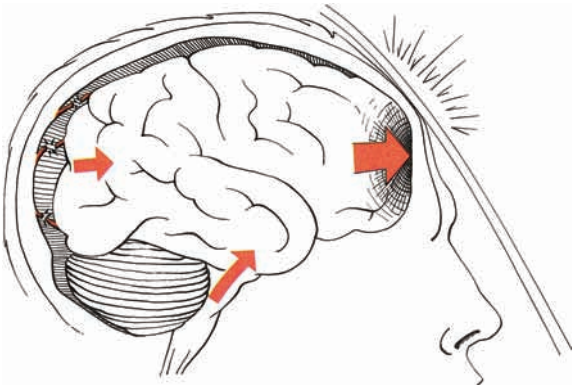


FIGURE 37-6 After cessation of forward motion of the skull the brain continues its motion, resulting in possible contusion and intracerebral hemorrhage.

Deceleration Injuries

When body organs are put into motion after an impact, they continue to move. They move in opposition to the structures that attach them to the body. Thus a risk exists of separation of body organs from their attachments. Injury to the vascular pedicle or mesenteric attachment can lead to brisk or exsanguinating hemorrhage.

HEAD INJURIES

When the head strikes a stationary object, the cranium comes to an abrupt stop. However, brain tissue inside the cranium continues to move. The brain moves until it is compressed against the skull (Figure 37-6). This movement can cause brain tissue to be bruised, crushed, or lacerated. Such movement also can cause blood vessels attached to the brain and skull to be torn, producing intracranial hemorrhage. Other injuries associated with deceleration of the head include central nervous system injury, caused by stretching of the spinal cord and its attachments, and cervical fracture.

THORACIC INJURIES

The aorta often is injured by severe deceleration forces. The aorta is affixed at several points. Proximally the aorta is affixed by the aortic valve in the descending portion of the aortic arch by the ligamentum arteriosum. The descending aorta also is attached to the thoracic spine. As the thorax hits a stationary object, the heart and aorta continue in motion. This motion is in opposition to their attachment at the lower end of the aortic arch. The aorta usually is sheared at the level of its ligamentum arteriosum attachment (Figure 37-7). Frank rupture of the aorta leads to rapid exsanguination. However, transection and dissection through to the internal lining (intima and media of the aorta) can result in cardiac tamponade. This can allow patients to arrive at an emergency department and survive the injury.

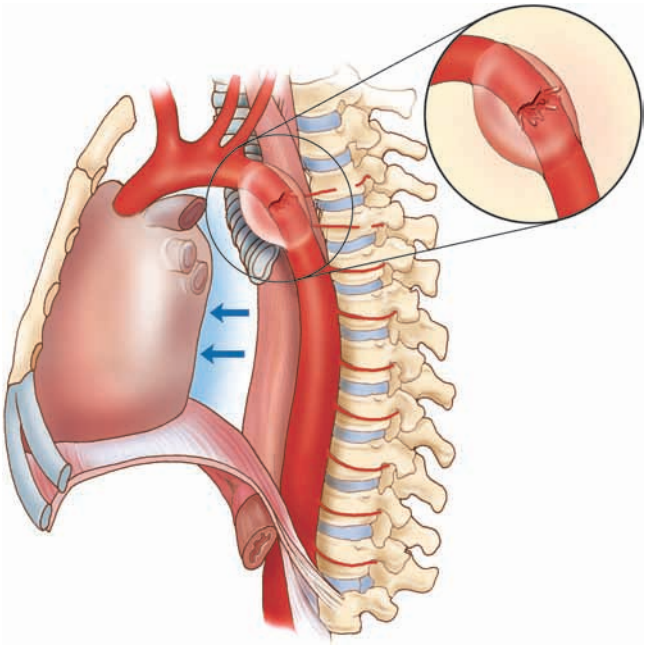

FIGURE 37-7 Shearing forces along the descending aorta move in opposition to the attachments at the lower end of the aortic arch. (From NAEMT: *Prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

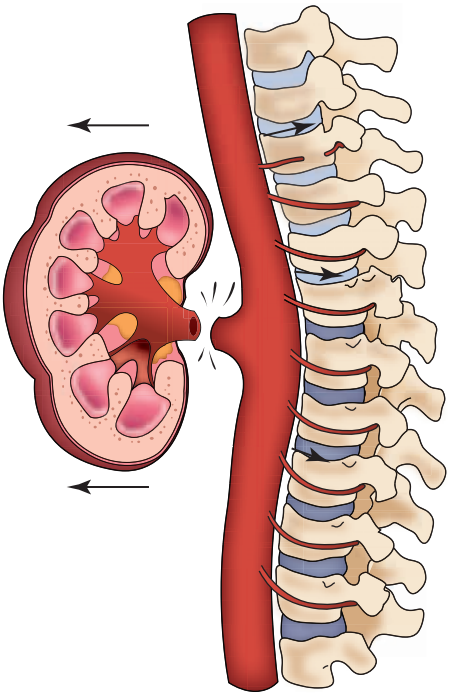

FIGURE 37-8 Forward motion of the kidney can cause separation at its midpoint from its vascular pedicle.

ABDOMINAL INJURIES

When deceleration forces are applied to the abdomen, intraabdominal organs and retroperitoneal structures (most commonly the kidneys) are affected. The forward motion of the kidneys can shear them away from their vascular pedicle attachments (Figure 37-8). The forward motion of the small and large intestines can result in mesenteric tears. The downward and forward motion of the liver can cause separation at its midpoint from its vascular and hepatic duct pedicle. The spleen is restrained by the diaphragm and abdominal wall attachments. The forward motion of the spleen can result in a tear of the splenic capsule.

Compression Injuries

Compressive forces can injure any portion of the body. This discussion is limited to injuries of the head, thorax, and abdomen.

HEAD INJURIES

Compression injuries to the head can result in open fractures, closed fractures, and bone fragment penetration (depressed skull fracture). Associated injuries include brain contusion and lacerations of brain tissue. Compression forces to the skull also can produce hemorrhage from fractured bone, meningeal vessels, or the brain itself. If facial structures are involved in the injury, soft tissue trauma and facial bone fractures can occur. The paramedic also should consider central nervous system injury. The paramedic should assume cervical fracture when evaluating injuries to the head. Compression injury to the vertebral bodies can result in compression fracture, hyperextension, and hyperflexion injury.

THORACIC INJURIES

Compression injury to the thorax often involves the lungs and heart. Associated injuries to external structures include fractured ribs and sternum, which can lead to an unstable chest wall, open pneumothorax, or both.

A serious lung injury that can occur from compression forces is called the paper bag effect. This injury occurs when increased intrathoracic pressure causes rupture of the lungs. For example, a driver of a car is threatened by an approaching vehicle. The driver notes the potential collision. Thus the driver instinctively takes a deep breath and holds it. This protective inhalation fills the lungs (paper bag) with air against the closed glottis and creates a closed container (Figure 37-9). As the thorax strikes the steering column, the inward motion of the chest wall causes an increase in lung pressure. This increased pressure results in alveolar rupture (as when a hand strikes the paper bag). This phenomenon is thought to be the cause of most pneumothoraces after vehicle trauma.[8] Penetration of a fractured rib through the pleura and laceration of the lung also contribute to pneumothorax after blunt trauma to the chest.

During compression injury to the thorax, the heart can become trapped between the sternum and the thoracic spine. Depending on the amount of energy applied, the compression of the contents of the abdomen, and an

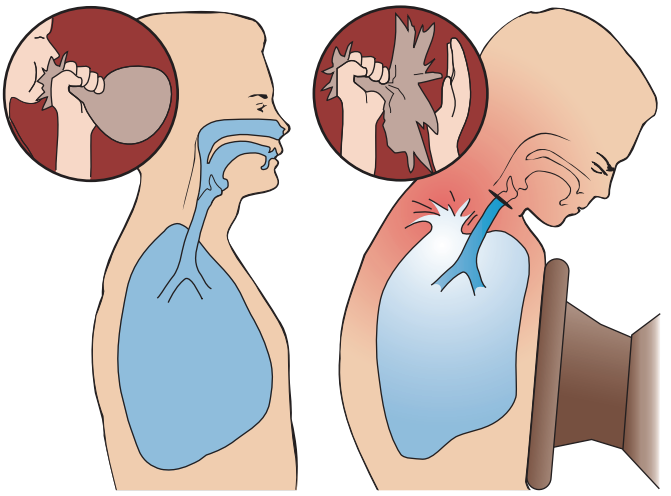

FIGURE 37-9 In a crash or collision, the lungs are similar to an air-filled paper bag held tightly at the neck and compressed with the other hand. Thoracic compression against the closed glottis causes the lungs to pop. (From NAEMT: *Prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

increase in the pressure in the aorta, the aortic valve could rupture. Compression of the patient's heart between the sternum and the vertebral column can cause cardiac dysrhythmias, myocardial contusion, or atrial or ventricular rupture.

ABDOMINAL INJURIES

Compression injuries to the abdominal cavity can have serious effects. Some of these effects include solid organ rupture, vascular organ hemorrhage, and hollow organ perforation into the peritoneal cavity. Common injuries include rupture of the bladder, especially if it is full, and lacerations to the spleen, liver, and kidneys.

Just as the paper bag effect produces a pneumothorax in thoracic injury, compression of the abdominal cavity can cause increases in intraabdominal pressure. This increase in pressure can exceed the tensile strength (resistance to lengthwise stretch) of the walls of hollow organs or the diaphragm. Predictable injuries include rupture or herniation of the diaphragm and rupture of hollow organs such as the gallbladder, urinary bladder, duodenum, colon, stomach, and small bowel.

OTHER MOTORIZED VEHICULAR COLLISIONS

Injuries from other motorized vehicular collisions include those involving motorcycles, all-terrain vehicles (ATVs), motorized personal transportation devices, snowmobiles, motorboats, water bikes, jet skis, and farm machinery. This text discusses only motorcycles and ATVs because of their common recreational use and popularity. According to the National Highway Traffic Safety Administration, about 88,000 motorcycle riders and passengers are injured each year. More than 2000 die from their injuries.

DID YOU KNOW?

Farm and Agricultural Injury

The farm as a workplace is dangerous. Farm and agricultural injuries also have high mortality and morbidity. Death from agricultural injuries ranks first among all occupations. In 2007, 715 deaths and 80,000 disabling injuries were attributed to agriculture.[13] In addition, approximately 100 unintentional injury deaths occur annually to children and adolescents on U.S. farms, and an additional 22,000 injuries to children younger than 20 years occur on farms.[14] Motorized vehicles and other machinery that are associated with many of these injuries include[15] the following:

- *Tractors.* Overturns are a common cause of severe injury with traumatic brain injury, spinal cord injury, and major thoracoabdominal injuries.
- *PTO (power take-off).* These devices deliver energy from the tractor to run other machines. The protective housing is often removed or becomes jammed, providing a site for entanglement.
- *ROPS (rollover protection structures).* These devices are often lacking or removed to provide access in low-clearance situations.
- *ATVs.* These vehicles are often used on farms and are a common cause of injury.

In addition to trauma caused by motorized vehicles and machinery, there are multiple other causes of injury common in farm or agricultural settings. Some of these include:

- *Animals.* Agricultural animals pose a threat because of size and unpredictability, resulting in a high incidence of injury. Animals also pose problems by causing cars to swerve and by their presence when using equipment at night.
- *Falls.* Farmers often work at heights without the use of protective gear.
- *Weather.* Impaired visibility, cold distraction, and equipment malfunction contribute to trauma in agricultural settings.
- *Suffocation.* Silos and pits present common risks.
- *Delayed discovery.* Farmers often work alone and at a distance from help or traffic.

Injury forces and kinematics for farm and agricultural injuries are the same as those for other injuries and injury patterns described in this chapter. In addition to patient care measures, some of the injuries will require specialized forms of rescue (see Chapter 55).

Small motorized vehicles are thought to be more dangerous than other motor vehicles because they offer little protection to the rider. They offer minimum protection from the transfer of energy associated with collisions. The injuries from small motor vehicle crashes usually are more severe than those from car crashes. As with other types of motor vehicle collision, predictable injuries depend on the type of collision that occurs.

Motorcycle Collision

Common motorcycle collisions result from impact that is head-on or at an angle. They also result from laying the motorcycle down.

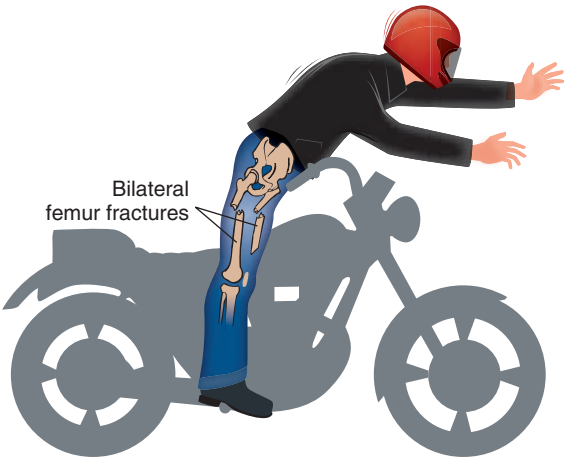

FIGURE 37-10 Head-on impact motorcycle collision. (Modified from NAEMT: *Prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

FIGURE 37-11 Road rash (abrasions). (From NAEMT: *Prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

HEAD-ON IMPACT

The center of gravity of a motorcycle is above the front axle, forward of the rider's seat. When the motorcycle strikes an object that stops its forward motion, the rest of the bike and the rider continue forward until acted on by an outside force. Usually, the motorcycle tips forward. At that point, the rider is propelled over the handlebars. Secondary impacts with the handlebars or other objects stop the forward motion of the rider. Predictable injuries caused by these secondary impacts include head and neck trauma and compression injuries to the chest and abdomen. If the feet remain on the foot rests during impact, the midshaft of the femur absorbs the rider's forward motion (Figure 37-10). This can result in bilateral fractures to the femur and lower leg. Severe perineal injuries can result if the rider's groin strikes the tank or handlebars of the motorcycle.

ANGULAR IMPACT

A motorcycle may strike an object at an angle. When this occurs, the rider often is caught between the motorcycle and the second object. Predictable injuries include crush-type injuries to the patient's affected side. Examples of such are open fractures to the femur, tibia, and fibula and fracture and dislocation of the malleolus.

LAYING THE MOTORCYCLE DOWN

Professional racers and recreational riders often use the strategy of laying the motorcycle down before striking an object. This protective maneuver separates the rider from the motorcycle and the object. The maneuver allows the rider to slide away from the bike. Predictable injuries include massive abrasions (road rash) and fractures to the affected side as the rider slides on the ground or pavement (Figure 37-11). These injuries can be severe. However, they usually are less serious than those that occur from other types of impacts.

All-Terrain Vehicles

Injuries from crashes involving ATVs are different from those seen in motorcycle collisions. All-terrain vehicles have a higher center of gravity than motorcycles. They also have a large, flat front tire that makes them difficult to steer. A specific balance different than that required for riding motorcycles or bicycles is necessary to keep the ATV from overturning.

A natural tendency is for the rider to put a foot down to support the ATV when stopping. This can lead to the rear tire running over the rider's foot, catching the leg, and throwing the rider forward off the vehicle and onto his or her shoulder or crushing the rider. Predictable injuries from ATV collisions include extremity injury and fracture, clavicular fracture, and serious head and neck injuries.

Personal Protective Equipment

Protective equipment for riders of small motor vehicles includes boots, leather clothing, eye protection, and helmets. Helmets are structured to absorb the energy of an impact, thereby reducing injuries to the face, skull, and brain, and are estimated to be 37% effective in preventing fatal injuries.[1] Nonuse of helmets increases head injuries by more than 300%.[3]

PEDESTRIAN INJURIES

In 2006, 70,000 persons were injured in auto-pedestrian collisions in the United States. Of those injuries, 6100 were fatal.[1] All collisions of this nature can cause serious injuries. They require a high degree of suspicion for multiple-system trauma.

Three main mechanisms of injury (multiple impacts) exist in auto-pedestrian collisions. The first impact occurs when the bumper of the vehicle strikes the body. The second occurs as the pedestrian strikes the hood of the vehicle. The

third occurs when the pedestrian strikes the ground or another object.

Predictable injuries depend on whether the pedestrian is an adult or a child. Variations in the height of the pedestrian in relation to the bumper and hood of the car affect the injury pattern. The velocity of the vehicle also is a major factor. However, even low speeds can result in serious trauma because of the mass of the vehicle and the transfer of energy. Another consideration in evaluating an auto-pedestrian collision is the possibility the patient may have been hit by another vehicle.

Adult Pedestrian

Most adult pedestrians who are threatened by an oncoming vehicle try to protect themselves by turning away from the vehicle. Therefore injuries often are a result of lateral or posterior impacts. During the initial impact, the adult usually is struck by the vehicle bumper in the lower legs. This often produces lower-extremity fractures.

The second impact occurs as the pedestrian falls toward the hood of the vehicle. This impact can result in fractures to the femur, pelvis, thorax, and spine. The impact also can produce intraabdominal or intrathoracic injury. In addition, the head and spine can be injured if the victim strikes the hood or windshield.

The third impact occurs as the victim strikes the ground or is thrown against another object. This can result in serious damage to the hip and shoulder of the affected side as the body makes contact with the landing surface. Sudden deceleration and compression forces are associated with this impact. These forces can cause fractures, internal hemorrhage, and head and spinal injury.

Child Pedestrian

As noted, adults try to protect themselves from auto-pedestrian injury. However, children tend to face the oncoming vehicle. Therefore their injuries often are the result of a frontal impact. Because children are smaller than most adults, the initial impact of the vehicle occurs higher on the body. Impact usually occurs above the knees or pelvis. Predictable injuries from the initial impact include fractures to the femur and pelvic girdle and internal hemorrhage.

The second impact occurs as the front of the hood of the vehicle continues forward, making contact with the victim's thorax. The victim instantly is thrown backward, forcing the head and neck to flex forward. Depending on the position of the patient in relation to the vehicle, the child's head and neck may contact the hood of the vehicle. Predictable injuries include abdominopelvic and thoracic trauma, facial trauma, and head and neck injury.

The third impact occurs as the child is thrown downward to the ground or another landing surface. Because of the child's smaller size and weight, the child can fall under the vehicle and be dragged for some distance. The child also can fall to the side of the vehicle and be run over by the front or rear wheels. Predictable injuries consist of those previously described and may include traumatic amputation.

OTHER CAUSES OF BLUNT TRAUMA

Other causes of blunt trauma include sports injuries, vertical falls, and blast injuries.

Sports Injuries

Persons of all ages take part in sports. Sports that often are associated with injuries include contact sports, such as football, basketball, hockey, and wrestling; high-velocity sports, such as downhill skiing, water skiing, bicycling, rollerblading, and skateboarding; racquet sports; water sports, such as swimming and diving; and recreational and competitive equestrian sports. Sports offer a range of health benefits. However, they also can produce severe injury.

NOTE

Each year in the United States, an estimated 30 million people ride horses. In 2008 there were 77,328 horse back riding injuries and more than 14,000 upper extremity fractures (the single most common site and type of injury).[1]

Injuries related to sports are caused by forces of acceleration and deceleration, compression, twisting, hyperextension, and hyperflexion. The paramedic can use the general principles of kinematics to predict injuries by determining the following:

- What energy forces were transferred to the patient?
- To what part of the body was the energy transferred?
- What associated injuries should be considered as a result of the energy transfer?
- How sudden was the acceleration or deceleration?
- Was compression, twisting, hyperextension, or hyperflexion involved in the injury?

CRITICAL THINKING

Injuries related to sports often occur outside. What other considerations will you have for patient care based on the environment?

If the patient used protective equipment, the paramedic should evaluate it. This will help the paramedic determine the mechanism of injury. For example, the condition and structural stability of a helmet can provide clues concerning the amount of energy transferred to the patient during the injury. Other examples include broken skis, broken hockey sticks, and structural deformities of bicycles.

Blast Injuries

Blast injury is damage to a patient who is exposed to a pressure field that is produced by an explosion of volatile substances. Explosions of this nature mainly have been a

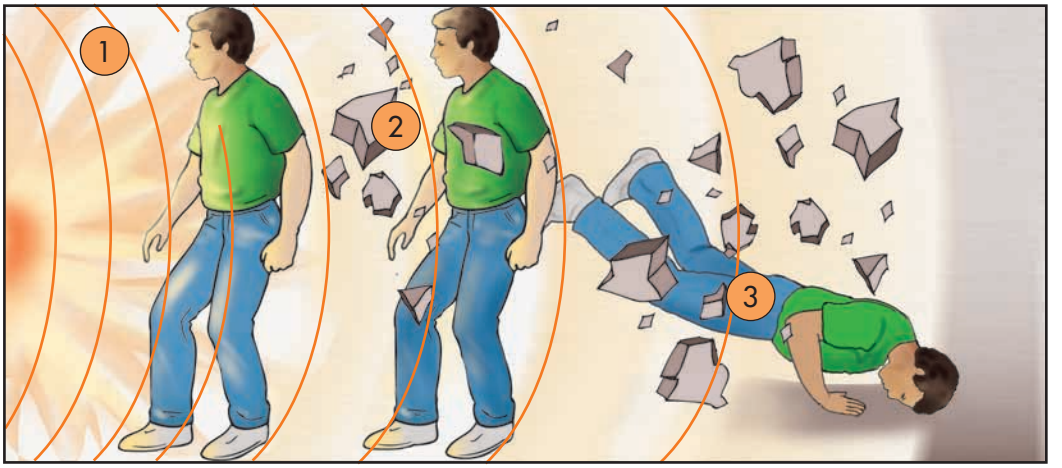

FIGURE 37-12 Three phases of injury occur during a blast. First, the pressure wave strikes the patient. Then flying debris can produce injury. In the third phase, the patient is thrown and is injured after impact with the ground or other objects.

wartime concern. However, in recent years the number of blast injuries has increased. These result from homemade bombs used in social protests and terrorist activities. Other causes include exploding car batteries, industrial use of volatile substances, chemical reactions in clandestine drug laboratories, explosions in mining, and transportation incidents or crashes involving hazardous materials.

CRITICAL THINKING
In all incidents related to blast injury, what is your first consideration on the scene?

Blasts release large amounts of energy. This energy is in the form of pressure and heat. If this release of energy is confined in a casing (e.g., a bomb), the pressure ruptures the casing and ejects fragments of the housing at a high velocity. The remaining energy is transmitted to the surrounding environment. This energy can severely injure bystanders. Blast injuries are classified as *primary, secondary, tertiary,* and *quaternary* (Figure 37-12).

PRIMARY BLAST INJURIES

Primary blast injuries result from sudden changes in environmental pressure. These injuries usually occur in gas-containing organs. The most severe damage occurs when poorly supported tissue is displaced beyond its elastic limit. The organs and tissues most vulnerable to primary blast injury are the ears, lungs, blast lung injury (BLI) (Box 37-7), central nervous system, and gastrointestinal tract. Predictable damage to these areas includes hearing loss, pulmonary hemorrhage, cerebral air embolism, abdominal hemorrhage, and bowel perforation. Thermal burns also can result from the release of energy in the form of heat. These injuries are likely to occur on unprotected areas that are close to the source of explosion (see Chapter 39). (For example, thermal burns might occur on the face and hands.) In closed spaces, because of blast reflection, victims farther from the explosion may be injured as severely as those close to the explosion.

SECONDARY BLAST INJURIES

Secondary blast injuries usually result when bystanders are struck by flying debris. (Examples of such debris include glass, metal, or falling mortar.) Obvious injuries are lacerations and fractures. Flying debris also can cause high-velocity missile-type injuries. This type of injury can result if nails, screws, or casing fragments are part of the debris.

TERTIARY BLAST INJURIES

Tertiary blast injuries occur when victims are propelled through space by an explosion and strike a stationary object. These injuries are similar to those from vertical falls. They also are similar to those from ejections from cars or small motor vehicles. In most cases, the sudden deceleration from the impact causes more damage than the acceleration through space because the deceleration is more sudden. Injuries from these forces include damage to the abdominal viscera, central nervous system, and musculoskeletal system.

QUATERNARY BLAST INJURIES

Quaternary blast injuries are all explosion-related injuries, illnesses, or diseases that are not caused by primary, secondary or tertiary mechanisms. This classification includes exacerbation or complications of existing conditions. Quaternary blast injuries can affect any body part. Types of injuries include burns (flash, partial- and full-thickness); radiation injuries, crush injuries; closed and open brain injuries; asthma, COPD, or other breathing problems from dust, smoke, or toxic gases (further described in Chapter 58); angina; hyperglycemia; and hypertension.

BOX 37-7 Blast Lung Injury: What Clinicians Need to Know

Blast lung injury (BLI) presents unique triage, diagnostic, and management challenges and is a direct consequence of the blast wave from high-explosive detonations upon the body. BLI is a major cause of morbidity and mortality for blast victims both at the scene and among initial survivors. The blast wave's impact upon the lung results in tearing, hemorrhage, contusion, and edema with resultant ventilation-perfusion mismatch. BLI is a clinical diagnosis and is characterized by respiratory difficulty and hypoxia, which may occur without obvious external injury to the chest.

Current patterns in worldwide terrorist activity have increased the potential for casualties related to explosions, yet few civilian health care personnel in the United States have experience treating patients with explosion-related injuries. Emergency care personnel are urged to learn more about the physics of explosions and other types of injuries that can result. Basic clinical information is provided here to inform practitioners of the presentation, evaluation, management, and outcomes of BLIs.

Clinical Presentation

- Symptoms may include dyspnea, hemoptysis, cough, and chest pain.
- Signs may include tachypnea, hypoxia, cyanosis, apnea, wheezing, decreased breath sounds, and hemodynamic instability.
- Associated pathology may include bronchopleural fistula, air emboli, and hemothoraces or pneumothoraces.
- Other injuries may be present.

Diagnostic Evaluation

- Chest radiography is necessary for anyone who is exposed to a blast.
- A characteristic "butterfly" pattern may be revealed upon x-ray.
- Arterial blood gases, computed tomography, and Doppler technology may be used.
- Most laboratory and diagnostic testing can be conducted per resuscitation protocols and further directed based upon the nature of the explosion (e.g., confined space, fire, prolonged entrapment or extrication, suspected chemical or biological event).

Management

- Initial triage, trauma resuscitation, treatment, and transfer should follow standard protocols; however, some diagnostic or therapeutic options may be limited in a disaster or mass casualty situation.
- In general, managing BLI is similar to caring for pulmonary contusion, which requires judicious fluid use and administration, ensuring tissue perfusion without volume overload.

Clinical Interventions

- All patients with suspected or confirmed BLI should receive supplemental high-flow oxygen sufficient to prevent hypoxemia (delivery may include nonrebreather masks, continuous positive airway pressure, or endotracheal intubation).
- Impending airway compromise, secondary edema, injury, or massive hemoptysis requires immediate intervention to secure the airway. Patients with massive hemoptysis or significant air leaks may benefit from selective bronchus intubation.
- Clinical evidence of or suspicion for a hemothorax or pneumothorax warrants prompt decompression.
- If ventilatory failure is imminent or occurs, patients should be intubated; however, caution should be used in the decision to intubate patients, because mechanical ventilation and positive end-expiratory pressure may increase the risk of alveolar rupture and air embolism.
- High-flow oxygen should be administered if air embolism is suspected, and the patient should be placed in prone, semi-left lateral, or left lateral position. Patients treated for air emboli should be transferred to a hyperbaric chamber.

Disposition and Outcome

- There are no definitive guidelines for observation, admission, or discharge following emergency department evaluation for patients with possible BLI following an explosion.
- Patients diagnosed with BLI may require complex management and should be admitted to an intensive care unit. Patients with any complaints or findings suspicious for BLI should be observed in the hospital.
- Discharge decisions will also depend upon associated injuries and other issues related to the event, including the patient's current social situation.
- In general, patients with normal chest radiographs and arterial blood gases (ABGs), who have no complaints that would suggest BLI, can be considered for discharge after 4 to 6 hours of observation.
- Data on the short- and long-term outcomes of patients with BLI are currently limited. However, in one study conducted on survivors 1 year after injury, no patients had pulmonary complaints, all had normal physical examinations and chest radiographs, and most had normal lung function tests.

From http://emergency.cdc.gov/masscasualties/blastlunginjury_prehospital.asp, accessed 3-6-10.

Vertical Falls

Falls accounted for 21,200 deaths in 2006 and were the third leading cause of accidental death in the United States.[1] (Nearly 8 million people were treated in an emergency department for fall-related injuries in 2005.) In predicting injuries associated with falls, the paramedic should evaluate three things: the distance fallen, the body position of the patient on impact, and the type of landing surface struck. Injuries associated with vertical falls are a result of deceleration and compression. More than half of all falls occur in homes; nearly four out of five involve a person 65 years of age or older.

Falls from some levels rarely are associated with fatal injury. However, falls from distances greater than 3 times

the height of an individual (15 to 20 feet) are more likely to be associated with severe injuries. As a point of reference for these distances, the roof of a one-story house is about 15 feet from the ground, and the roof of a two-story house is about 30 feet from the ground.

CRITICAL THINKING
What patients may be susceptible to serious injury from a fall that is from a low level?

Adults who have fallen more than 15 feet usually land on their feet. A predictable injury from this vertical fall is bilateral calcaneus fractures. As the energy dissipates from the initial impact, the head, torso, and pelvis push downward. The body is forced into flexion. When this occurs, hip dislocations and compression fractures of the spinal column in the thoracic and lumbar areas are seen. About 10% of patients with calcaneal fracture have associated spinal fractures. If the patient leans forward or tries to break the fall with outstretched hands, bilateral Colles' fractures to the wrists (clinically evident by the so-called silver fork deformity) are likely.

If the distance fallen is less than 15 feet, most adults land in the position in which they fell. For example, an adult who falls head first strikes the landing surface with the head, arms, or both. Predictable injuries depend on the body part that strikes the landing surface and the route of transfer of energy through the body. The paramedic should suspect internal injuries if the trunk of the body is the initial impact area. The ability of the landing surface to absorb energy influences the severity of injury. For example, less damage is expected from a fall on a soft, grassy surface than from a fall on asphalt or concrete.

Children tend to fall head first, regardless of distance fallen or body position during the fall. They fall head first because their heads are proportionally larger and heavier. For this reason, children who experience a vertical fall usually are victims of head injury. Older adult patients sustain a high number of low-distance falls, often resulting in hip fracture.

SECTION THREE
Penetrating Trauma

PENETRATING TRAUMA

Penetrating trauma is an injury that occurs when an object pierces the skin and enters a tissue of the body, creating an open wound. All penetrating objects, regardless of velocity, cause tissue disruption. This damage occurs as a result of two types of forces: crushing and stretching. The character of the penetrating object, its speed of penetration, and the type of body tissue it passes through or into determine which of the two mechanisms of injury predominates.

Cavitation

Cavitation is an opening produced by a force that pushes body tissues laterally away from the tract of a projectile. The amount of cavitation produced by a projectile is related directly to the density of tissue it strikes. Cavitation also is related directly to the ability of the body tissue to return to its original shape and position. For example, consider a person who receives a high-velocity blow to the abdomen. This person experiences abdominal cavitation at the moment of impact. However, because of the lower density of the abdominal musculature, the cavitation is temporary. (Cavitation lasts only a few microseconds.) Cavitation is temporary even in the presence of severe intraabdominal injury (Figure 37-13).

Permanent cavities are produced by penetrating injuries in which the force of the projectile exceeds the tensile strength of the tissue. Tissues with high water density (e.g., liver, spleen, and muscle) or solid density (e.g., bone) are more prone to permanent cavitation. Certain injuries (e.g., a stab wound to the abdomen) can produce cavitations as tissues are displaced in frontal and lateral directions.

Ballistics

The energy created and dissipated by the object into surrounding tissues determines the effect of a projectile on the body. The paramedic should consider the principles of

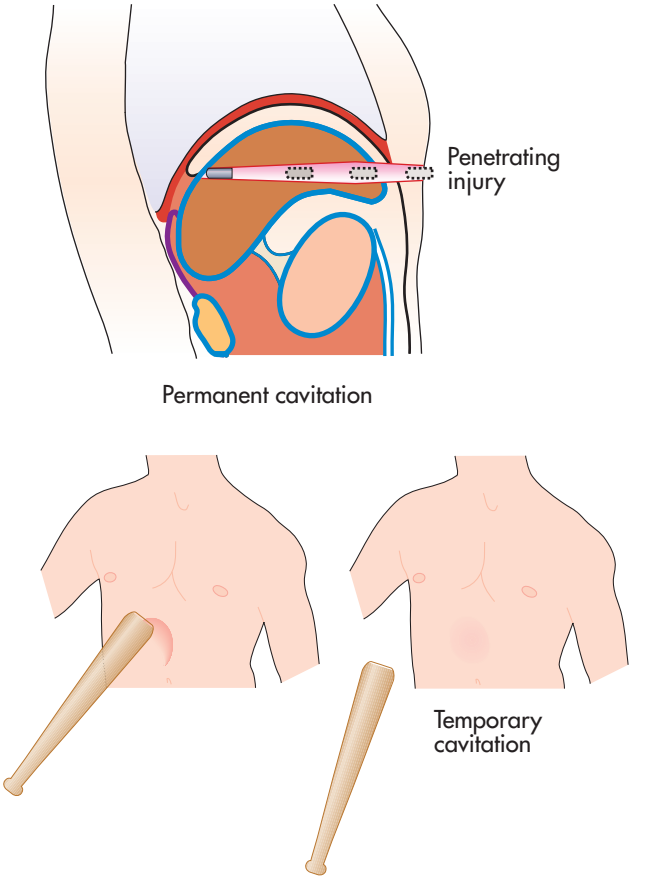

FIGURE 37-13 Permanent and temporary cavitation.

FIGURE 37-14 Stab wound in which a knife has pierced the liver and pancreas and entered the splenic vein.

kinematics when dealing with injuries from penetrating trauma. To review, kinetic energy equals half the mass of an object multiplied by the square of its velocity. With reference to ballistic trauma, doubling the mass doubles the energy. However, doubling the velocity quadruples the energy. Therefore a small-caliber bullet traveling at a high speed can produce more serious injury than a large-caliber bullet traveling at a lower speed. This is the case as long as the large-caliber bullet does not strike a major vessel or organ.

DAMAGE AND ENERGY LEVELS OF PROJECTILES

Injuries caused by penetrating trauma result from three energy levels. The levels are low, medium, and high. This discussion considers hand-driven weapons as low-energy projectiles and bullets as medium- and high-energy projectiles.

Low-energy projectiles such as knives, needles, and ice picks cause tissue damage by their sharp, cutting edges (Figure 37-14). The amount of tissue crushed in these injuries usually is minimal because the amount of force applied in the wounding process is small. The more blunt the penetrating object, the more force that must be applied to cause penetration. The more force needed to cause penetration, the more tissue crushed. The damage of tissue from low-energy injuries usually is limited to the pathway of the projectile.

When evaluating a patient with a stab wound, the paramedic should attempt to identify the weapon used to cause the wound. The paramedic also should consider the possibility of multiple wounds, embedded weapons, hidden yet extensive internal damage to organs of the thorax and abdomen, and penetration of multiple body cavities. A high degree of suspicion of serious injury is also indicated for stab wounds to areas of the back and flank. These wounds may be associated with penetrating injuries to hollow organs and injuries to retroperitoneal organs, specifically the kidneys. Penetrating injuries of the thorax can involve the abdomen, just as abdominal injuries can involve the thorax.

CRITICAL THINKING

Your patient has a stab wound in the midaxillary line, lateral to the left nipple. What organs may be affected by this mechanism? What else would you like to know about this injury?

Firearms can be labeled as medium- and high-energy weapons. Medium-energy weapons include handguns and some rifles. The injury tract produced by medium-energy weapons usually is 2 to 3 times the diameter of the projectile. Examples of high-energy weapons include military/assault rifles such as AR-15s, M-16s, and AK 47/74s and some hunting rifles. As with medium-energy injuries, the injury tract produced by high-energy weapons usually is 2 to 3 times the diameter of the projectile.

IMPLICATIONS OF SOFT BODY ARMOR

Some emergency medical services agencies have adopted soft body armor policies. The armor offers extra protection for paramedics against blunt and penetrating trauma. Most agencies follow U.S. Department of Justice guidelines to determine the type of body armor protection for the types of weapons most commonly found in their community. There are seven levels of body armor protection. Authorities generally recommend a type III or higher protection level for emergency medical services personnel. These soft vests protect against low-velocity and some medium-velocity and high-velocity weapons (see Chapter 56).

WOUNDING FORCES OF MEDIUM- AND HIGH-ENERGY PROJECTILES

A firearm cartridge is composed of a bullet made of metal, gunpowder to propel the bullet, a primer to explode and ignite the gunpowder, and a cartridge case that surrounds these components. When the trigger is pulled, the metal hammer strikes the firing pin, which ignites the primer. The gunpowder ignites and forces the bullet to exit the cartridge case.

The mechanism of injury from firearms is related to the energy created and dissipated by the bullet into the surrounding tissues. When a firearm is discharged, several events affect this dissipation of energy and ultimately the wounding forces of the missile:

1. As the missile travels through air, it experiences wind resistance, or *drag*. The greater the drag, the greater the slowing effect on the missile. Therefore a firearm discharged at close range usually produces a more severe injury than the same firearm discharged at a greater distance.
2. As the missile travels through air, a sonic pressure wave spreads out behind the missile. Because the speed of sound in tissue is about 4 times the speed of sound in air, the sonic pressure wave jumps ahead and precedes the missile through the tissue. This pressure wave displaces tissue and sometimes stretches it dramatically.

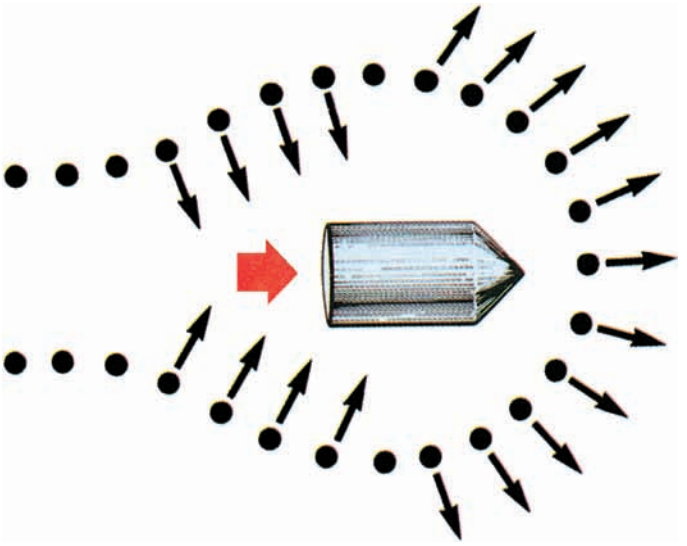

FIGURE 37-15 Bullet passing through tissue. Outward stretching of the permanent cavity as the tissue particles move away from the penetrating missile cause the temporary cavity. (From Moylan J: *Principles of trauma surgery,* ed 2, New York, 1992, Gower Medical Publishing.)

3. The localized crush of tissue in the path of the missile and the momentary stretch of the surrounding tissue cause tissue disruption.

When a projectile strikes a body, tissue stretches at the point of impact to allow entry of the penetrating object (*temporary cavitation*). The energy of the projectile exceeds the tensile strength of the tissue. Thus tissue crush occurs, forcing surrounding tissues outward from the path of the projectile (*permanent cavitation*). The differences in wounds caused by projectiles vary with the amount and location of crushed and stretched tissue (Figure 37-15). The wounding forces of a missile depend on the projectile mass, deformation, fragmentation, type of tissue struck, striking velocity, and range.[16]

Projectile Mass. Tissue crush is limited by the physical size or profile of the projectile. If the missile strikes point first, the crushed area is no larger than the diameter of the bullet. If the missile is tilted as it strikes the body, the amount of crushed tissue is no larger than the length and longitudinal cross section of the bullet.

Deformation. Some firearm missiles deform when striking tissue (e.g., expanding hollow-point or soft-point hunting bullets). The points of these projectiles typically flatten on impact. The diameter of the bullet expands, creating a larger area of crushed tissue. Military use of these bullets in war is forbidden.

Fragmentation. Each piece of missile crushes its own path through tissue, causing extensive tissue damage. These fragments produce a larger frontal area than a single, solid bullet and disperse energy into the surrounding tissues rapidly. Tissues weaken from the multiple fragment tracts and increase the subsequent stretch of the temporary cavity. The higher the velocity, the more likely the bullet is to fragment. If a bullet fragments, there may be no exit wound.

Type of Tissue Struck. Tissue disruption varies greatly with tissue type. For example, elastic tissues such as the bowel wall, lung, and muscle tolerate stretch much better than nonelastic organs such as the liver.

Striking Velocity. The velocity of a missile determines the extent of cavitation and tissue damage. Low-velocity missiles localize injury to a small radius from the center of the injury tract. These missiles have little disruptive effect, pushing the tissue aside. High-velocity missiles produce more serious injuries because they lose more energy to the tissues and produce more cavitation.

Bullet yaw, or tumble, in tissue also contributes to cavitation and tissue damage. The center of gravity of a wedge-shaped bullet is nearer to the base than to the nose. As the missile strikes body tissue, it slows rapidly. Momentum carries the base of the bullet forward; the center of gravity becomes the leading part of the missile. This forward rotation around the center of mass causes an end-over-end motion. This movement in turn produces more energy exchange and more tissue damage.

Range. The distance of the weapon from the target is a key factor in the severity of ballistic trauma. Air resistance (drag) slows the missile significantly; therefore increasing the distance of the projectile from the target decreases the velocity at the time of impact.

If the firearm is discharged at close range (within 3 feet), cavitation can occur from the combustion of powder and the forceful expansion of gases. The gas and powder can enter the body cavity and cause internal explosion of tissue. This is common with shotgun wounds. Internal explosion of tissue is less common with handguns because they produce a small amount of gas and create a small entrance wound. The expansion of only gas can cause extensive tissue destruction, especially in an enclosed area (e.g., the skull).

NOTE
Blanks are ammunition without projectiles. The explosion of gas explains how blanks can cause injury or death when fired at short range.

SHOTGUN WOUNDS

Shotguns are short-range, low-velocity weapons. They fire multiple lead pellets. These pellets are encased in a larger shell. Each pellet (there may be 9 to 400 or more, depending on pellet size and gauge of gun) is considered a missile capable of producing tissue damage. Each shell contains pellets, gunpowder, and a plastic or paper wad that separates the pellets from the gunpowder. This wad of unsterile material increases the potential for infection in shotgun wounds.

The energy transferred to body tissue and the tissue damage that results depend on several factors: gauge of the gun, size of the pellets, powder charge, and distance from the victim. For example, a 12-gauge, full-choke shotgun with number 6 shot (275 pellets) concentrates 95% of the

BOX 37-8 Forensic Considerations in Managing Gunshot Wounds

Lifesaving procedures always take precedence over forensic considerations. However, the paramedic should not touch or move weapons or other environmental clues unless it is absolutely necessary for patient care. Other forensic considerations follow:

- Document the exact condition of the patient and wound appearance on arrival at the scene. This should include environment of the patient and body position in relation to objects and doorways.
- Disturb the scene as little as possible.
- If possible, cut or tear clothing along a seam to avoid altering tears made by a penetrating object.
- Avoid cutting through a bullet hole in the clothing.
- Do not shake clothing.
- Keep all clothing in a paper bag rather than a plastic bag that may alter evidence. Do not give clothing to the victim's family members.
- Save any avulsed tissue for forensic pathological examination.
- If the bullet is retrieved, place it in a padded container to prevent marring and secure the evidence until it is delivered to the authorities (obtain a receipt).

pellets into a 7-inch circle at 10 yards. At close range a shotgun injury can create extensive tissue damage similar to that from a high-velocity missile weapon.

ENTRANCE AND EXIT WOUNDS

The presence of entrance and exit wounds is affected by several factors, including range, barrel length, caliber, powder, and weapon (Figure 37-16). In general, an entrance wound over soft tissue is round or oval and may be surrounded by an abrasion rim or collar. If the firearm is discharged at intermediate or close range, powder burns (tattooing) may be present (Box 37-8).

Exit wounds, if present, are generally larger than entrance wounds because of the cavitational wave that occurs as the bullet passes through the tissues. As the bullet exits the body, the skin can explode, resulting in ragged and torn tissue. This splitting and tearing often produces a starburst or stellate wound.

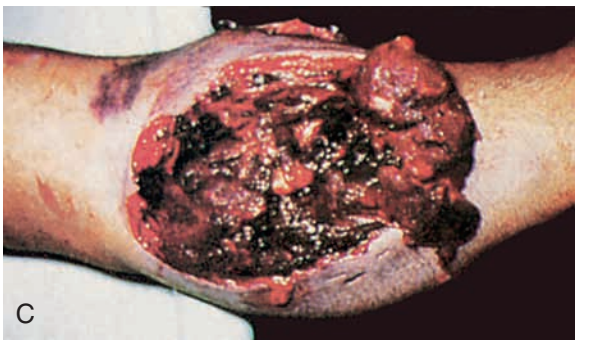

FIGURE 37-16 **A,** The powder marks show that this .22-caliber bullet wound was inflicted at close range. **B,** A short-range shotgun wound to the forearm. **C,** Exit wound caused by a powerful shotgun fired at close range. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

CRITICAL THINKING

You locate an entrance wound but no exit wound on a patient who was shot. Does this mean that the injury is not serious?

If the muzzle is in direct contact with the skin at the time of firearm discharge, expanding gases can enter the tissue. These gases can produce crepitus. The burning gases also can produce thermal injury at the entrance site and along the injury tract.

NOTE

The paramedic should describe and document the appearance of all wounds. However, the paramedic should refrain from commenting or speculating on which is the entry or exit wound. Such speculation can result in the paramedic being served a subpoena. The paramedic may be subpoenaed to testify in court in an area that is beyond the scope of paramedic practice.

SPECIAL CONSIDERATIONS FOR SPECIFIC INJURIES

Locating ballistic injuries requires a thorough physical examination of the patient because the resulting trauma from high- and medium-velocity missiles is unpredictable. The impact of any projectile is critical in determining the type and severity of injury. Fractions of an inch can make a significant difference in the amount of trauma the patient suffers. These differences often are impossible to distinguish in the field.

Head Injuries. Gunshot wounds to the head typically are devastating because of the direct destruction of brain tissue and subsequent swelling. Patients with head wounds often sustain severe face and neck injuries as well. These can result in major blood loss, difficulty in maintaining airway control, and spinal instability.

As a medium-energy projectile penetrates the skull, the energy is absorbed within the closed space of the cranium. The force of the injury compresses brain tissue against the cranial cavity, often fracturing orbital plates and separating the dura from the bone. Depending on the qualities of the missile, the bullet may not have enough force to exit the skull after penetration. This is what occurs with .22- and .25-caliber handguns. In these injuries the bullet follows the curvature of the interior of the skull. As it follows this curvature, it produces significant damage.

High-velocity wounds to the skull produce massive destruction. Pieces of the skull and brain typically are destroyed. At close range, high-velocity wounds result in part from the large quantities of gas produced by combustion of the propellant. If the weapon is held in contact with the head, the gas follows the bullet into the cranial cavity, producing an explosive effect.

Thoracic Injuries. Gunshot wounds to the thorax can result in severe injury to the pulmonary and vascular systems. If the lungs are penetrated by a missile, the pleura and pulmonary parenchyma (the tissue of an organ, as distinguished from supporting and connective tissue) are likely to be disrupted, producing a pneumothorax. On occasion, the pulmonary defect allows air that cannot be expelled to continue to flow into the thoracic cavity. The subsequent increase in pressure eventually can cause collapse of the lung and a shift in the mediastinum to the unaffected side (tension pneumothorax).

Vascular trauma from penetrating injuries can result in massive internal and external hemorrhage. For example, if the pulmonary artery or vein, venae cavae, or aorta is injured, the patient can bleed to death within minutes. Other vascular injuries from penetrating trauma to the thorax can result in hemothorax and, if the heart is involved, myocardial rupture or pericardial tamponade.

Penetrating injury can cause thoracic trauma in the absence of visible chest wounds. For example, a bullet can enter the abdomen and travel upward through the diaphragm and into the thorax. The paramedic should evaluate all victims of abdominal gunshot wounds for thoracic injury. Likewise, the paramedic should evaluate all victims of thoracic gunshot wounds for abdominal injury.

Abdominal Injuries. Gunshot wounds to the abdomen usually require surgery to determine the extent of injury. Penetrating trauma can affect multiple organ systems, causing damage to air-filled and solid organs, vascular injury, trauma to the vertebral column, and spinal cord injury. The paramedic should assume a serious injury when managing victims of penetrating abdominal trauma. This should be the rule even if a patient appears to be stable.

Extremity Injuries. At times, gunshot wounds to the extremities are life threatening. Sometimes such wounds can result in lifelong disability. Special considerations with these injuries include vascular injury with bleeding into soft tissues and damage to nerves, muscles, and bones. The paramedic should evaluate any extremity that has sustained penetrating trauma for bone injury, motor and sensory integrity, and the presence of adequate blood flow (e.g., pulses and capillary refill).

Vessels can be injured by being struck by the bullet or by temporary cavitation. Either mechanism can damage the lining of the blood vessel, producing hemorrhage or thrombosis. Penetrating trauma can damage muscle tissue by stretching it as the muscle expands away from the path of the missile. Stretching that exceeds the tensile strength of the muscle produces hemorrhage.

Bone struck by a penetrating object can be deformed and fragmented. If this occurs, the transfer of energy causes pieces of bone to act as secondary missiles, crushing their way through surrounding tissue.

TRAUMA ASSESSMENT

Assessment and management of the trauma patient will be presented in depth throughout this textbook by subject matter. For most injury scenes, there are nine major components of assessment for trauma patients. The order of assessment is[2]:

1. Standard precautions
2. Scene size-up
3. General impression
4. Mechanism of injury
5. Primary survey
6. Baseline vital signs
7. Patient history and history of the event
8. Secondary assessment
9. Reassessment

Assessment Strategies Using Mechanism of Injury

Mechanism of injury (MOI) can be used to guide assessment for trauma patients.[2] MOI can be categorized as *significant* or *nonsignificant*. Examples of significant and nonsignificant MOI are provided in Box 37-9.

Using MOI as a guide for the potential for severe injury allows the paramedic to make decisions about on-scene assessment and care. For example, if the MOI is significant, the patient usually is in serious or critical condition. These

BOX 37-9 Mechanism of Injury

Significant MOI—Adult (Including, but Not Limited to):

- Injuries to multiple body systems
- Vehicle crashes with intrusion into the driver/passenger compartments
- Falls from heights >20 feet
- Pedestrian-vehicle collisions
- Motorcycle crashes >20 mph
- Death of an occupant in the same vehicle
- Ejection
- Vehicle telemetry system indicates high risk of injury
- Intrusion >12 inches near occupant; intrusion >18 inches anywhere

Significant MOI—Child (Including, but Not Limited to):

- Falls >10 feet without loss of consciousness
- Falls <10 feet with loss of consciousness
- Bicycle collision
- Medium to high-speed vehicle collision (<25 mph)

Nonsignificant MOI—All Ages (Including, but Not Limited to):

- Isolated trauma to a body part
- Falls without loss of consciousness

patients need to be rapidly assessed; stabilized if possible; and quickly transported to an appropriate facility for definitive care. Scene time should be limited to that required for airway, breathing, and circulatory support; spinal immobilization; and control of severe hemorrhage.

NOTE

In some cases even low-impact MOI can cause injury. For example, an infant improperly restrained in the front seat of a car that crashes or a low-speed collision with air bag deployment can result in serious injury. Every patient requires careful evaluation.

By comparison, on-scene assessment and care for patients with nonsignificant MOI can be modified as needed. After completing the primary survey, it may be appropriate to perform a thorough secondary assessment while at the scene. This assessment is focused on the patient's chief complaint or on findings in the initial assessment. Then the patient is transported for definitive care.

NOTE

MOI must be reevaluated during the patient care encounter. For example, the paramedic may initially find the patient to have a nonsignificant MOI. However, findings in the secondary assessment might indicate a more serious injury requiring rapid assessment and transport.

ROLE OF DOCUMENTATION IN TRAUMA

As described in Chapter 4, findings at the scene and the provision of patient care should be well documented on the patient care report. A thorough written record of the EMS response will help "paint a picture," or recreate the injury event for others who will be involved in the patient's care. A complete report is essential and will be referred to by hospital personnel. Documentation should include notations on an anatomical drawing for the location of wounds. It also should include a description of the scene and history of the event. Other important components of the patient care report are:

- Mechanism of injury
- Response time
- Time on-scene
- Initial findings
- Trauma scoring scales
- Changes in assessment findings
- Care provided
- Important negative findings
- Bystander care before EMS arrival

SUMMARY

- Trauma is the leading cause of death among persons 1 to 44 years of age and is the fifth leading cause of death among all Americans.
- Trauma care is divided into three phases: preincident, incident, and postincident.
- Components of the trauma system include injury prevention, prehospital care, emergency department care, interfacility transportation (if needed), definitive care, trauma critical care, rehabilitation, data collection, and trauma registry.
- Transport decisions for trauma patients should be made based on structured triage guidelines.
- Injuries are caused by a transfer of energy from some external source to the human body. The extent of injury is determined by the type of energy applied, by how quickly it is applied, and by the part of the body to which the energy is applied.
- Four laws of physics describe energy and forces that produce injury. They are Newton's first law of motion; conservation of energy law; Newton's

second law of motion; and the formula for kinetic energy.

- Kinematics is the process of predicting injuries based on mechanism of injury, forces involved, anatomy, and energy.
- Blunt trauma is an injury produced by the wounding forces of compression and change of speed, which can disrupt tissues.
- Four restraining systems are available in the United States. These are lap belts, diagonal shoulder straps, child safety seats, and air bags. All of these significantly reduce injuries. However, if they are used inappropriately, these protective devices also can produce injuries.
- Organ injuries can result from sudden movement caused by deceleration and compression forces. The recognition of these injuries requires a high degree of suspicion. The paramedic must use the principles of kinematics.
- Small motorized vehicles such as motorcycles, all-terrain vehicles, snowmobiles, motorboats, water bikes, and farm machinery are considered to be more dangerous than other motor vehicles. They are more dangerous because they offer little protection to the rider. They offer minimal protection from the transfer of energy associated with collisions.
- All auto-pedestrian collisions can produce serious injuries. They require a high degree of suspicion for multiple-system trauma.
- Sports provide a variety of health benefits. However, they also can produce severe injury. Sports injuries are related to acceleration/deceleration, compression, twisting, hyperextension, and hyperflexion mechanisms of injury.
- Blast injury is damage to a patient exposed to a pressure field that is produced by an explosion of volatile substances. Blasts release large amounts of energy in the form of pressure and heat. Blast injuries are classified as primary, secondary, tertiary, and miscellaneous.
- Falls from greater than 3 times the height of a person (15 to 20 feet) are associated with an increased incidence of severe injuries. In predicting injuries associated with falls, the paramedic should evaluate three factors: the distance fallen, the body position of the patient on impact, and the type of landing surface struck.
- All penetrating objects, regardless of velocity, cause tissue disruption. The character of the penetrating object, its speed of penetration, and the type of body tissue it passes through or into determine whether crushing or stretching forces will cause injury.

CHAPTER

38 Bleeding and Soft Tissue Trauma

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the normal structure and function of the skin.
2. Describe the pathophysiological responses to soft tissue injury.
3. Discuss pathophysiology as a basis for key signs and symptoms, and describe the mechanism of injury and signs and symptoms of specific soft tissue injuries.
4. Outline management principles for prehospital care of soft tissue injuries.
5. Describe, in the correct sequence, patient management techniques for control of hemorrhage.
6. Identify the characteristics of general categories of dressings and bandages.
7. Describe prehospital management of specific soft tissue injuries not requiring closure.
8. Discuss factors that increase the potential for wound infection.
9. Describe the prehospital management of selected soft tissue injuries.

KEY TERMS

abrasion A partial-thickness injury caused by scraping or rubbing away of a layer or layers of skin.

amputation A complete or partial loss of a limb caused by mechanical force.

avulsion A full-thickness skin loss in which the wound edges cannot be approximated.

compartment syndrome The result of a crush injury, usually caused by compressive forces or blunt trauma to muscle groups confined in tight fibrous sheaths with minimal ability to stretch.

contusion A closed, soft tissue injury characterized by swelling, discoloration, and pain.

crush injury Injury from exposure of tissue to a compressive force sufficient to interfere with the normal structure and metabolic function of the involved cells and tissues.

crush syndrome A life-threatening and sometimes preventable complication of prolonged immobilization; a pathological process that causes destruction, alteration, or both of muscle tissue.

deep fascia The dense layer of fibrous tissue beneath the dermis; provides for insulation, cushioning, caloric reserve, and body substance and shape.

degloving injury An injury usually involving the hand or finger in which the soft tissue is removed down to the bone.

dermis Dense, irregular connective tissue that forms the deep layer of the skin.

ecchymosis Skin discoloration (bruising) caused by the escape of blood into the tissues from ruptured blood vessels.

epidermis The outer portion of skin; it is formed of epithelial tissue that rests on or covers the dermis.

fasciotomy Incision of fascia to relieve elevated intracompartmental pressure.

hematoma A closed injury characterized by blood vessel disruption and swelling beneath the epidermis.

hemorrhage Flowing of blood.

hypertrophic scar An excess accumulation of scar tissue within the original wound borders.

keloid An excessive accumulation of scar tissue that extends beyond the original wound borders.

laceration A torn or jagged wound.

puncture wound An open injury that results from contact with a penetrating object.

rhabdomyolysis An acute, sometimes fatal, disease characterized by destruction of skeletal muscle.

tourniquet A constricting or compressing device used to control venous and arterial bleeding in an extremity.

The skin and its accessory organs are the primary defensive structures of the body. These structures perform many functions that are critical to survival. The paramedic must fully understand hemorrhage and soft tissue trauma. This knowledge allows the paramedic to quickly assess life-threatening injury and to intervene to promote normal healing and function.

(Courtesy Ray Kemp, St. Charles, Mo.)

NOTE

Each year about 40 million persons in the United States seek care in emergency departments for soft tissue injuries that result from falls, motor vehicle crashes, blunt and penetrating trauma, and burns. Although most soft tissue injuries are not life threatening, more than 70,000 people die each year as a result of these injuries.[1]

HEMORRHAGE

Hemorrhage occurs when there is a disruption, or "leak," in the vascular system. Sources of hemorrhage can be external or internal.

External Hemorrhage

External hemorrhage results from soft tissue injury. External hemorrhage accounted for about 2.3 million emergency department visits in the United States in 2005.[1] Most soft tissue trauma is accompanied by mild hemorrhage and does not pose a threat to life. However, even mild soft tissue trauma can carry major risks of morbidity and disfigurement. The seriousness of the injury depends on three factors: the anatomical source of the hemorrhage (arterial, venous, capillary), the degree of vascular disruption, and the amount of blood loss that the patient can tolerate.

NOTE

Education and prevention before the event are the best ways to avoid significant trauma. One strategy to this effect is to educate the public. (For example, the use of personal restraint systems can be emphasized.) Another strategy is the enforcement of laws. (An example is the enactment of helmet laws.) A third strategy involves modifications to the environment and engineering strategies. (For example, walk signals at busy intersections can be installed.) These and other strategies can help reduce the occurrence of significant injury (see Chapter 3: Injury Prevention and Public Health).

Internal Hemorrhage

Internal hemorrhage can result from a blunt or penetrating trauma. Internal hemorrhage also can result from acute or chronic illnesses. Internal bleeding that leads to an insufficient amount of circulating blood can occur in one of four body cavities: the chest, abdomen, pelvis, or retroperitoneum. Intracranial hemorrhage also can cause grave hemodynamic instability from loss of blood. Internal hemorrhage is associated with higher morbidity and mortality rates than external hemorrhage. Signs and symptoms that can indicate significant internal hemorrhage include the following:

- Bright red blood from mouth, rectum, or other orifice
- Coffee-ground appearance of vomitus
- Melena (black, tarry stools)
- Hematochezia (passage of red blood through the rectum)
- Dizziness or syncope on sitting or standing
- Orthostatic hypotension (described later in this chapter)

CRITICAL THINKING

Internal hemorrhage is associated with an increase in morbidity and mortality rates. Why do you think this is the case?

ANATOMY AND PHYSIOLOGY OF THE SKIN

The anatomy and physiology of the skin was described in Chapter 10. The following discussion will serve as a review.

The skin is a tough, supple membrane that covers the entire body. The skin constitutes the largest and most dynamic organ of the body, covering more than 20 square feet and making up 16% of total body weight. The skin comprises two distinct layers of tissue: the outer layer (epidermis) and the inner layer (dermis) (Figure 38-1).

LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 155-158.

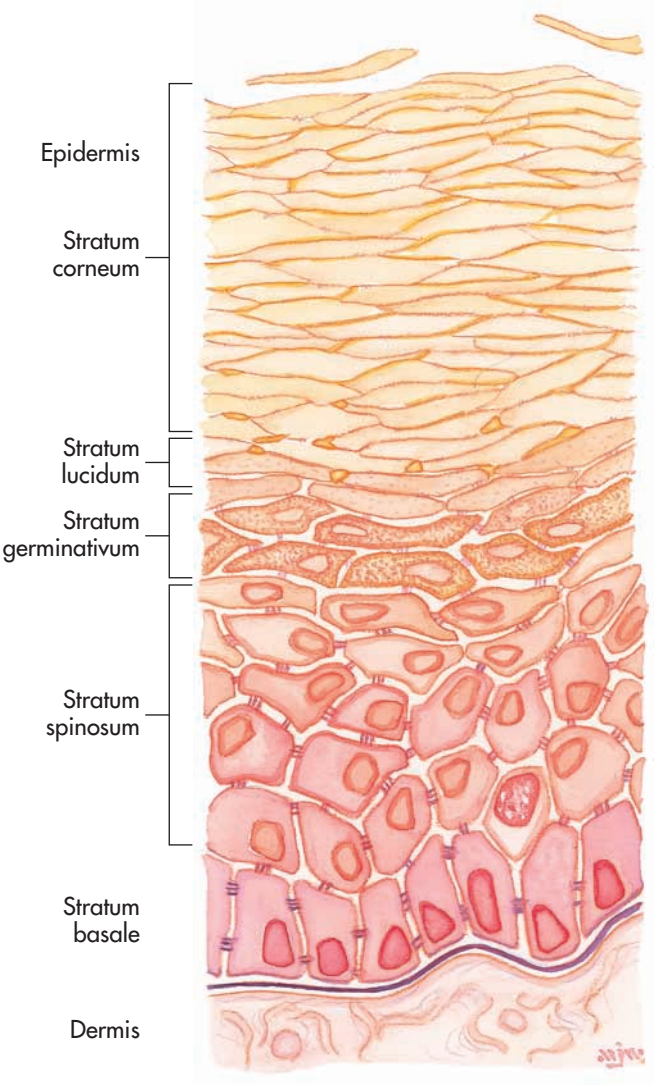

FIGURE 38-1 Tissue layers of the skin.

Epidermis

The **epidermis** is a thin, nonvascular epithelial tissue that derives its nourishment from the capillaries of the dermis. Although the epidermis is only as thick as a page of this text, the epidermis is composed of five layers: stratum basale, the innermost layer; stratum spinosum; stratum granulosum; stratum lucidum; and stratum corneum, the most superficial layer of the epidermis. The stratum corneum is composed of about 20 layers of dead skin cells that are filled with the waterproofing protein keratin.

Dermis

The **dermis** lies beneath the epidermis. The dermis contains connective tissue, elastic fibers, blood vessels, lymph vessels, and motor and sensory fibers. The dermis also houses other structures of the integumentary system. These other structures include hair, nails, and sebaceous and sweat glands. This layer of skin offers protection against bacterial invasion and helps maintain fluid balance as well.

Connective tissue and elastic fibers in the dermis give skin its strength and elasticity. Blood vessels in the dermis nourish all skin cells. They also aid in body temperature regulation through vasoconstriction or vasodilation. Nerves in the dermis generate impulses to dermal muscles and glands. These nerves also are responsible for carrying impulses away from sensory receptors in the skin in response to pain, touch, heat, and cold.

CRITICAL THINKING

Predict the effects of destruction of a large segment of skin, which includes the dermis, based on your knowledge of its functions.

The dermis has a reservoir of defensive and regenerative elements. These elements combat infection and repair deep wounds. They do this by use of specialized white blood cells, lymphatics, and other cellular components.

The dense layer of fibrous tissue beneath the dermis is the **deep fascia.** This layer provides for insulation, cushioning, caloric reserve, and body substance and shape. The primary function of this tissue is to support and protect underlying structures.

PATHOPHYSIOLOGY

Surface trauma can disrupt the normal distribution of body fluids and electrolytes. Surface trauma also can interfere with the maintenance of body temperature. The two physiological responses to surface trauma are vascular and inflammatory reactions. These reactions can lead to healing, scar formation, or both. The extent and success of these responses are influenced by the amount of tissue that has been disrupted.

Hemostasis of Wound Healing

As described in Chapter 32: Hematology, *hemostasis* is the initial physiological response to wounding. This vascular reaction involves vasoconstriction, formation of a platelet plug, coagulation, and the growth of fibrous tissue into the blood clot that permanently closes and seals the injured vessel. To review, vasoconstriction resulting from injury is rapid but temporary. In response to injury, severed blood vessels constrict and retract with the aid of the surrounding subcutaneous tissues. This vessel spasm slows blood loss immediately and may completely close the ends of the injured vessels. The vasoconstriction usually is sustained for as long as 10 minutes. During this time, blood coagulation mechanisms are activated to produce a blood clot.

Platelets adhere to injured blood vessels and to collagen in the connective tissue that surrounds the injured vessel. As platelets contact collagen, they swell, become sticky, and secrete chemicals that activate other surrounding platelets.

This process creates a platelet plug in the injured vessel. If the opening in the vessel wall is small, the plug may be sufficient to completely stop blood loss. For larger wounds, however, a blood clot is necessary to stop the flow of blood (Figure 38-2).

Blood coagulation occurs as a result of a chemical process that begins within seconds of a severe vessel injury and within 1 to 2 minutes of a minor wound. Coagulation progresses rapidly; within 3 to 6 minutes after the rupture of a vessel, the entire end of the vessel is filled with a clot. Within 30 minutes the clot retracts and the vessel is sealed further. As described in Chapter 32: Hematology, the clotting cascade is a complex process and includes the following three mechanisms:

1. Prothrombin activator is formed in response to rupture or damage of the blood vessel.
2. Prothrombin activator stimulates the conversion of prothrombin to thrombin.
3. Thrombin acts as an enzyme to convert fibrinogen into fibrin threads. These threads entrap platelets, blood cells, and plasma to form the clot.

The process of hemostasis usually is protective and is required for survival. However, hemostasis also can result in responses that threaten life and function. Examples include blood clots that form in atherosclerotic vessels that lead to myocardial infarction or stroke (see Chapter 22).

CRITICAL THINKING

List some drugs that may impair the normal clotting functions.

Inflammatory Response

The release of chemicals from the injured vessel and various blood components (platelets, white blood cells) causes localized vasodilation of arterioles, precapillary sphincters, and venules. This response increases the permeability of the affected capillaries and vessels. Plasma, plasma proteins, electrolytes, and chemical substances from the leaking venules accumulate in the extracellular space for about 72 hours after the injury. Blood flow increases to the area of injury to supply the metabolic demands of the tissues during healing. This results in the redness, swelling, and pain associated with inflammation.

The transportation of granulocytes, lymphocytes, and macrophages to the injured area also increases local blood flow. These specialized cells prepare the wound for healing. They clear foreign bodies and dead tissue. They trigger new vessel formation as well. Within 12 hours of the injury, new epithelial cells are regenerated. (This is the *epithelialization phase*.) These cells begin the process of healing through the reestablishment of skin layers (Figure 38-3).

Collagen is the main structural protein of most body tissues. The normal repair of tissues depends on collagen synthesis and deposition. In the healthy body, fibroblasts synthesize and deposit collagen within 48 hours after injury. Collagen increases the tensile strength of the tissue. However, most injured tissue will not regain its full strength and function until at least 4 months later.[2]

Alterations of Wound Healing

Many factors can affect or alter wound healing. These include anatomical factors, concurrent drug use, medical condition and disease, and wounds that are high risk.

ANATOMICAL FACTORS

Some tissues of the body heal better and faster than others because of the body region and the amount of tension on the tissues (lines of tension). The elasticity of the skin and lines of tension vary in different areas of the body. Moreover, they are affected by muscular contraction and the body movements of flexion and extension. Thus these factors affect wound healing and scar formation. For example, a soft tissue injury to the forearm generally heals better and faster than one over a joint. Other anatomical factors that may adversely affect wound healing and scar formation include oily skin and pigmentation.

CONCURRENT DRUG USE, EXISTING MEDICAL CONDITIONS, AND DISEASE

Certain factors can delay or interfere with the normal wound-healing process through various mechanisms.[3] For instance, a patient's concurrent drug use can interfere with or delay this process. Existing medical conditions also may have this effect. In addition, disease can delay or interfere with the process. Common drugs that can alter wound healing include corticosteroids, nonsteroidal antiinflammatory drugs (***aspirin***), penicillin, colchicine, anticoagulants, and antineoplastic agents. Medical conditions and diseases that can result in delayed healing include the following:

- Advanced age
- Severe alcoholism
- Acute uremia
- Diabetes
- Hypoxia
- Peripheral vascular disease
- Malnutrition
- Advanced cancer
- Hepatic failure
- Cardiovascular disease

HIGH-RISK WOUNDS

High-risk wounds have an increased potential for infection because of the location of the wound or the nature of the wounding force. Examples of high-risk wounds include those located on or near the hands, feet, and perineal areas. Wound forces that are associated with a high risk for infection include those produced by human and animal bites, foreign bodies, and injection (e.g., high-pressure grease guns). Other high-risk wounds are those contaminated with organic material or that have a significant amount of

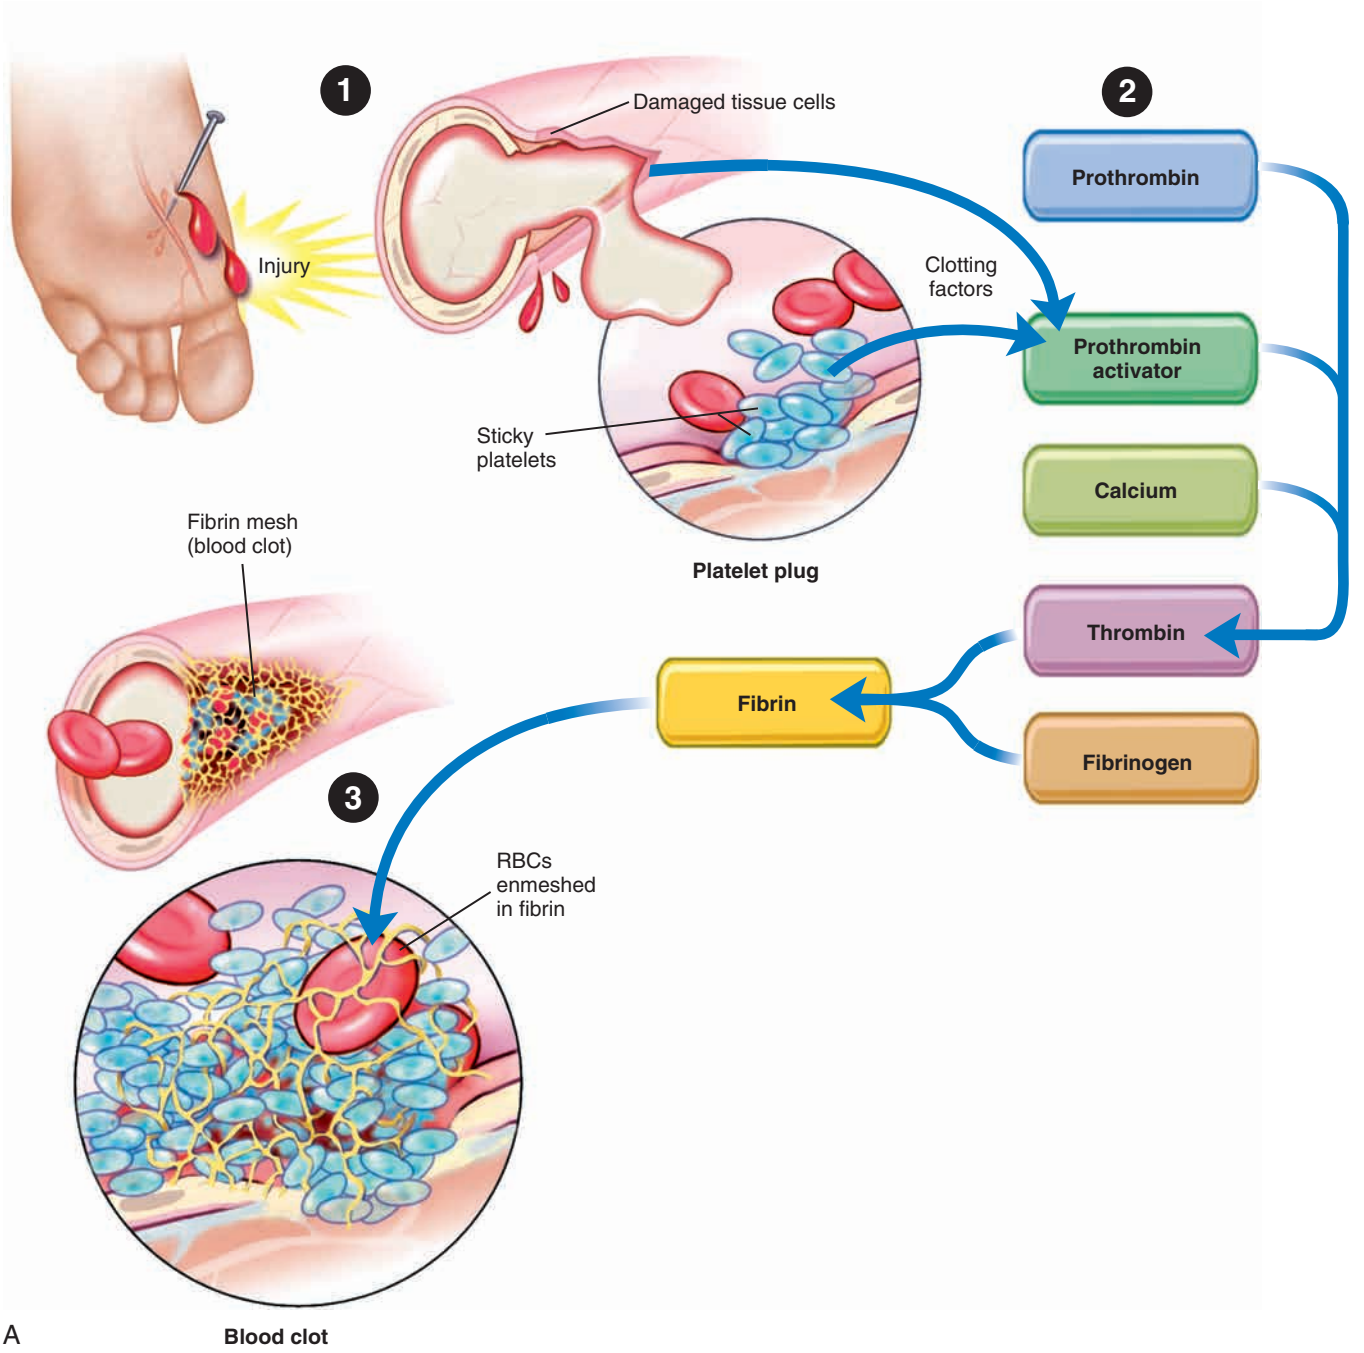

FIGURE 38-2 Blood clotting. **A,** The extremely complex clotting mechanism can be condensed into three basic steps: *1,* release of clotting factors from both injured tissue cells and sticky platelets at the injury site (which form a temporary platelet plug); *2,* series of chemical reactions that eventually result in the formation of thrombin; and *3,* formation of fibrin and trapping of red blood cells to form a clot. **B,** Red blood cells (RBCs) and white blood cells (WBCs) entrapped in a fibrin (yellow) mesh during clot formation (WBCs are blue). (From Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

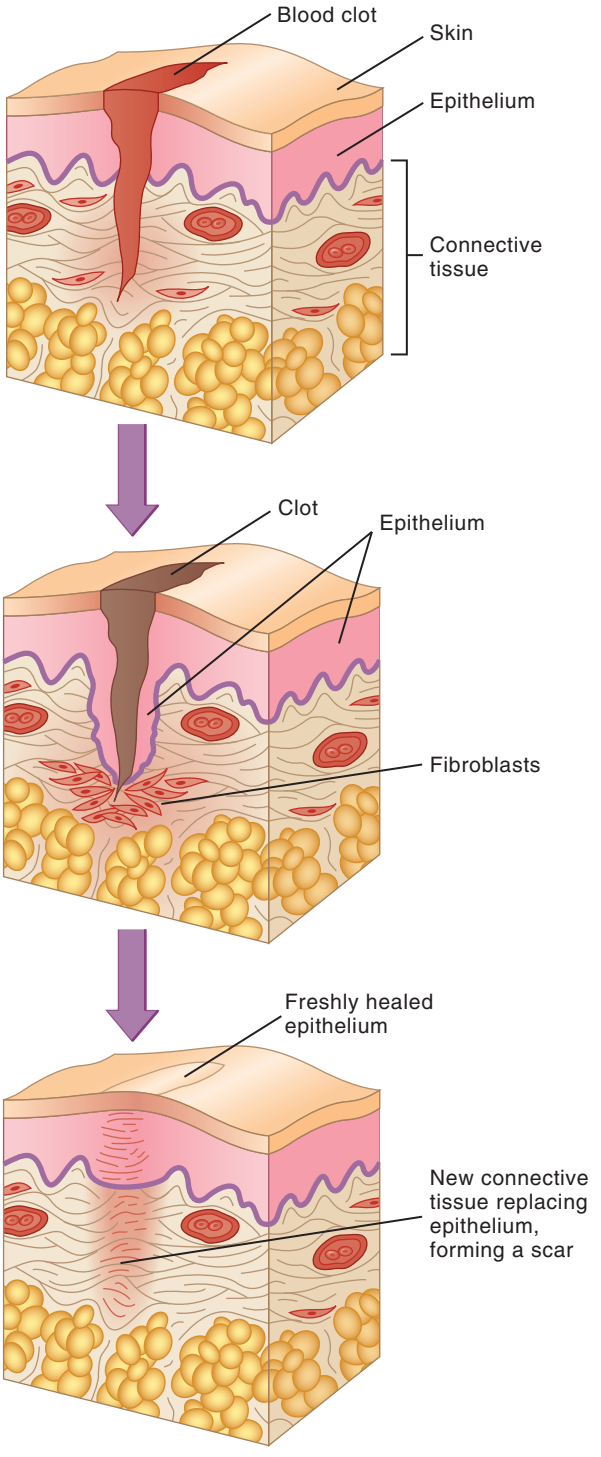

FIGURE 38-3 Healing of a minor wound. (From Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

dead (devitalized) tissue; crush wounds; and any wounds in patients who are immunocompromised or who have poor peripheral circulation.

ABNORMAL SCAR FORMATION

Abnormal scar formation can result in a keloid or hypertrophic scar. A **keloid** is the excessive accumulation of scar tissue that extends beyond the original wound borders. This abnormal scar is more common in darkly pigmented patients. The scar also is more common in those who have injuries to the ears, upper extremities, lower abdomen, or sternum. A **hypertrophic scar** has an excess accumulation of scar tissue within the original wound borders. This scar is more common in areas of high tissue stress such as the flexion creases across joints.

WOUNDS REQUIRING CLOSURE

Although all serious wounds should be evaluated by a physician, the paramedic should expect the following types of wounds to require closure:

- Wounds to cosmetic regions (e.g., face, lips, and eyebrows)
- Gaping wounds
- Wounds over tension areas (e.g., joints)
- Degloving injuries (described later in this chapter)
- Ring finger injuries
- Skin tearing

Many techniques are used to close a wound, including suture, tape, staples, and tissue adhesives.

PATHOPHYSIOLOGY AND ASSESSMENT OF SOFT TISSUE INJURIES

Soft tissue injuries are classified as closed or open. This classification depends on the absence or presence of a break in the continuity of the epidermis. Soft tissue wounds often are the most evident injury. However, they generally are considered low-priority injuries, unless life-threatening hemorrhage or associated airway compromise is present.

Closed Wounds

Closed soft tissue injuries usually are associated with little blood loss. However, some of these injuries can cause significant hemorrhage in the cavities of the thorax, abdomen, pelvis, or soft tissues of the legs. This text classifies closed wounds as contusion, hematoma, and crush injury.

CONTUSIONS AND HEMATOMATA

Blunt trauma causes contusions and hematomata. A **contusion** is characterized by blood vessel disruption beneath the epidermis. A contusion results in swelling, pain, and **ecchymosis** (bruising) that can occur 24 to 48 hours after the injury. A **hematoma** is a collection of blood beneath the skin. A hematoma may occur with a contusion. However, the hematoma represents a larger amount of tissue damage and the disruption of larger vessels (Figure 38-4). These

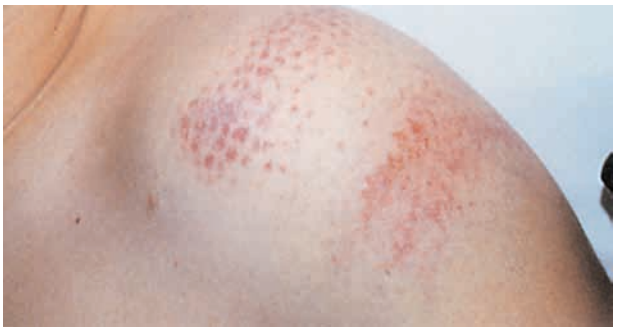

FIGURE 38-4 Spotty bruising in a well-padded part of the shoulder. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

FIGURE 38-5 Appearance of a woman's leg after it had been run over by the wheel of a milk van. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

wounds usually are superficial. Sometimes, though, they are associated with underlying fractures, vascular involvement, and significant hemorrhage.

CRUSH INJURY

Crush injury can occur when a crushing force is applied to a body area (Figure 38-5). These injuries can be severe. Sometimes they are associated with internal organ rupture, major fractures, and hemorrhagic shock. Overlying skin may remain intact with crush injury, even in the presence of severe injury and shock. Crush injuries are further described later in this chapter.

CRITICAL THINKING
What are some mechanisms of crush injury?

FIGURE 38-6 Deep abrasion caused by a fall from a bicycle. (From Henry MC, Stapleton ER: *EMT prehospital care,* ed 4, St Louis, 2009, Mosby.)

FIGURE 38-7 Large wound caused by a broken power saw. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

Open Wounds

Open soft tissue injuries are classified as abrasion, laceration, puncture, avulsion, amputation, and bites. (*NOTE:* Burns that include open and closed injury are addressed in Chapter 39.)

ABRASION

An **abrasion** is a partial-thickness skin injury. Abrasion is caused by the scraping or rubbing away of a layer or layers of skin (Figure 38-6). The wound usually results from friction with a hard object or surface. (For example, abrasions occur in sports injuries and motorcycle crashes.) Although these wounds often are superficial, they are painful and are at high risk for infection from contamination.

LACERATION

A **laceration** results from a tear, a split, or an incision of the skin (Figure 38-7). Lacerations most often are caused by a knife or other sharp object, resulting in a linear wound or incision. The sizes and depths of lacerations vary greatly depending on the injury sites and wounding mechanism. Lacerations can be sources of significant bleeding.

PUNCTURE

Contact with a sharp, pointed object commonly causes a **puncture wound** (Figure 38-8). (Examples of such objects include a wooden splinter, needle, staple, glass, or nail.) The entrance wound generally is small. Yet these injuries often may be associated with deep penetration and injury to underlying tissues. Punctures can be difficult to assess in the prehospital setting. Even an injury that appears to be minor can conceal a considerable amount of internal damage.

In some penetrating injuries, the object remains embedded or impaled in the wound (Figure 38-9). If the chest or abdomen is involved, severe bleeding and major underlying damage to internal organs can occur. Examples include the following:

- Chest injury
- Pneumothorax (simple, open, tension)
- Hemothorax
- Pericardial tamponade
- Penetrating heart wound
- Rupture of the esophagus, aorta, diaphragm, main stem bronchus
- Abdominal injury
- Hollow and solid organ damage
- Peritonitis (bacterial, chemical)
- Evisceration

FIGURE 38-8 Puncture wounds caused by broken glass from a shattered windshield. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

FIGURE 38-9 Piece of wood impaled in the right side of the chest, piercing the diaphragm and lacerating the spleen, stomach, and liver. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

CRITICAL THINKING

Why should a person always seek medical care to have a penetrating object removed?

The injection of a substance into the body under high pressure also can cause a puncture wound (Figure 38-10). (Examples include grease, paint, turpentine, dry-cleaning fluids, and molten plastics.) These injuries often have life- or limb-threatening potential. They often require rapid surgical decompression and debridement. These injuries usually are associated with minimal bleeding. In addition, they may not appear serious. Numbness and blanching of the involved area often occur because of increased tissue pressure of the injected substance. Most patients with injection injuries are surgical emergencies. Moreover, most of these patients are at high risk for developing compartment syndrome (described later in this chapter). Definitive care for injection injuries usually requires surgery and hospitalization to prevent infection. Amputation may be needed if treatment is delayed.

AVULSION

An **avulsion** is a full-thickness skin loss (Figure 38-11) in which the wound edges cannot be approximated. Frequently involved body areas are the earlobes, nose tip, and fingertips. A common cause of avulsion injury is industrial equipment, such as meat slicers or sawing devices. Another common cause is domestic violence, such as human bites.

FIGURE 38-10 Injection of paraffin into the hand resulted in amputation of the index finger. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

FIGURE 38-11 Ring avulsion injury. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

FIGURE 38-12 Degloving injury of the foot. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

A **degloving injury** is a type of avulsion. In this injury, shearing forces separate the skin from the underlying tissues (Figure 38-12). A common cause of such an injury is industrial machinery. This machinery may entangle an extremity, producing circumferential tearing. Another common cause is finger jewelry that gets caught on a stationary object. This can produce a shearing of the soft tissue and possibly of the bone of the digit. Another common cause is machinery that entraps hair, resulting in scalp avulsion. Degloving injuries sometimes are associated with underlying skeletal damage. They also sometimes are associated with massive loss of tissue in the affected area. Bleeding can be significant.

AMPUTATION

Traumatic **amputation** involves a complete or partial loss of a limb by a mechanical force (Figure 38-13). The digits, lower leg, hand and forearm, and the distal part of the foot most often are injured in this way. Bleeding is a possible fatal complication of an amputation injury. In cases in which a complete amputation has occurred, injured arteries often retract. Hemorrhage may be less severe than in partial amputation injuries.

FIGURE 38-13 Amputation of the fingertip. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

BITES

An animal or human bite wound frequently is a combination of puncture, laceration, avulsion, and crush injury (Figure 38-14). (Insect bites and stings also are a source of soft tissue injury. They are addressed in Chapter 34: Toxicology.) The pressure from a bite can be as great as 400 psi. The bite can involve deep structures such as tendons, muscles, and bones. Complications from bite wounds, particularly human bites, include abscesses, lymphangitis, cellulitis, osteomyelitis, tenosynovitis, tuberculosis, hepatitis B, and tetanus. Although it is theoretically possible for a human bite to transmit human immunodeficiency virus, the Centers for Disease Control and Prevention suggest that the potential for salivary transmission of the virus is remote.[4] Other less common complications of mammalian bites include the transmission of diseases such as actinomycosis, syphilis, and, rarely, rabies. All patients who have been bitten should seek physician evaluation.

NOTE

There is a common misperception that dog bites are "clean" bites, and that a dog's mouth has less germs than a human mouth. In reality, the mouths of dogs (and cats) are filled with bacteria, many of which can cause disease if they enter broken skin. Over 130 disease-causing microbes have been isolated from dog and cat bite wounds.[5] Animal saliva is also heavily contaminated with bacteria. Diseases that can be transmitted to humans through a bite from a dog or cat include pasteurellosis, streptococcal and staphylococcal infections, and *Capnocytophaga* infection (among others).

FIGURE 38-14 Human bite to the hand. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

CRITICAL THINCKING

Consider that you are caring for a person who has sustained an animal bite. Aside from caring for the patient's wounds and documenting that care, what other concerns and responsibilities do you have?

Crush Injury

Crush injury is one of the three injuries that occurs when tissue is exposed to a compressive force. This force can be sufficient to interfere with the normal structure and metabolic function of the involved cells and tissues. The degree of injury produced by the crushing force depends on the amount of pressure applied to the body, the amount of time the pressure remains in contact with the body, and the specific body region in which the injury occurs. A massive crush injury to vital organs can cause immediate death.

Crush injury usually involves the upper or lower extremities, torso, or pelvis. Crush injury can result from entrapment under a heavy object, as in a foundation collapse, or from some other massive compressive force. Examples of situations that can cause crush injury include the following:

- Collapse of masonry or steel structures
- Collapse of earth (e.g., mud slides and earthquakes)
- Motor vehicle crashes

FIGURE 38-15 Appearance that can follow prolonged crushing, as when an unconscious person lies on a body part for several hours.

- Warfare injuries
- Industrial incidents
- Prolonged application of a pneumatic antishock garment and improperly applied casts

COMPARTMENT SYNDROME

Compartment syndrome is a result of crush injury and is a surgical emergency (Figure 38-15). Compartment syndrome usually results from compressive forces or blunt trauma to muscle groups confined in tight fibrous sheaths with minimal ability to stretch (below the knee, above the elbow). Other less common causes of compartment syndrome include the following[2]:

- Extreme exertional exercise
- Low-level repetitive injury
- Electrical injury
- Hemorrhage into a compartment (e.g., coagulopathy among hemophiliacs)
- Circumferential deep burns and electrical burns
- Vascular occlusion
- High-pressure injection injuries
- Immobility with the development of pressure necrosis (e.g., among alcoholics, drug addicts, and victims of stroke)

CRITICAL THINKING

Why would alcoholics, drug addicts, and stroke victims be at risk for compartment syndrome?

Compartment syndrome develops as associated hemorrhage and edema increase pressure in the closed fascial space (compartment). This results in ischemia to the muscle. This ischemia causes further muscle cell swelling. The intracompartmental pressure continues to rise. As this occurs, circulation is compromised. Irreversible tissue damage from lack of oxygen develops within several hours

to several days after injury. In addition to muscular damage, any nerves that travel through the compartment can undergo necrosis if the condition remains untreated. Signs and symptoms of compartment syndrome in an extremity include those of vascular insufficiency (the five P's; Box 38-1). Other signs and symptoms that can indicate the presence of compartment syndrome include the following:

- Pain seemingly out of proportion to injury
- Swelling (tautness of the compartment)
- Tenderness to palpation
- Weakness of the involved muscle groups
- Pain on passive stretch (earliest finding)

The recognition of compartment syndrome calls for a high degree of suspicion based on patient history and mechanism of injury. Compartment syndrome most often is associated with tibial fracture of the lower leg. Yet compartment syndrome also can occur with crush injury or fracture of the femur, forearm, or upper arm. Delayed treatment can result in nerve death, muscle necrosis, and crush syndrome.

CRUSH SYNDROME

Crush syndrome is a life-threatening and sometimes preventable complication of prolonged immobilization or compression. The syndrome is a pathological process that causes destruction or alteration of muscle tissue. Crush syndrome is rare and is most likely to occur in catastrophic events in which patient rescue and extrication are delayed beyond 4 to 6 hours. (Examples of such events are earthquake or building collapse.) The prehospital management of crush syndrome often determines patient outcome.

The compressive forces of entrapment are believed to produce crush syndrome.[6] The pathological process disrupts vascular integrity and causes loss of structure of the cell and the cell membranes. Patients with crush syndrome may appear stable for hours or days, as long as the compressive forces remain in place. But when the patient is released from the entrapment, three harmful processes occur at the same time that can lead to death:

1. Oxygen-rich blood returns to the ischemic extremity. This produces a pooling of intravascular volume into crushed tissue. This reperfusion reduces total circulating volume, which in turn often leads to shock.
2. With the return of oxygen-rich blood, various toxic substances and waste products of anaerobic metabolism are released into the systemic circulation. This causes metabolic acidosis. High levels of intracellular solutes and water are released from damaged cells. This results in hyperkalemia, hyperuricemia, hypocalcemia, and hyperphosphatemia.
3. Myoglobin is released from the damaged muscle cells of the injured extremity. Myoglobin is filtered through the kidneys (**rhabdomyolysis**) and results in acute renal failure.

BOX 38-1 Five P's of Vascular Insufficiency

1. **P**ain
2. **P**aresis (late finding)
3. **P**aresthesia
4. **P**allor (variable)
5. **P**ulselessness (late finding)

Blast Injuries

As described in Chapter 36, severe injuries can result from an initial air blast, from flying debris, and from secondary contact with another object as the victim is thrown by the blast. Examples of situations that can result in blast injury include natural gas or gasoline explosions, fireworks explosions, explosions in grain elevators, and terrorist bombs. Scene and personal safety is of the highest priority. Paramedics should not enter the scene where a blast injury occurred until the scene has been made safe by the authorities. (The appropriate authorities include, for example, law enforcement, fire service, specialized rescue teams, hazardous materials teams, and other public service agencies.)

Injuries from blasts can be superficial or deep (Figure 38-16). The deep injuries can damage internal organs. Patients who suffer blast injury require rapid stabilization (airway and ventilatory support with spinal precautions; circulatory support) and rapid transportation for physician evaluation. Blast injuries and associated trauma can be difficult to identify in the prehospital setting. These patients

FIGURE 38-16 Blast injury to the face. His eardrums were normal. He was admitted because of the risk of swelling to his face and airway with potential airway obstruction. (From Beattie T, et al: *Pediatric emergencies,* London, 1997, Mosby-Wolfe.)

will need extensive evaluation in a trauma center. Compression injuries that occur to air-filled organs include rupture of the eardrum, sinuses, lungs, stomach, and intestines.

CRITICAL THINKING
What injury do you suspect if a patient who has suffered a blast injury has a sudden onset of hearing loss?

MANAGEMENT PRINCIPLES FOR SOFT TISSUE INJURIES

Personal and scene safety is always the priority in any emergency response. If indicated, law enforcement and rescue personnel should advise the EMS crew that the scene is relatively safe to enter and that any perpetrators have been apprehended. Even so, the paramedic must always be alert for possible hazards at the scene (e.g., a second perpetrator or secondary explosive device). Help from other public service agencies also may be needed if other types of dangers exist. Examples of such dangers may include hazardous materials or bombs.

Treatment Priorities

The assessment of life-threatening injuries and resuscitation precedes evaluation and intervention of non–life-threatening soft tissue injuries. The paramedic should evaluate wounds that do not pose a threat to life later in the physical exam. General wound assessment should include a history of the wounding event and a careful examination of the injury. Figure 38-17 shows a treatment plan based on assessment findings for a patient with soft tissue injury.

Wound History

A wound history should include the following:

- Time of injury
- Environment where the injury occurred (risk of infection is greater in unclean environments)
- Mechanism of injury and likelihood of concurrent or associated injuries
- Volume of blood loss
- Severity of pain
- Medical history, including use of medications that may impair hemostasis
- Tetanus immunization

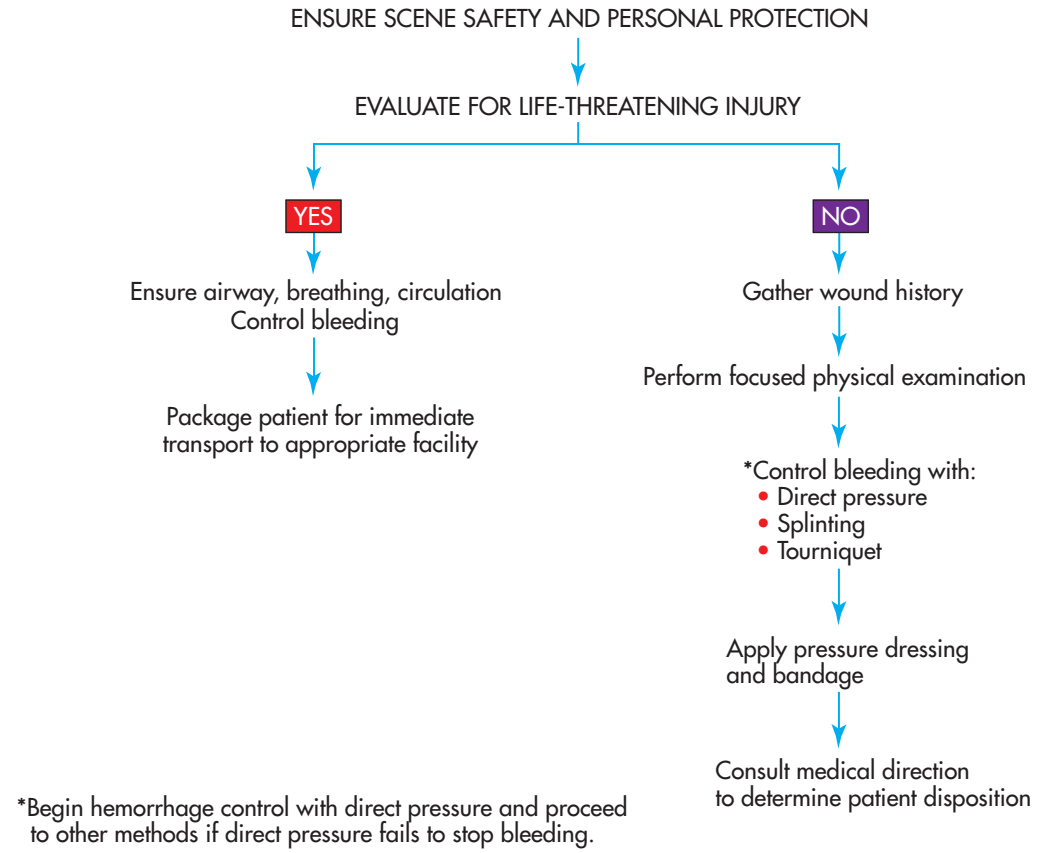

FIGURE 38-17 Treatment plan for a patient with soft tissue injury.

Physical Examination

Physical examination of a wound should include the following:

- Inspection of the wound for bleeding, size, depth, presence of foreign bodies, amount of tissue lost, edema, and deformity
- Inspection of the area surrounding the wound for damage to underlying structures, arteries, nerves, tendons, or muscle

CRITICAL THINKING
Will you perform this physical examination on every wound in the prehospital setting?

- Assessment of sensory or motor function of the extremity
- Evaluation of the perfusion status of the wound and tissue distal to the wound
- Palpation of the injury and associated structures to evaluate capillary refill, distal pulses, tenderness, temperature, edema, and crepitus (if underlying bony injury is suspected)

HEMORRHAGE AND CONTROL OF BLEEDING

Blood loss often is associated with soft tissue injury. The blood loss may result from damage to arteries, veins, capillaries, or a combination of these. Generally, arterial bleeding is characterized as bright red and spurting. Venous bleeding is dark reddish-blue and flowing. Capillary bleeding is bright red and oozing. But differentiation among the types of vessel hemorrhage often is difficult. In the prehospital setting the main concern in hemorrhage, regardless of origin, is to control bleeding.

Methods of hemorrhage control include direct pressure, immobilization by splinting, pneumatic pressure devices (air splints, pneumatic antishock garment), and the use of tourniquets. As in any patient encounter in which contact with body fluids is likely, the paramedic must take personal protective measures. (The use of pressure on an artery proximal to a wound and elevation of an extremity to control hemorrhage is no longer recommended as part of prehospital care.[3] There are insufficient data to support the effectiveness of these measures.[7])

Direct Pressure

The paramedic can control external hemorrhage by applying direct pressure over the injury site (Figure 38-18). Direct pressure controls most types of hemorrhage within 4 to 6 minutes. To maintain control, a pressure dressing can be applied over the site and held in place with an elastic bandage. The paramedic must continue direct pressure, even with a pressure dressing. Once the dressing has been applied, the paramedic should not remove it because removal can disrupt the fresh blood clot. If bleeding resumes and the dressing becomes soaked with blood, a second dressing should be applied on top of the first one and held in place with direct pressure until the bleeding is controlled.

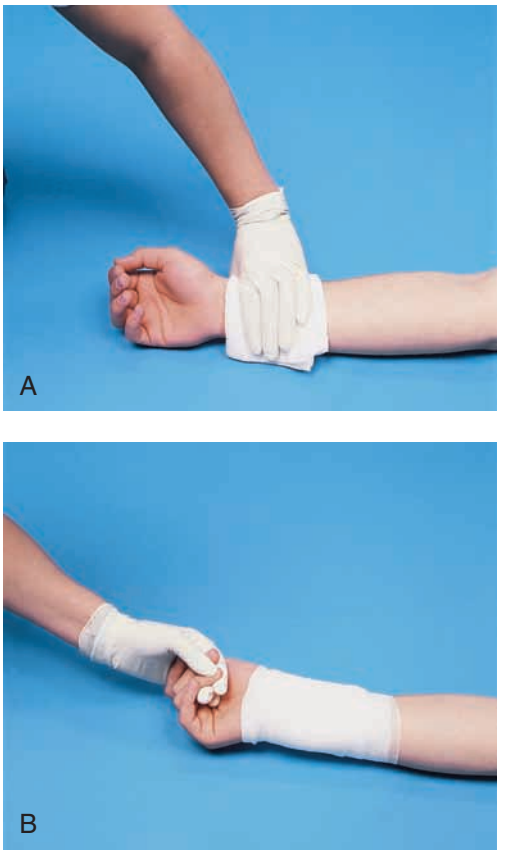

FIGURE 38-18 **A,** Application of direct pressure to control hemorrhage. **B,** Pressure dressing.

CRITICAL THINKING
Why should the pressure point chosen to control hemorrhage be proximal to the injury?

Immobilization by Splinting

Patient movement promotes the flow of blood. This movement can disrupt the clot or increase vascular injury. Thus patients should be immobilized whenever possible (Figure 38-19). The paramedic can immobilize extremity injuries with appropriate splinting devices. The patient can be immobilized fully with a long spine board. Immobilization is not effective alone as a method to control bleeding. Immobilization should be used as an adjunct.

Pneumatic Pressure Devices

Pneumatic pressure devices can provide uniform direct pressure to an immobilized injury site. (Examples of such devices are inflatable air splints applied to an extremity or the use of the pneumatic antishock garment.) These devices should be applied over a dressed wound only after other methods have controlled the bleeding (Figure 38-20).

FIGURE 38-19 Immobilization by splinting to control hemorrhage.

FIGURE 38-20 Application of pneumatic pressure device to control hemorrhage.

Tourniquet

The use of a **tourniquet** to control bleeding was once considered a "last resort" in bleeding control. However, recent studies based on wartime injuries in Iraq and Afghanistan have proven tourniquets to be safe and effective when properly applied.[8] Guidelines for application of a tourniquet are as follows (Figure 38-21)[9]:

1. Consult with medical direction.
2. Select a site for the tourniquet. The site should be about 2 inches proximal to the wound and over the supplying brachial or femoral artery. A blood pressure cuff applied over the brachial artery also can act as a tourniquet. If a blood pressure cuff is used, note the time of application on the cuff itself.
3. Place the commercial tourniquet (e.g., Combat Application Tourniquet [C-A-T], Emergency Military Tourniquet [EMT], Special Operations Force Tactical Tourniquet [SOFTT]) or 4-inch wide, flat material just above the wound and over the artery to be compressed. Never use thin material such as rope or twine because it may damage underlying tissue. If a blood pressure cuff is used as a tourniquet, inflate the cuff until the cuff pressure exceeds the arterial pressure or to the point at which the hemorrhage stops.
4. Place the pad (a roll of gauze or thick folded dressings) over the artery to be compressed.
5. Encircle the tourniquet twice around the extremity and pad, and tie it in a half knot over the pad.
6. Place a windlass (stick, pen, or similar object) on the half knot, and secure it in place with a square knot.
7. Tighten the windlass by twisting *only* until hemorrhage stops. Secure the windlass in that position. Never loosen the tourniquet once it is tightened.
8. Note the time of tourniquet application and secure it to the patient, or clearly mark "TK" on the patient's forehead. Document the tourniquet procedure on the patient care report (Figure 38-22).

FIGURE 38-21 Application of a tourniquet to control hemorrhage.

NOTE

The improper application of a tourniquet may cause damage to nerves and blood vessels and result in the eventual loss of an extremity. A poorly applied tourniquet can produce venous occlusion, only restricting the outflow but not the inflow of blood and producing an increase in blood loss. Use of a tourniquet should be considered only when other methods have failed to control bleeding and when its use is essential to save the patient's life. An example of such an extreme circumstance is a partial or complete traumatic amputation of a limb. Other indications for tourniquet use include mass casualty incidents with multiple bleeding injuries that overwhelm rescuer capabilities, tactical or combat situations in which the scene is not safe to render care, and when a greater priority exists, such as airway or respiratory management or initiating the treatment for shock.[10]

FIGURE 38-22 Commercial tourniquet application.

DRESSING MATERIALS USED WITH SOFT TISSUE TRAUMA

A variety of bandages and dressings are used in trauma care. The six general categories of dressings are as follows:

1. *Sterile dressings* are processed to eliminate bacteria. They should be used whenever infection of the wound is a concern.
2. *Nonsterile dressings* are not sterilized. They can be used when infection is not a prime concern.
3. *Occlusive dressings* do not allow the passage of air through the material. These dressings are useful in treating wounds of the thorax and major vessels where negative pressure can cause air to enter the body, resulting in a pneumothorax or air embolism, respectively (see Chapter 42).
4. *Nonocclusive dressings* allow air to pass through the material and are indicated for managing most soft tissue injuries.
5. *Adherent dressings* attach to the wound surface by incorporating wound exudate into the dressing mesh. Use of these dressings sometimes can assist in controlling acute bleeding.
6. *Nonadherent dressings* allow the passage of wound exudate and do not adhere to the wound surface. These dressings do not damage the wound when removed and often are used after wound closure.

Bandages hold dressings in place. Bandages are classified as absorbent, nonabsorbent, adherent, and nonadherent. Like dressings, bandages are sterile or nonsterile.

Complications of Improperly Applied Dressings and Bandages

Improperly applied dressings and bandages can harm the patient and can cause discomfort. For example, dressings that are applied too loosely often do not stop bleeding. Bandages that are applied too tightly can cause tissue ischemia and structural damage to vessels, nerves, tendons, muscles, and skin.

Basic Concepts of Open Wound Dressing

The basic concepts of open wound dressing include the following steps:

1. Assess the wound for size, depth, location, and contamination.
2. Properly prepare the wound for dressing. Prehospital care usually is limited to cleaning the injured surface of gross contaminants by irrigation of the wound with sterile water or normal saline. Do not attempt extensive debridement in the prehospital setting. Apply antibacterial ointment if the patient is not allergic (per protocol).
3. Apply the appropriate dressing.
4. Secure the dressing in place with bandages or gauze wrappings.
5. Tape the loose ends of the bandage.

MANAGEMENT OF SPECIFIC SOFT TISSUE INJURIES NOT REQUIRING CLOSURE

The paramedic will encounter many minor open wounds that do not require closure or the evaluation by a physician. In these cases, basic first aid and instructions for self-care should be provided to the patient.

Dressings and Bandages

Depending on the nature and location of the patient's injury, dressings, bandages, and immobilization may be indicated to care for the wound properly. (Figure 38-23 illustrates basic dressing and bandaging procedures for various wounds.) Open wounds that usually require physician evaluation include those with the following:

- Neural, muscular, or vascular compromise
- Tendon or ligament compromise
- Heavy contamination
- Cosmetic complications (e.g., facial trauma)
- Foreign bodies
- Animal bites with deep punctures

Patients with soft tissue injuries that pose a threat to life or limb require rapid assessment, stabilization, and rapid transportation for physician evaluation.

NOTE

Some EMS agencies carry hemostatic dressings for wound care. These special dressings have multiple layers of resorbable materials and fibrin patches that contain coagulation proteins. Examples of these dressings include CELOX, QuikClot, and HemCon.

FIGURE 38-23 Types of dressings. **A,** Shoulder dressing. **B,** Ankle dressing. **C,** Torso dressing. **D,** Thigh dressing. **E,** Finger dressing. **F,** Elbow dressing.

SHOW ME THE EVIDENCE

Amylopectin (Chitosan) dressings have been in use since the 1990s. These researchers sought to determine the effectiveness of amylopectin powder when directly poured into a wound. Using a pig model, the researchers induced femoral artery hemorrhage. In one group pressure was applied with gauze. In the other 100 g of powder was applied to the bleeding and then pressure was applied with gauze.

Additional powder was applied after 3 minutes in the intervention group if bleeding was not controlled.

The researchers concluded that the amylopectin group had less blood loss and higher mean arterial pressure at 180 minutes, and needed less fluid volume for resuscitation. In the amylopectin group the mean time to hemostasis was 9.0 minutes and hemostasis was never achieved in the control group. All animals in the amylopectin group survived whereas none survived in the control group.

From Kilbourne M, Keledjian K, Hess J, et al: Hemostatic efficacy of modified amylopectin powder in a lethal porcine model of extremity arterial injury, *Ann Emerg Med* 53(6):804-810, 2009.

Evaluation

Local protocol may permit the paramedic to manage and release the patient with minor soft tissue injury to the patient's own care. Local protocol also may allow the paramedic to manage and refer the patient to the patient's private physician for follow-up care. Some EMS systems allow paramedics to provide tetanus vaccine. Paramedics also may be permitted to give written and verbal instructions regarding care to patients who will not be transported by ambulance for physician evaluation.

TETANUS VACCINE

Tetanus is a serious and at times fatal disease. Tetanus is a disease of the central nervous system caused by the infection of a wound with spores of the bacterium *Clostridium tetani*. The patient can be protected against tetanus by periodic immunization with a tetanus vaccine. About

half a million cases of tetanus occur across the world each year. In the United States only about 50 or fewer cases are reported each year. All cases occur in nonimmunized persons. Tetanus infection occurs mostly in those more than 50 years of age. Deaths are most likely to occur in people 60 years or older and in people with diabetes.[11]

Children and adults in the United States routinely receive a combined immunization against diphtheria, tetanus, and pertussis (whooping cough). (*Acellular pertussis* [TDaP] is given to those older than 7 years of age; *whole-cell pertussis* [DTaP] is given to infants and toddlers.) After initial immunization during childhood, children receive booster vaccines every 5 to 10 years. Patients who have not been previously immunized against tetanus receive tetanus immune globulin because it confers instant immunity. During wound care, the paramedic should ascertain the patient's last tetanus immunization. The paramedic also should determine any prior allergic reactions to tetanus preparations. Normal side effects from the vaccine include slight fever, sore injection site, or minor rash. The tetanus vaccine is contraindicated in infants less than 6 weeks of age, in pregnant patients, and in those who are hypersensitive to the vaccine.

CRITICAL THINKING

Why is it crucial for you to be knowledgeable about tetanus and to ask the patient about tetanus vaccination if the vaccine is not carried on your ambulance?

PATIENT INSTRUCTIONS

Verbal and written instructions sometimes are referred to as a "patient instruction sheet." These instructions relate to wound care (Figure 38-24). Paramedics should give instructions to all patients who are not transported for physician evaluation. These instructions should include the following:

- Protection and care of wounded area
- Dressing change and follow-up
- Wound cleansing recommendations
- Signs of wound infection

Wound Infection

Infection is a common complication of soft tissue injury. It results from a break in the continuity of the skin and subsequent exposure to the nonsterile external environment. Most infections are minor. However, some can be serious. The goals of wound care are to prevent infection and protect from infection. Factors that influence the likelihood of infection include unclean wounds and wound mechanisms (e.g., wounds contaminated by soil, dirt, or grease) and a patient's poor state of health. These factors can have both local and systemic complications and can affect the patient's general recovery.

Causes of Wound Infection

Many factors can cause wound infection. Nine of the most common factors are[4]:

1. *Time*. The risk of infection can be reduced greatly if the wound is cleaned and repaired within 8 to 12 hours after injury. Bacterial proliferation to a level that can result in infection can occur as early as 3 hours after injury.
2. *Mechanism*. Lacerations caused by fine cutting forces resist infection better than crush injuries. High-velocity missile injuries can produce internal damage that may not be apparent for several days.
3. *Location*. Injuries of the foot, lower extremity, hand, and perineum have a higher-than-normal risk for infection.
4. *Severity*. The more tissue damage produced by the injury, the higher the risk for infection.
5. *Contamination*. The presence of foreign matter in a wound decreases resistance to infection. Of particular concern are wounds contaminated by soil, saliva, and feces.
6. *Preparation*. Body, facial, and head hair removed by clipping versus shaving is less likely to result in wound infection. Shaving can cause additional injury by abrading the skin and potentially moving skin flora into the larger wound.
7. *Cleansing*. Wound cleansing should be performed with normal saline and a high-pressure syringe.
8. *Technique of repair*. Wounds at high risk for infection (e.g., animal bites) may need to be cleaned, debrided, left open for 4 to 5 days, and then closed through traditional techniques.
9. *General patient condition*. Elderly patients and patients with concurrent illness or preexisting disease (e.g., diabetes) often are less able to ward off infection.

Assessment of Wound Healing

A paramedic can assess a wound for proper healing by doing the following:

- Examine dressings for excess drainage. Change saturated dressings to prevent contamination of the wound.
- Examine wounds for early signs of infection or delayed healing. Inflammation, edema, and bloody drainage are normal during the first 3 days but should subside gradually as the wound heals.

Signs of wound infection include increasing inflammation or edema, purulent drainage, foul odor, persistent pain, delayed healing, enlarged lymph nodes proximal to the wound, and fever. If any of these is present, the paramedic should consult with medical direction. Medical

WOUND CARE INSTRUCTION SHEET

Patient name: _____

1. Call your physician. He/she may have further instructions to offer for your care.
2. Keep the wound and dressing as dry as reasonably possible, since water aids bacterial growth.
3. Remove the dressing applied after 2 days.
4. Check for signs of infection:
   a. Swelling
   b. Excessive redness
   c. Pain
   d. Heat—either locally or systemically as reflected by a fever
   e. Excessive drainage from wounds
5. Reapply a sterile gauze dressing, taping it down at the edges. Repeat this every 2 days until the wound heals.
6. Wounds in areas of high mobility, such as around joints, are subject to excessive tension. Appropriate precautions should be taken to decrease the motion of the affected joint to assist in healing.

direction may advise patient transport to the emergency department or may direct patient referral to a private physician for follow-up care.

SPECIAL CONSIDERATIONS FOR SOFT TISSUE INJURIES

As stated before, assessment of life-threatening injuries and resuscitation precede evaluation of and intervention for non–life-threatening soft tissue injuries. The paramedic can proceed with wound care after ensuring adequate airway, breathing, and circulatory status (with spinal precautions if indicated); controlling severe hemorrhage; and maintaining normal body temperature. Special considerations for specific wounds are described in the following sections.

Penetrating Chest or Abdominal Injury

Open wounds to the chest and upper abdomen must be covered properly with sterile and occlusive dressings. (Open wounds to the neck must also be covered with occlusive dressings to prevent air embolism, described in Chapter 40: Head, Face, and Neck Trauma.) Open chest wounds can involve severe pulmonary injuries. These injuries can include pneumothorax and tension pneumothorax (described in Chapter 42). Major complications of penetrating abdominal injury include hemorrhage from a major vessel or solid organ and perforation of a segment of bowel (see Chapter 43). The paramedic should observe the following guidelines in managing a penetrating wound to the chest or abdomen in which an impaled object is present:

1. Do not remove the impaled object; severe hemorrhage or damage to underlying structures can occur.
2. Do not manipulate the impaled object unless it is necessary to shorten the object for extrication or for patient transportation.
3. Control bleeding with direct pressure applied around the impaled object.
4. Stabilize the object in place with bulky dressings; immobilize the patient to prevent movement.

Avulsion

Prehospital management of avulsed tissue varies by protocol, but two guidelines generally apply:

1. If the tissue is still attached to the body, do the following:
   a. Clean the wound surface of gross contaminants with sterile saline.
   b. Gently fold the skin back to its normal position.
   c. Control bleeding, dress the wound with bulky pressure dressings, and maintain direct pressure.
2. If the tissue is completely separated from the body, do the following:
   a. Control the bleeding with application of direct pressure.
   b. Retrieve the avulsed tissue if possible, but do not delay transport to locate amputated body parts.
   c. Wrap the tissue in gauze, either dry or moistened with lactated Ringer's or saline solution (per protocol).
   d. Seal the tissue in a plastic bag.
   e. Place the sealed bag on crushed ice; never place tissue directly on ice.

CRITICAL THINKING

Why should you use normal saline or lactated Ringer's solution instead of sterile water to wrap or clean avulsed tissue?

Amputations

As with other open wounds, hemorrhage control for amputation should be managed initially with direct pressure. (A severe amputation may require the use of a tourniquet. However, a tourniquet can cause tissue damage and may interfere with reimplantation attempts. Therefore direct pressure is the preferred method to control bleeding.) An amputated limb should be retrieved and managed in the same manner as avulsed tissue.

Crush Syndrome

Crush syndrome is complex and is difficult to diagnose and treat because of the many variables involved. These variables include the extent of tissue damage, duration and force of compression, patient's general health, and associated injuries. The management of crush syndrome is controversial. A medical direction physician who is familiar with this pathological process must supervise the prehospital care. Scenarios where crush injury may occur include earthquakes where victims are trapped in collapsed buildings, and people who have lain immobile in one position (e.g., from stroke or alcohol intoxication) for long periods of time.

Paramedics should consider possible crush syndrome when prolonged immobilization or compression occurs. The emergency care must be coordinated with rescue efforts so that the timing of the release from entrapment follows medical treatment. This will help to prevent hypovolemic shock and crush syndrome. After ensuring adequate airway and ventilatory support, initial prehospital care is focused on aggressive IV hydration to manage hypotension and to prevent renal failure. Other care at the scene should be guided by on-scene or online medical direction. Box 38-2 lists patient care measures for crush syndrome.[6]

BOX 38-2 Patient Care Measures for Crush Syndrome

Initial Management: Prehospital Setting

- Administer intravenous fluids before releasing the crushed body part. This step is especially important in cases of prolonged crush (more than 4 hours); however, crush syndrome can occur in crush scenarios of less than 1 hour.
- If this procedure is not possible, consider short-term use of a tourniquet on the affected limb until intravenous hydration can be initiated.

Initial Management: Hospital Setting

Hypotension

- Initiate (or continue) IV hydration—up to 1.5 L/hour.

Renal Failure

- Prevent renal failure with appropriate hydration, using IV fluids and mannitol to maintain diuresis of at least 300 mL/hr.
- Triage to hemodialysis as needed.

Metabolic Abnormalities

- Acidosis: Alkalinization of urine is critical; administer IV ***sodium bicarbonate*** until urine pH reaches 6.5 to prevent myoglobin and uric acid deposition in kidneys.
- Hyperkalemia/hypocalcemia: Consider administering the following (adult doses): ***calcium gluconate*** 10% 10 mL or ***calcium chloride*** 10% 5 mL IV over 2 minutes; ***sodium bicarbonate*** 1 mEq/kg IV slow push; regular insulin 5 to 10 units and D_{50} 1 to 2 ampules IV bolus; Kayexalate 25 to 50 g with sorbitol 20% 100 mL PO or rectally.
- Cardiac dysrhythmias: Monitor for cardiac dysrhythmias and cardiac arrest, and treat accordingly.

Secondary Complications

- Monitor casualties for compartment syndrome; monitor compartmental pressure if equipment is available; consider emergency **fasciotomy** (surgical relief of tension or pressure) for compartment syndrome.
- Treat open wounds with antibiotics, tetanus toxoid, and debridement of necrotic tissue.
- Apply ice to injured areas and monitor for the 5 P's: pain, pallor, paresthesias, pain with passive movement (i.e., paresis), and pulselessness.
- Observe all crush casualties, even those who look well.
- Delays in hydration of greater than 12 hours may increase the incidence of renal failure; delayed manifestations of renal failure can occur.

Disposition

- Patients with acute renal failure may require up to 60 days of dialysis treatment; unless sepsis is present, patients are likely to regain normal kidney function.

SUMMARY

- Hemorrhage can be internal or external.
- The skin and its accessory organs are the main cosmetic structures of the body. These structures perform many functions that are critical to survival. The skin is composed of two distinct layers of tissue: the outer layer (epidermis) and the inner layer (dermis).
- Surface trauma can disrupt the normal distribution of body fluids and electrolytes. Surface trauma also can interfere with the maintenance of body temperature. The two physiological responses to surface trauma are vascular and inflammatory reactions. These can lead to healing, scar formation, or both. Many factors can affect or alter wound healing.
- Soft tissue injuries are classified as closed or open. Classification is determined by the absence or presence of a break in the continuity of the epidermis. Closed wounds include contusions, hematoma, and crush injury. Open wounds are classified as abrasions, lacerations, punctures, avulsions, amputations, and bites.
- Assessment of life-threatening injuries and resuscitation precedes evaluation and intervention of non–life-threatening soft tissue injuries. General wound assessment should include a history of the event that caused the wound and a careful examination of the injury.
- Methods of hemorrhage control include direct pressure, immobilization by splinting, pneumatic pressure devices, and the use of tourniquets.
- The general categories of dressings used in trauma care are sterile, nonsterile, occlusive, nonocclusive, adherent, and nonadherent. The general categories of

bandages are absorbent, nonabsorbent, adherent, and nonadherent.
- Depending on the nature and location of the patient's injury, cleansing, dressings, bandages, and immobilization may be indicated to care for a wound properly.
- The goals of wound care are to prevent infection and protect from infection. Factors that influence the likelihood of infection include unclean wounds and wound mechanisms and a patient's poor state of health.
- Special considerations for specific wounds include penetrating chest or abdominal injury, avulsion, amputation, and crush syndrome.

CHAPTER

39 Burns

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the incidence, patterns, and sources of burn injury.
2. Describe the pathophysiology of local and systemic responses to burn injury.
3. Classify burn injury according to depth, extent, and severity based on established standards.
4. Discuss the pathophysiology of burn shock as a basis for key signs and symptoms.
5. Outline the physical examination of the burned patient.
6. Describe the prehospital management of the patient who has sustained a burn injury.
7. Discuss pathophysiology as a basis for key signs, symptoms, and management of the patient with an inhalation injury.
8. Outline the general assessment and management of the patient who has a chemical injury.
9. Describe specific complications and management techniques for selected chemical injuries.
10. Describe the physiological effects of electrical injuries as they relate to each body system based on an understanding of key principles of electricity.
11. Outline assessment and management of the patient with electrical injury.
12. Describe the distinguishing features of radiation injury and considerations in the prehospital management of these patients.

KEY TERMS

burn shock Shock that results from local and systemic responses to thermal trauma.

carboxyhemoglobin A compound produced by the exposure of hemoglobin to carbon monoxide.

circumferential burns Burns that encircle a body part, producing a tourniquet-like effect that may quickly compromise circulation.

consensus formula A formula used to calculate the fluid needs of a burn-injured patient over the first 24 hours after injury.

contracture deformity An abnormal, usually permanent condition of a joint characterized by flexion and fixation and caused by atrophy and shortening of muscle fibers or by loss of elasticity of the skin.

eschar A scab or dry crust resulting from a thermal or chemical burn.

escharotomy Surgical incision into necrotic tissue caused by a severe burn; escharotomy sometimes is necessary to prevent edema from building up sufficient interstitial pressure to impair capillary filling and cause ischemia.

full-thickness burn A burn injury in which the entire thickness of the epidermis and dermis is destroyed; also known as a third-degree burn.

inhalation injury An upper and/or lower airway injury that results from thermal and/or chemical exposure.

Lund and Browder chart A method to estimate burn injury that assigns specific numbers to each body part and that accounts for developmental changes in percentages of body surface area.

partial-thickness burn A burn injury that extends through the epidermis to the dermis; considered a deep partial-thickness injury if it extends to the basal layers of the skin; also known as a second-degree burn.

rule of nines A method to estimate burn injury that divides the total body surface area into segments that are multiples of 9%.

skin graft A portion of skin implanted to cover areas where skin has been lost through burns or injury or by surgical removal of diseased tissue.

smoke inhalation injury Inhalation injury caused by the accumulation of toxic by-products of combustion.

superficial burn A burn injury in which only a superficial layer of epidermal cells is destroyed; also known as a first-degree burn.

zone of coagulation In a burn wound, the central area that has sustained the most intense contact with the thermal source; in this area coagulation necrosis of the cells has occurred and the tissue is nonviable.

zone of hyperemia An area in which blood flow is increased as a result of the normal inflammatory response to injury; it lies at the periphery of the zone of stasis.

zone of stasis The area of burn tissue that surrounds the critically injured area; it consists of tissue that is potentially viable despite the serious thermal injury.

The management of burns often poses a challenge for the paramedic. Understanding the long-term results of a serious burn injury is important. Appropriate prehospital management can reduce morbidity and mortality for burn patients.

INCIDENCE AND PATTERNS OF BURN INJURY

Burns are a devastating form of trauma. They are associated with high mortality rates, lengthy rehabilitation, cosmetic disfigurement, and permanent physical disabilities. Each year, more than 2 million Americans seek medical attention for burns. Of these, 40,000 persons are hospitalized and about 3500 die as a result of thermal injury or burn-related infection.[1] Box 39-1 lists common complications that contribute to thermal injury deaths.

Morbidity and mortality rates from burn injury follow significant patterns regarding gender, age, and socioeconomic status. For example, two thirds of all fire fatalities are men; the death rate from thermal injury is highest among children and older adults; and three fourths of all fire deaths occur in the home, with the highest incidence in lower-income households.[2] A key part of the professional role of the paramedic is community education. This education should stress prevention as the most effective management of these injuries (see Chapter 3: Injury Prevention and Public Health) (Box 39-2).

Major Sources of Burns

A burn injury is caused by contact between energy and living cells. The source of this energy may be thermal, chemical, electrical, or radiation.

THERMAL BURNS

The majority of burns are thermal. These burns commonly result from flames, scalds, or contact with hot substances. (*Frostbite* is also a thermal injury. Frostbite is addressed in Chapter 45.) Studies have shown that surface temperatures of 44° C (111° F) do not produce burns unless exposure time exceeds 6 hours.[3] At temperatures between 44° and 51° C (111° and 124° F), the rate of epidermal necrosis approximately doubles with each degree of temperature increase. At 70° C (185° F) or greater, the exposure time required to cause transepidermal necrosis is less than 1 second.[4] The degree of tissue destruction depends on the temperature and on the duration of exposure. Factors that influence the ability of the body to resist burn injury

BOX 39-1 Physiological and Systemic Complications of Thermal Injuries

Depending on the severity of thermal injury, physiological and systemic complications may include the following:

- Acidosis
- Anoxia
- Dysrhythmias
- Electrolyte loss
- Fluid loss
- Heart failure
- Hypothermia
- Hypovolemia
- Hypoxia
- Infection
- Liver failure
- Renal failure

BOX 39-2 Burn Facts: Selected Statistics on Admissions to Burn Centers, 1999-2008

Survival rate: 96%

Total body surface area (TBSA) burned: more than one third of admissions (33%) exceeded 10% TBSA, 10% exceeded 30% TBSA, and only 4.8% exceeded 40% TBSA. Most included severe burns of such vital body areas as the face, hands, and feet

Gender: 71% male, 29% female

Ethnicity: 63% Caucasian, 17.4% African American, 13% Hispanic, 3.7% other, 2.2% Asian, 0.8% Native American

Burn cause: 41.8% fire/flame, 30.1% scald, 8.5% hot object contact, 3.8% electrical, 2.9% chemical, 9% other

Place of occurrence: 65.5% home, 7.2% street/highway, 11.1% industrial, 16.2% other

From American Burn Association National Burn Repository 2009 Report, Version 5.0, database includes information on more than 127,000 acute burn admissions from 79 hospitals from 33 states. http://www.ameriburn.org/2009NBRAnnualReport.pdf, accessed 6-17-11.

include the water content of the skin tissue; thickness and pigmentation of the skin; presence or absence of insulating substances such as skin oils or hair; and peripheral circulation of the skin, which affects dissipation of heat. Anatomy and physiology of the skin is presented in Chapter 38. The reader should refer to those chapters for review.

LOOK AGAIN

See Chapter 38: Bleeding and Soft Tissue Trauma, pp. 1101-1102.

CRITICAL THINKING

Based on these facts and your knowledge of life span development, would you predict a deeper burn from the same energy source in an 18-year-old or a 75-year-old patient? Why?

SHOW ME THE EVIDENCE

In this descriptive study, researchers in Arizona measured pavement temperatures over 24 hours. They also retrospectively reviewed cases of pavement burns. During the test period, pavement reached temperatures high enough to cause burns within 35 seconds between 10 AM and 5 PM. The patients who sustained pavement burns had neurological compromise (seizures, neuropathy) or were restrained, very young or old, or intoxicated. The mean burn size was 6% (range 1% to 13%). Air temperature ranged from 101° to 112° F (38.3° to 44.4° C) at the time of injury.

From Harrington WZ, Strohschein B, Reedy D, et al: Pavement temperature and burns: streets of fire, *Ann Emerg Med* 26(5):563-568, 1995.

CHEMICAL BURNS

Chemical burns are caused by a substance capable of producing chemical changes in the skin. These chemical changes disrupt the protein structure of the skin, with or without the production of heat. Heat may be generated during the burning process. Yet the chemical changes in the skin, not the heat, produce the greatest injury. Chemical burns differ from thermal burns. With chemical burns, the topical agent usually adheres to the skin for prolonged periods, producing continuous tissue destruction. The severity of the chemical injury is related to the tissue affected, the type of agent, the concentration and volume of the agent, and the duration of contact. Chemical agents that often cause burn injury include acids and alkalis. These agents are found in many household cleaning products and organic compounds. Chemical burns are associated with high morbidity. This is especially the case when they involve the eyes. Inhalation injury (described later in this chapter) may also result from thermal and/or chemical exposure.

NOTE

There are more than 25,000 chemicals used in industry, farming, and in homes that are known to cause burns. These chemicals constitute only about 3% of all burns. However, they have high morbidity (often needing surgery), often involve cosmetic areas of the body, and have a high mortality (about 30%).[5]

ELECTRICAL BURNS

Electrical injuries (including lightning injuries) result from direct contact with an electrical current. Electrical injuries can also result from the arcing of electricity between two contact points near the skin. In a direct contact injury the current itself is not considered to have any thermal properties. The potential energy of the current, however, is changed into thermal energy. This transformation occurs when electricity meets the electrical resistance of biological tissue interposed between the entrance and exit sites. Arc injuries are localized at the termination of current flow. They are caused by the intense heat or flash that occurs when the current "jumps," making contact with the skin. Flame burn also may occur as a result of arcing if the heat generated ignites clothing or another fuel source near the patient.

CRITICAL THINKING

Electrical energy is transformed to heat, causing tissue damage in a human being. Then why does an electrical cord not feel hot when you touch it?

RADIATION BURNS

Radiation injury is caused by ionizing and nonionizing radiation (described later in this chapter). Burns may result from a high level of radiation exposure to a specific body area. However, radiation injuries make up a small percentage of burn injuries.

Local Response to Burn Injury

Burn injury immediately destroys cells or so fully disrupts their metabolic functions that cellular death ensues. Cellular damage is distributed over a spectrum of injury. Some cells are destroyed instantly. Others are irreversibly injured. Some injured cells, though, may survive if rapid and appropriate intervention is provided in the prehospital setting and in-hospital care.

Major thermal burns have three distinct zones of injury (*Jackson's thermal wound theory*). These zones usually appear in a bull's-eye pattern (Figure 39-1). The central area of the burn wound, which has sustained the most intense contact with the thermal source, is the **zone of coagulation.** In this area, coagulation necrosis of the cells has occurred, and the tissue is nonviable. The **zone of stasis** surrounds the critically injured area. It consists of potentially viable tissue

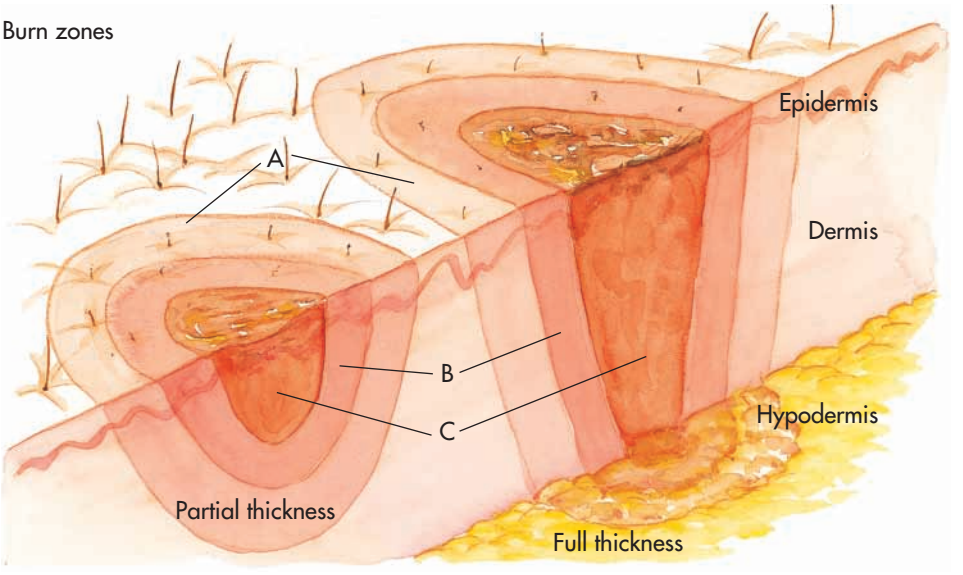

FIGURE 39-1 Three zones of intensity: **(A)** zone of hyperemia (peripheral); **(B)** zone of stasis (intermediate); and **(C)** zone of coagulation (central).

despite the serious thermal injury. In this zone, cells are ischemic because of clotting and vasoconstriction. The cells die within 24 to 48 hours after injury if no supportive measures are undertaken. At the periphery of the zone of stasis is the **zone of hyperemia.** This zone has increased blood flow as a result of the normal inflammatory response. The tissues in this area recover in 7 to 10 days if infection or profound shock does not develop.

Tissue damage from burns depends on the degree of heat and on the duration of exposure to the thermal source. As a rule, the burn wound swells rapidly because of the release of chemical mediators. These mediators cause an increase in capillary permeability and a fluid shift from the intravascular space into the injured tissues. The increased permeability is accentuated by injury to the sodium pump in the cell walls. As sodium moves into the injured cells, it causes an increase in osmotic pressure. This increase in osmotic pressure increases the influx of vascular fluid into the wound. Finally, the normal process of evaporative loss of water to the environment is accelerated (5 to 15 times that of normal skin) through the burned tissue. In a small wound, these physiological alterations produce a classic local inflammatory response (pain, redness, swelling) without major systemic effects. If the wound covers a large area, however, these local tissue responses can produce effects throughout the body and life-threatening hypovolemia.

Systemic Response to Burn Injury

As local events occur at the injury site, other organ systems become involved in a general response to the stress caused by the burn. One of the earliest manifestations of the systemic effects of a large thermal injury is hypovolemic shock. This hypovolemic shock is known as *burn shock* (described later in this chapter). Burn shock is associated with a decrease in venous return, decreased cardiac output, and increased vascular resistance. Burn shock can lead to renal failure. Box 39-3 lists other systemic responses to major burn injury.

BOX 39-3 Systemic Responses to Major Burn Injury

- Pulmonary response
  - Hyperventilation to meet increased metabolic needs
- Gastrointestinal response
  - Decrease in splanchnic perfusion that may lead to mucosal hemorrhage and transient adynamic ileus
  - Vomiting and aspiration
  - Stress ulcers
- Musculoskeletal response
  - Decreased range of motion from immobility and edema
  - Possible osteoporosis and demineralization (late)
- Neuroendocrine response
  - Increased amounts of circulating epinephrine and norepinephrine and transient elevation of aldosterone levels
- Metabolic response
  - Elevated metabolic rate, particularly with infection or surgical stress
- Immune response
  - Altered immunity, resulting in increased susceptibility to infection
  - Depressed inflammatory response
- Emotional response
  - Physical pain
  - Isolation from loved ones and familiar surroundings
  - Fear of disfigurement, deformities, and disability
  - Altered self-image
  - Depression

CLASSIFICATIONS OF BURN INJURY

Burns must be assessed and classified (body surface area involvement and depth) as correctly as possible in the field. This will help to ensure the proper treatment and transport to a proper facility. It also will help to monitor the progression of tissue damage. However, this usually is not possible in the prehospital setting because of the progressive nature of the injury. The amount of tissue damage may not be evident for hours or even days after a burn injury.

DID YOU KNOW?

Skin Grafts

A skin graft is a patch of skin that is removed by surgery from one area of the body (*autografting*) and transplanted, or attached, to another area. Healthy skin is taken from an area on the patient's body called the *donor site*. (Commercial skin substitutes [*heterografts*] or temporary skin substitutes [*cadaver allografts*] are used in some patients instead of autografting.) Most grafts are split-thickness skin grafts; that is, the epidermis and dermis are transplanted from the donor site. The donor site can be any area of the body (most often an area that is hidden by clothes, such as the buttock or inner thigh). The transplanted graft is held in place by special pressure dressings, staples, fibrin glue, synthetic adhesives and/or tapes, or small sutures. The donor site area is covered with a sterile dressing for 3 to 5 days.

Patients with deeper tissue loss may need a full-thickness skin graft; that is, the entire thickness of the skin is transplanted from the donor site. The flap of skin from the donor site includes the epidermis, dermis, and the muscles and blood supply. New blood supply is established within 36 hours following transplantation. Common donor sites for full-thickness grafts include skin and muscle flaps from the back or the abdominal wall. Full-thickness grafts require a longer recovery period than split-thickness grafts. Most patients will be hospitalized for 1 to 2 weeks following the procedure. Possible complications of skin grafts include:

- Bleeding (which can be severe)
- Infection
- Loss of grafted skin (poor graft take)
- Scarring
- Reduced or lost skin sensation and/or increased sensitivity
- Chronic pain (rarely)
- Uneven skin surface, discoloration, and disfigurement

Excision and grafting of large areas of burns is stressful. The surgery is tolerated poorly by patients with advanced age, other severe injuries (especially smoke inhalation injury and blunt trauma), and preexisting or coexisting medical conditions (especially diabetes or cardiovascular and peripheral vascular disease).[7]

Depth of Burn Injury

Burns are classified in terms of depth as superficial, partial-thickness, and full-thickness.[6] Superficial and **partial-thickness burns** usually heal without surgery, if the burns are uncomplicated by infection or shock. **Full-thickness burns** usually require **skin grafts.** Other depth classifications may be preferred by medical direction.

SUPERFICIAL BURNS

Superficial burns are also known as *first-degree burns*. These burns characteristically are painful, red, and dry and blanch with pressure (Figure 39-2). Superficial burns usually occur after prolonged exposure to low-intensity heat or a short-duration flash exposure to a heat source. In these burns, only a superficial layer of epidermal cells is destroyed. The cells slough (peel away from healthy tissue underneath the wound) without residual scarring. Superficial burn injuries usually heal within 2 to 3 days. An example of a superficial burn is *sunburn*.

PARTIAL-THICKNESS BURNS

Partial-thickness burns are also known as *second-degree burns*. These burns may be divided into two groups: superficial partial-thickness and deep partial-thickness wounds. The superficial partial-thickness injury is characterized by blisters. It often is caused by skin contact with hot but not boiling water or other hot liquids, explosions producing flash burns, hot grease, and flame.

In superficial partial-thickness and deep partial-thickness burns (Figure 39-3), injury extends through the epidermis

FIGURE 39-2 Superficial burn. (From Shade BR: *Mosby's EMT-intermediate for the 1999 national standards curriculum,* ed 3, St Louis, 2007, Mosby.)

FIGURE 39-3 Superficial partial-thickness second-degree burn. (Courtesy St John's Mercy Medical Center, St Louis, Mo.)

to the dermis. However, the basal layers of the skin are not destroyed, and the skin regenerates within a few days to a week. Edematous fluid infiltrates the dermal-epidermal junction, creating the blisters characteristic of this depth of wound. Intact blisters provide a seal. This seal protects the wound from infection and excessive fluid loss. (For this reason, blisters should not be broken in the prehospital setting unless it is a chemical burn.) The injured area usually is red, wet, and painful and may blanch when the tissue around the injury is compressed. In the absence of infection, these wounds heal without scarring, usually within 14 days.

NOTE

The dermal layer of skin in children and the elderly is significantly thinner than in the average adult. Therefore, a burn that "looks like" a partial-thickness burn may actually be a more serious full-thickness burn in these patients.

If the depth of the partial-thickness burn involves the basal layer of the dermis, the burn is considered a deep partial-thickness burn (Figure 39-4). As in superficial partial-thickness burns, edema forms at the epidermal-dermal junction. Sensation in and around the wound may be diminished because of the destruction of basal layer nerve endings. The injury may appear red and wet or white and dry. The appearance depends on the degree of vascular injury. Wound infection and subsequent sepsis and fluid loss are major complications of these injuries. If uncomplicated, deep partial-thickness burns generally heal within 3 to 4 weeks. Skin grafting may be needed to promote timely healing and minimize thick scar tissue formation. The formation of thick scar tissue may severely restrict joint movements and may cause persistent pain and disfigurement.

FULL-THICKNESS BURNS

In **full-thickness burns** (also known as *third-degree burns*), the entire thickness of the epidermis and dermis is destroyed; thus skin grafts are necessary for timely and proper healing (Figure 39-5). The wound is characterized by coagulation necrosis of the cells. The wound appears pearly white, charred, or leathery. A definitive sign of a full-thickness burn is a translucent surface in the depths of which thrombosed veins are visible. **Eschar,** a tough, nonelastic coagulated collagen of the dermis, is present in these injuries.

NOTE

Escharotomy is the surgical incision through the eschar to release constricting tissues. This surgery is sometimes performed to allow body tissue and organs to maintain normal perfusion and function. Escharotomy releases the constriction caused by burns, but does not remove the eschar. Additional surgery may be required.

Sensation and capillary refill are absent in full-thickness burns because small blood vessels and nerve endings are destroyed. This often results in large plasma volume loss, infection, and sepsis. Natural wound healing may produce **contracture deformity** (a fixed tightening of the muscles, bones, ligaments, and skin that prevents normal movement). Severe scarring also may develop. Surgical intervention with skin grafting is necessary to close full-thickness wounds, minimize complications, and allow restoration of maximal function.

Some burn classifications also describe a full-thickness injury (sometimes called a *fourth-degree burn*) that penetrates the subcutaneous tissue, muscle, fascia, periosteum, or bone. These burns often result from incineration-type exposure and electrical burns in which the heat is great enough to destroy tissues below the skin.

Extent and Severity of Burn Injury

There are several methods to evaluate the extent of burn injury. Two common methods include the **rule of nines** and the **Lund and Browder chart.** The paramedic should use a method for determining the extent of burn injury

FIGURE 39-4 Deep partial-thickness burn. (Courtesy St John's Mercy Medical Center, St Louis, Mo.)

FIGURE 39-5 Full-thickness burn. (Courtesy St John's Mercy Medical Center, St Louis, Mo.)

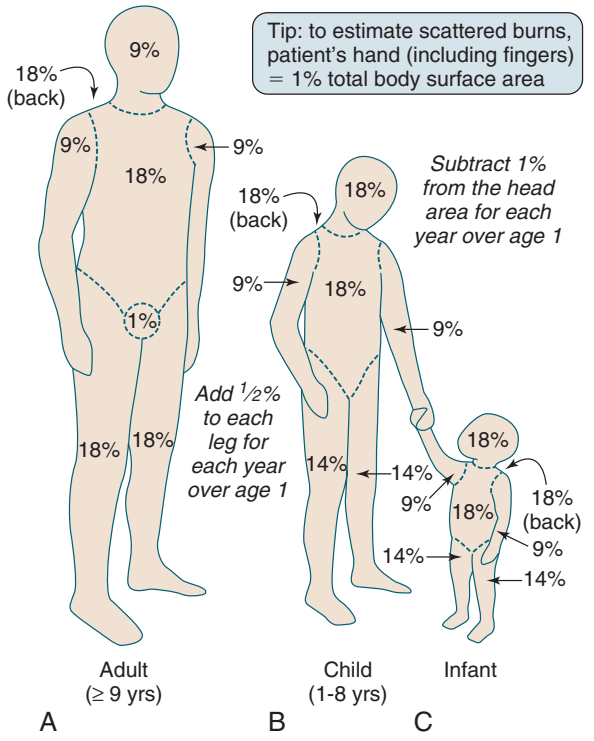

FIGURE 39-6 The rule of nines. **A,** Adult; **B,** child; **C,** infant. (Modified from Sole ML: *Introduction to critical care nursing,* ed 5, Philadelphia, 2009, Saunders. Courtesy University of Michigan Trauma Burn Center, Ann Arbor, Mich.)

approved by medical direction. Use of any method to evaluate a burn injury should never delay patient care or transport.

RULE OF NINES

The rule of nines commonly is used in the prehospital setting. The measurement divides the total body surface area (TBSA) into segments that are multiples of 9%. This method provides a rough estimate of burn injury size and is most accurate for adults and children older than 10 years of age. Figure 39-6 explains the rule of nines.

CRITICAL THINKING

Why is the calculation of body surface area different for children less than 10 years of age?

If the burn is irregularly shaped or has a scattered distribution throughout the body, the rule of nines is difficult to apply. In these cases, burn size can be estimated by visualizing the patient's hand as an indicator of percentage. (This is the *rule of palms*.) The surface of the patient's hand, including fingers, equals about 1% of the TBSA.

NOTE

Only partial- and full-thickness burns are included when calculating total body surface area. For large burns, total body surface area may be calculated more easily by subtracting the percentage of unburned area from 100.

LUND AND BROWDER CHART

The Lund and Browder chart (Figure 39-7) is a more accurate method of determining the area of burn injury because it assigns specific numbers to each body part. The chart allows for developmental changes in percentages of body surface area. For example, the adult head is 9% of TBSA, but the newborn head is 18% of TBSA.

AMERICAN BURN ASSOCIATION CATEGORIZATION

The American Burn Association has devised a method of categorizing burns to determine severity. The method is based on extent, depth, and location of burn injury; age of the patient; etiological agents involved; presence of inhalation injury; and coexisting injuries or preexisting illness. Using these criteria, burn injuries are categorized as *major, moderate,* and *minor* (Box 39-4).

BOX 39-4 Classification of Burn Severity

Major Burns

1. Partial-thickness burns greater than 25% of body surface area (BSA) in adults or greater than 20% of BSA in children or the elderly
2. Full-thickness burns greater than 10% of BSA
3. All burns involving the face, eyes, ears, hands, feet, or perineum that may result in functional or cosmetic impairment
4. Burns caused by caustic chemical agents
5. High-voltage electrical injury
6. Burns complicated by inhalation injury, major trauma, or in poor-risk patients

Moderate Burns

1. Partial-thickness burns 15% to 25% of BSA in adults and 10% to 20% of BSA in children or the elderly
2. Full-thickness burns less than 10% of BSA
3. Not involving risk to areas of specialized function such as the face, eyes, ears, hands, feet, or perineum

Minor Burns

1. Burns less than 15% of BSA in adults or 10% of BSA in children or the elderly
2. Full-thickness burns less than 2% of BSA
3. No functional or cosmetic risk to areas of specialized function

Adapted from the American Burn Association Injury Severity Grading System. American Burn Association, *J Burn Care Rehabil* 11:98-104, 1990, with additional information from Hartford CE: Care of outpatient burns. In Herndon DN, editor. *Total burn care*, pp. 71-80, Philadelphia, 1996, Saunders.

Age	0-1	1-4	5-9	10-14	15
A—1/2 of head	9 1/2%	8 1/2%	6 1/2%	5 1/2%	4 1/2%
B—1/2 of one thigh	2 3/4%	3 1/4%	4%	4 1/4%	4 1/2%
C—1/2 of one leg	2 1/2%	2 1/2%	2 3/4%	3%	3 1/4%

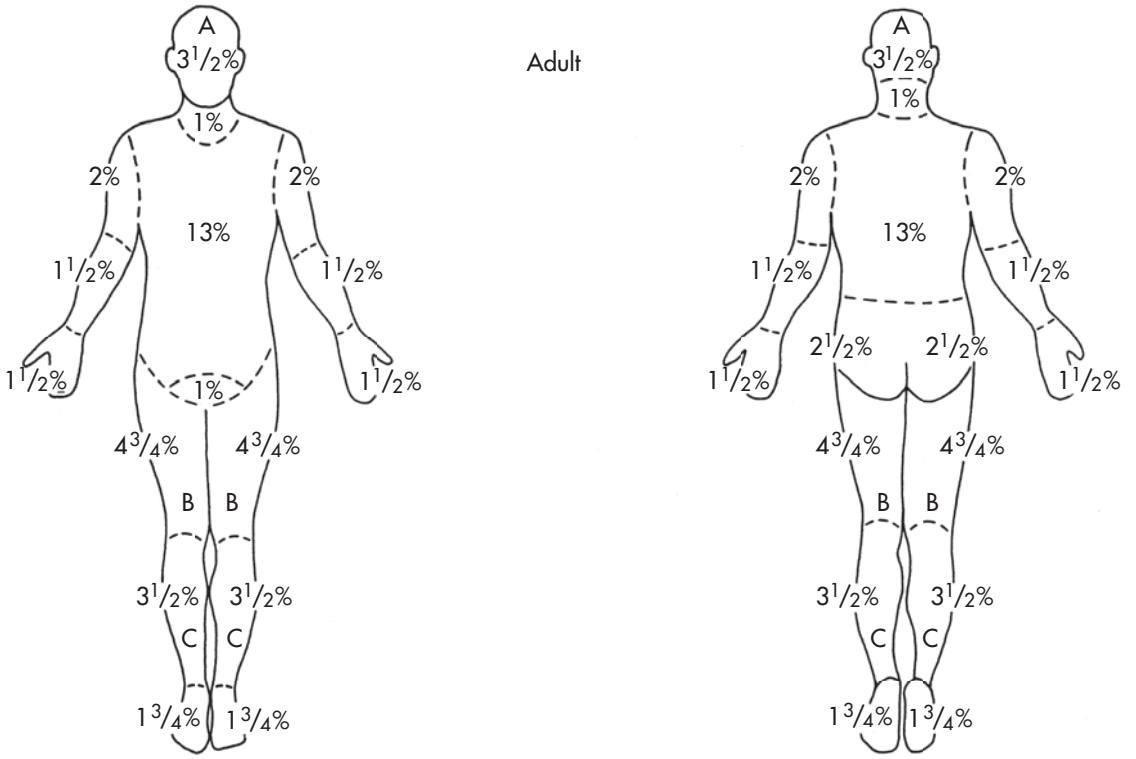

FIGURE 39-7 Lund and Browder chart. (From Lee G: *Flight nursing: principles and practice,* St Louis, 1991, Mosby.)

In determining severity, the paramedic also must consider factors such as the patient's age, the presence of concurrent medical or surgical problems, and the complications that accompany certain types of burns, such as those of the face and neck, hands and feet, and genitalia. For example, burns of the face and neck may cause respiratory compromise. They also may interfere with the ability to eat or drink. Burns of the hands and feet may interfere with ambulation and activities of daily living. Perineal burns present a high risk of infection because of the contaminants in this region. These burns may disrupt the normal patterns of elimination.

Burn Center Referral Criteria

Many emergency medical services use categories or other criteria determined by medical direction as the basis for determining which patients need transport to specialized burn centers. (See the CDC Triage Guidelines, described in Chapter 37.) According to the Committee on Trauma of the American College of Surgeons and the American Burn Association, burn injuries usually requiring referral to a burn center include the following[8]:

1. Partial-thickness burns greater than 10% total body surface area
2. Burns that involve the face, hands, feet, genitalia, perineum, or major joints
3. Third-degree burns in any age group
4. Electrical burns, including lightning injury
5. Chemical burns
6. Inhalation injury
7. Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
8. Any patients with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn unit. Physician judgment will be necessary in such situations and should be in

concert with the regional medical control plan and triage protocols
9. Burned children in hospitals without qualified personnel or equipment for the care of children
10. Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention

NOTE
Verification of burn centers is a joint program of the American Burn Association (ABA) and the American College of Surgeons (ACS). It is a rigorous review program designed to verify a burn center's resources that are required for the provision of optimal care to burn patients from the time of injury through rehabilitation. About 55% of the 45,000 U.S. hospitalizations for burn injury each year are now admitted to the 125 hospitals with specialized burn centers.[9]

PATHOPHYSIOLOGY OF BURN SHOCK

As stated previously, shock can occur from large body surface area burns. **Burn shock** results from local and systemic responses to thermal trauma. The trauma leads to edema and accumulation of vascular fluid in the tissues in the area of injury. Locally, a brief initial decrease in blood flow to the area occurs (this is the *emergent phase*). This is followed by a considerable increase in arteriolar vasodilation. A concurrent release of vasoactive substances from the burned tissue causes increased capillary permeability. This in turn produces intravascular fluid loss and wound edema (the *fluid shift phase*). The fluid shifts cause cardiovascular changes such as a compromised cardiac output, increased systemic vascular resistance, and reduced peripheral blood flow.

NOTE
Hypovolemia caused by burn trauma usually is not seen in the prehospital setting. This is because burn edema develops over the first several hours after the burn. A hypovolemic patient with burns should be evaluated at the scene for other injuries that may be responsible for the volume loss.

Hypovolemia results from fluid loss in the injured tissues and fluid that evaporates from the body because of the loss of the skin. Despite the compensatory effort of the body to retain sodium and water, sodium is lost and potassium is released into the extracellular fluid. The blood becomes concentrated. In severe burns, red blood cells may burst (hemolyze). When combined with hemolysis, rhabdomyolysis, and subsequent hemoglobinuria and myoglobinuria seen with major burns and electrical injury, this hypovolemic state can lead to renal failure (see Chapter 11: General Principles of Pathophysiology). Impaired peripheral blood flow can damage tissue further and can result in metabolic acidosis.

The greatest loss of intravascular fluid occurs in the first 8 to 12 hours. This loss is followed by a continued, moderate loss over the next 12 to 16 hours. At some point within 24 hours, the leaking of fluid from the cells greatly diminishes (this is the *resolution phase*). At this point, a balance between the intravascular space and the interstitial space is reached. Peripheral vascular resistance will increase in response to hypovolemia and the resulting decrease in cardiac output. With volume replacement, cardiac output can increase to levels above normal (this is the *hypermetabolic phase* of thermal injury) (Figure 39-8).

Fluid Replacement

Within minutes of a major burn injury, all capillaries in the circulatory system (not just those in the area of the burn) lose the ability to retain fluid. This increase in capillary permeability prevents the creation of an osmotic gradient between the intravascular and extravascular space. This change allows colloid solutions to equilibrate quickly across the capillaries and into the surrounding tissue. The process of burn shock continues for about 24 hours, at which time the normal capillary permeability is restored.[10] Therefore therapy for burn shock is aimed at supporting the patient's vital organ function through the period of hypovolemic shock. Crystalloid solution (e.g., lactated Ringer's solution or normal saline) usually is considered the fluid of choice in initial resuscitation.

NOTE
Fluid resuscitation in burn-injured persons is controversial. As a rule, fluid resuscitation should be initiated in the prehospital setting in patients with >20% TBSA burns if IV access can be quickly accomplished.[11] Transport should not be delayed to initiate intravenous therapy.

Several fluid resuscitation formulae consider body size and extent of burned body surface area. These formulae have proved clinically useful in replacing fluids. The two most common formulae for estimating fluid replacement are the *Parkland formula* and the *modified Brooke formula.* These formulae have been combined into the **consensus formula.** All three formulae stipulate that half of the total calculated amount of fluid should be infused over the first 8 hours from the time of the injury. The second half should be infused over the following 16 hours. Fluid resuscitation must be guided by regular monitoring of measures of hemodynamic function, including the patient's vital signs, respiratory rate, lung sounds, capillary refill, and, in some cases, urinary output. *When determining the percentage of burn for fluid resuscitation, the paramedic should calculate only partial- and full-thickness burns.*

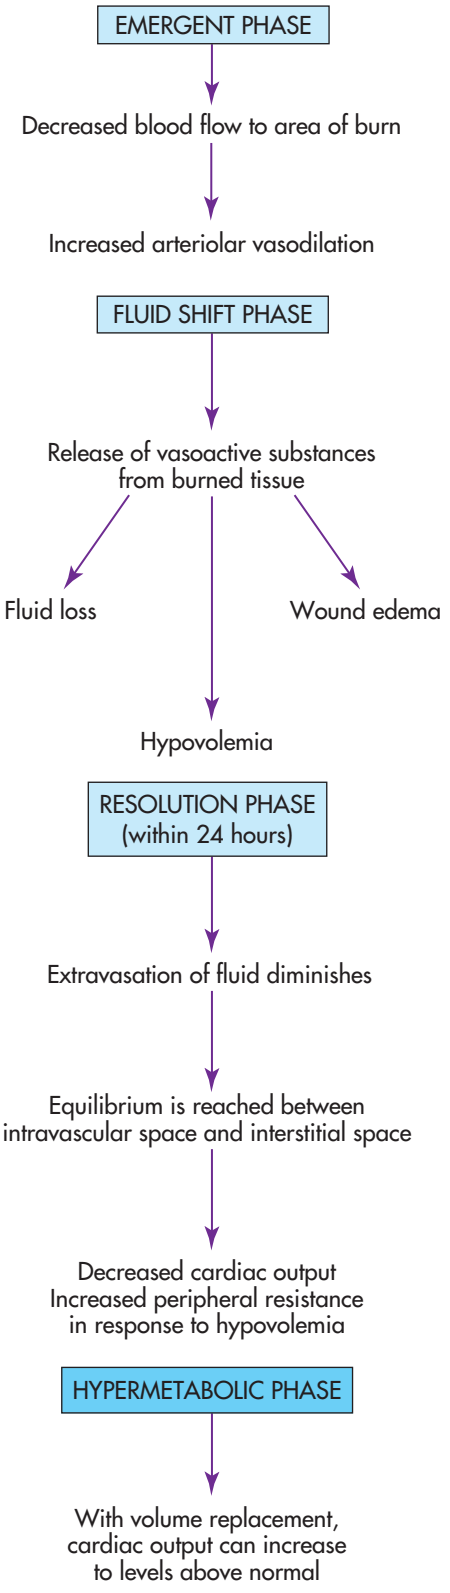

FIGURE 39-8 Phases of burn shock.

CONSENSUS FORMULA

The consensus formula is applied as follows:

1. The first 24 hours: 4 mL/kg lactated Ringer's solution or normal saline multiplied by percent of TBSA burned
   a. 50% of the calculated amount infused in the first 8 hours
   b. 25% of the calculated amount infused in the second 8 hours
   c. 25% of the calculated amount infused in the third 8 hours

Example:

A patient who weighs 100 kg has 30% body surface area (BSA) burns. Total fluid to be infused in the first 24 hours at 4 mL/kg is calculated as follows: 4 mL × 30% BSA × 100 kg = 12,000 mL. Of the 12,000 mL, 6000 mL should be infused in the first 8 hours at a rate of 750 mL/hr. Note that the volume of fluid actually infused may be adjusted according to patient needs as prescribed by medical direction.

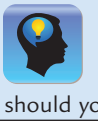
The amount and type of fluids required after the first 24 hours are vastly different from those administered during the first 24 hours. Fluid replacement is dictated by the patient's response to the burn and the treatment regimen.

ASSESSMENT OF THE BURN PATIENT

As with any other trauma patient, emergency care for a burn patient begins with scene safety and the primary survey. In this assessment the paramedic should recognize and treat injuries that pose a threat to life. In burn patients, however, the dramatic appearance of burns, the patient's intense pain, and the characteristic odor of burnt flesh may distract the paramedic from life-threatening problems. A confident assessment by the paramedic and direction of efforts away from the burn wound and toward the patient as a whole are crucial.

Primary Survey

The evaluation of the patient's airway is a major concern, particularly for the patient with an inhalation injury (described later in this chapter). The paramedic should observe for stridor (an ominous sign of airway narrowing), facial burns, soot in the nose or mouth, singed facial or nasal hair, edema of lips and the oral cavity, coughing, inability to swallow secretions in the pharynx, hoarse voice, and **circumferential burns** around the neck or thorax. Airway management should be aggressive with these patients (Figure 39-9).



CRITICAL THINKING

Consider a patient who has a large burn. Your initial assessment reveals that the airway is patent. Why should you perform frequent reassessment of the airway?

The paramedic should evaluate breathing for rate, depth, and the presence of wheezes, crackles, or rhonchi. The patient's circulatory status is evaluated by assessing the presence, rate, character, and rhythm of pulses; capillary

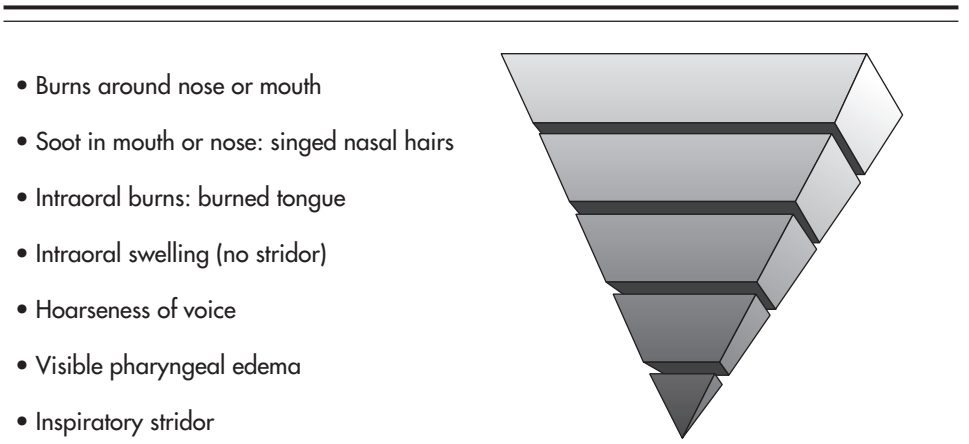


FIGURE 39-9 Decreasing probability of upper airway obstruction.

refill; skin color and temperature; pulse oximetry, which may be inaccurate in the presence of carbon monoxide; and obvious arterial bleeding. The paramedic should determine the patient's neurological status by using the AVPU scale or similar method. The paramedic should evaluate carefully any deviations from normal for underlying cause. Abnormalities include hypoxia, decreased cerebral perfusion from hypovolemia, and cerebral injury resulting from head trauma. After the primary survey, a history of the event should be obtained while performing the secondary assessment.

An accurate history from the patient or bystanders can help the paramedic to determine the potential for inhalation injury, concomitant trauma, or preexisting conditions that may influence the physical examination or patient outcome. When obtaining the patient history, the paramedic should ascertain the following information:

1. What is the patient's chief complaint (e.g., pain or dyspnea)?
2. What were the circumstances of the injury?
   - Did the injury occur in an enclosed space?
   - Were explosive forces involved?
   - Were hazardous chemicals involved?
   - Is there related trauma?
3. What was the source of the burning agent (e.g., flame, metal, liquid, or chemical)?
4. Does the patient have any significant medical history?
5. What medications does the patient take (including recent ingestion of illegal drugs or alcohol)?
6. Did the patient lose consciousness at any time? (Suspect inhalation injury.)
7. What is the status of tetanus immunization?

Physical Examination

At the start of the physical exam, the paramedic should obtain a full set of vital signs. The paramedic should obtain a blood pressure measurement from an unburned extremity, if available. If all extremities are burned, the paramedic may place sterile gauze under the blood pressure cuff and attempt to auscultate a blood pressure. Patients with severe burns or preexisting cardiac or medical illness should be monitored with pulse oximetry and electrocardiogram. Lead placement may need to be modified to avoid placing electrodes over burned areas (see Chapter 22). Field care and hospital destination are determined by the depth, size, location, and extent of burned tissue and the presence of associated illness or injury.

GENERAL PRINCIPLES IN BURN MANAGEMENT

Goals for prehospital management of the severely burned patient include preventing further tissue injury, maintaining the airway, administering oxygen and ventilatory support, managing pain, providing fluid resuscitation (per protocol), providing rapid transport to an appropriate medical facility, using clean technique to minimize the patient's exposure to infectious agents, and providing psychological and emotional support. Patients with burns also should be evaluated for other types of trauma that pose a threat to life. Some will have additional injuries associated with the burn event. Examples include blunt or penetrating trauma sustained in automobile crashes, blast injury, and skeletal or spinal injury from attempts to escape the thermal source or contact with electrical current.

NOTE

Some burns will be very painful for the patient. Medications used to manage pain may include ***morphine, fentanyl,*** hydromorphone, and others. The presence or absence of IV access directly influences analgesic drug choice, particularly in children in whom IV access may be problematic.

Stopping the Burning Process

The first step in managing any burn is to stop the burning process. This step must be achieved with the safety of the emergency crew in mind because it often occurs in proximity to the source that caused the burn. With superficial burns the burning process can be terminated by cooling the local area with cool tap water.[11] Ice-cold water, ice, snow, or ointments should not be applied to the burn. These agents may increase the depth and severity of thermal injury. In addition, ointments may impair or delay assessment of the injury when the patient arrives in the emergency department.

In cases of severe burns the paramedic should move the patient rapidly and safely from the burning source to an area of safety if possible. A person whose clothing is in flames or smoldering should be placed on the floor or ground and rolled in a blanket to smother the flames or should be doused with large quantities of the cleanest available room-temperature water. (Cool water to decrease skin temperature rapidly is preferred.) Contaminated water sources, such as lakes or rivers, should be avoided. These patients should never be allowed to run or remain standing. Running may fan the flame, and an upright position may increase the likelihood of the patient's hair being ignited.

NOTE

The National Fire Protection Association developed a training program called *Stop, Drop, and Roll*. The program was designed to teach children and adults that in the event their clothing catches fire, they should *stop* (do not run); *drop* (cover your face with your hands and drop to the ground in a prone position); and *roll* (to smother the fire until the flames are extinguished).

The paramedic should remove the patient's clothing completely while cooling the burn so that heat is not trapped under the smoldering cloth. If pieces of smoldering cloth have adhered to the skin, the paramedic should cut, not pull, the clothing and gently remove it. Melted synthetic fabrics that cannot be removed should be soaked in water to stop the burning process. After the burn is cooled, the patient with a large body surface area injury should be covered with a clean, preferably sterile sheet to prevent hypothermia. Blankets may be placed over the sheet when ambient temperatures are low. The duration of cooling is controversial; cooling should continue at least until pain is relieved[12] and probably for a total duration of 15 to 30 minutes. Local cooling of less than 9% TBSA can be continued longer than 30 minutes to relieve pain.

Airway, Oxygen, and Ventilation

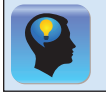
The paramedic should evaluate the adequacy of airway and breathing in all burn patients. Humidified high-concentration oxygen (if available) should be given to any patient with severe burns. Breathing should be assisted as needed. Use of continuous pulse oximetry is indicated in these patients. If inhalation injury is suspected, the paramedic should observe the patient closely for signs of impending airway obstruction. Life-threatening laryngeal edema may be progressive and may make tracheal intubation difficult if not impossible. The decision to intubate these patients should not be delayed. The paramedic should make every attempt to intubate the patient's trachea with a normal (not smaller) size endotracheal tube. The lungs of these patients often are difficult to ventilate, even with an appropriately sized tube. The decision to intubate in the field should be guided by transport time to the receiving hospital and indications of impending airway obstruction.

Circulation

The need for fluid resuscitation is based on the severity of the injury, the patient's vital signs, and the transport time to the receiving hospital. Some authorities contend that prompt intervention of intravenous therapy in the critically burned patient is essential to prevent long-term complications such as burn shock and renal failure. (The paramedic should consult with medical direction and follow local protocol regarding fluid replacement via the intravenous [IV] or intraosseous [IO] route.)

If intravenous therapy is to be performed, it should be initiated with a large-bore catheter in a peripheral vein in an unburned extremity. (The arm is the preferred site.) If an unburned site is not available, the paramedic may insert the catheter through burned tissue, although the risk of subsequent infection is greater. Care should be taken to secure the catheter with a dressing; tape may not adhere to the injured area as the tissue begins to leak fluid.

The administration of pain medication is an early intervention. Medical direction may recommend that patients with painful burns be given IV ***morphine*** or ***fentanyl,*** or other analgesic agents (e.g., ***nitrous oxide***). Some of these medications can cause vasodilation and respiratory depression. Thus fluid resuscitation and ventilation support must be adequate. Other pharmacological therapy that may be given after arrival in the emergency department includes topical applications (e.g., silver sulfadiazine or special synthetic dressings), oral analgesics, and tetanus immunization.



CRITICAL THINKING

How should you administer pain medicine to a patient with a large burn? Why did you choose this route?

At times, transport of the burn patient is delayed. A lengthy interfacility transport may be anticipated as well. In either case, other patient care procedures may be required. One such procedure includes the placement of a nasogastric tube to prevent gastric distention or vomiting. Another

procedure is the placement of an indwelling urinary catheter. This will measure urine output and maintain patency of the urethra in patients with burns to the genitalia (see Chapter 52).

NOTE
Urine output is a means to evaluate the effectiveness of fluid resuscitation. When the Parkland consensus formula is used, the patient is titrated to maintain urine output of 0.3 to 1.0 mL/kg/hr and a mean arterial pressure of 60 mm Hg or greater.[13]

Special Considerations

All burn injuries warrant good patient assessment and care. However, burns of specific body regions require special consideration. These include burns to the face and extremities and circumferential burns.

Burns of the face swell rapidly. These burns may be associated with airway problems. The head of the ambulance stretcher should be elevated at least 30 degrees, if not contraindicated by spinal trauma, to minimize the edema. If the patient's ears are burned, the paramedic should avoid use of a pillow to minimize additional injury to the area.

If burns involve the extremities or large areas of the body, the paramedic should remove all rings, watches, and other jewelry as soon as possible. This will help to prevent vascular compromise with increased wound edema. Peripheral pulses should be assessed frequently and burned limbs should be elevated above the patient's heart if possible.

CRITICAL THINKING
What life- or limb-threatening problems can develop from this swelling?

Burn injuries that encircle a body region can pose a threat to the patient's life or limbs. Circumferential burns that occur to an extremity may produce a tourniquet-like effect that may quickly compromise circulation. The effect can cause irreversible damage to the limb. Circumferential burns of the chest can severely restrict movement of the thorax. These burns may impair chest wall compliance significantly. If this occurs, the depth of respirations is reduced; tidal volume is decreased; and the patient's lungs may become difficult to ventilate, even by mechanical means. Definitive treatment for circumferential burns involves an in-hospital escharotomy to reduce compartment pressure and allow adequate blood volume to flow to and from the affected limb or thorax.

INHALATION BURN INJURIES

Smoke inhalation injury affects between 5% and 35% of all patients admitted to hospitals. The presence of inhalation injury increases the mortality from burns by 20%, and when combined with pneumonia by 60%.[11] Prehospital considerations in caring for patients with inhalation injury include recognition of the dangers inherent in the fire environment, awareness of the pathophysiological principles of inhalation injury, and early detection and treatment of impending airway or respiratory problems.

Smoke inhalation most often occurs in a closed environment such as a building, a vehicle, or an airplane. Such injury is caused by the accumulation of toxic by-products of combustion. Inhalation injury also can occur in an open space. Therefore all burn victims should be evaluated for this injury. Dangers that contribute to inhalation injury in a fire environment are:

- Heat
- Consumption of oxygen by the fire
- Production of carbon monoxide
- Production of other toxic gases such as cyanide and hydrogen sulfide

Inhalation injury also may occur in the absence of significant thermal injury from exposure to toxic gases (e.g., carbon monoxide).

NOTE
Responding to a scene with a possibility of smoke inhalation injury also poses a threat to EMS personnel. Carbon monoxide meters and other testing devices to measure dangerous gases should be used to ensure scene safety.

Pathophysiology

Smoke inhalation and inhalation injury can produce a large number of complications. For this text, these complications are classified as carbon monoxide poisoning, inhalation injury above the glottis (*supraglottic*), and inhalation injury below the glottis (*infraglottic*).

Carbon Monoxide Poisoning

Carbon monoxide is a colorless, odorless, tasteless gas produced by incomplete burning of carbon-containing fuels. Carbon monoxide does not harm lung tissue physically. However, it displaces oxygen from the hemoglobin molecule, forming **carboxyhemoglobin.** The result is low circulating volumes of oxygen despite normal partial pressures. In addition, the presence of carboxyhemoglobin requires that tissues be hypoxic before oxygen is released from the hemoglobin to fuel the cells. This condition is reversible.

Carbon monoxide has about 250 times the attraction to hemoglobin that oxygen has. Therefore small concentrations of carbon monoxide in inspired air can result in severe physiological impairments, including tissue hypoxia, inadequate cellular oxygenation, inadequate cellular and organ function, and eventually death. The physical effects of carbon monoxide poisoning are related to the level of carboxyhemoglobin in the blood (Box 39-5).

BOX 39-5 Physical Effects of Carbon Monoxide Blood Levels

Carbon monoxide levels less than 10% usually do not cause symptoms; they are common in smokers, traffic police, truck drivers, and others who are exposed to carbon monoxide chronically. At carbon monoxide levels of 20% a healthy patient may complain of headache, nausea, vomiting, and loss of manual dexterity. At 30% the patient may become confused and lethargic, and electrocardiogram abnormalities may be present. At levels between 40% and 60%, coma may develop. Levels above 60% often are fatal. Tachypnea and cyanosis usually are not present in these patients because arterial oxygen tension is normal. Patients with high carboxyhemoglobin levels may have a skin appearance that is bright red. More commonly, though, the patient has normal or pale skin and lip coloration.

NOTE
As discussed in Chapter 15, the pulse oximeter is unreliable in determining effective oxygenation in a patient with carbon monoxide poisoning.

Prehospital care for the patient with carbon monoxide poisoning includes ensuring a patent airway, providing adequate ventilation, and administering high-concentration oxygen. The half-life of carbon monoxide at room air is about 4 hours. This half-life can be reduced to 30 to 90 minutes if 100% oxygen and adequate ventilations are provided.[14] The use of hyperbaric oxygen therapy may be recommended in treating carbon monoxide poisoning. This therapy promotes increased oxygen uptake by hemoglobin molecules that have not yet been bound to carbon monoxide. The paramedic should follow local protocol.

In addition to carbon monoxide, other gases (e.g., cyanide and hydrogen sulfide) may be released when some materials are burned. The inhalation of these toxic gases can result in inhalation poisoning (e.g., *thiocyanate intoxication*). This may require pharmacological therapy (e.g., ***hydroxycobalamin,*** cyanide antidote kit) as described in Chapter 34.

LOOK AGAIN
See Chapter 34: Toxicology, pp. 993-994.

CRITICAL THINKING
Can carbon monoxide poisoning be ruled out if the patient does not have these signs or symptoms?

FIGURE 39-10 Signs of inhalation injury.

Inhalation Injury Above the Glottis

The structure and function of the airway superior to the glottis make it susceptible to injury if exposed to high temperatures. The upper airway is vascular and has a large surface area. This allows the upper airway to normalize temperatures of inspired air. Because of this design, actual thermal injury to the lower airway is rare. The upper airway sustains the impact of injury when environmental air is superheated.

Thermal injury to the airway can result in immediate edema of the pharynx and larynx (above the level of the true vocal cords). This can progress rapidly to complete airway obstruction. Signs and symptoms of upper airway inhalation injury include the following (Fig. 39-10):

- Facial burns
- Singed nasal or facial hairs
- Carbonaceous sputum
- Edema of the face, oropharyngeal cavity, or both
- Signs of hypoxemia
- Hoarse voice
- Stridor
- Brassy cough
- Grunting respirations

Prompt assessment of the airway is critical in these patients. The paramedic must establish and protect the airway. If impending airway obstruction is suspected, early nasotracheal or orotracheal intubation may be warranted because progressive edema can make intubation hazardous if not impossible.

Inhalation Injury Below the Glottis

The two main mechanisms of direct injury to the lung tissue are heat and toxic material inhalation. Thermal injury to the lower airway is rare. One cause of such injury is the inhalation of superheated steam. This steam has 4000 times the heat-carrying capacity of dry air.[15] Another cause is the aspiration of scalding liquids. Explosions are another cause. These occur as the patient is breathing high concentrations of oxygen under pressure.

Most lower airway injuries in fires result from the inhalation of toxic chemicals. Such chemicals include the gaseous by-products of burning materials. Signs and symptoms of lower airway injury may be immediate, but more often they are delayed. Signs and symptoms may begin several hours after the exposure and include the following:

- Wheezes
- Crackles or rhonchi
- Productive cough
- Signs of hypoxemia
- Spasm of bronchi and bronchioles

Prehospital care should be directed at maintaining a patent airway providing high-concentration oxygen and ventilatory support. Specific airway and ventilatory management should be guided by online/direct medical direction. This may include nasal or oral tracheal intubation and drug therapy with bronchodilators.

SHOW ME THE EVIDENCE

These researchers used data from a trauma registry to compare burn patients injured in methamphetamine-related incidents to another group of burn patients.

Body surface area burned was similar in both groups. Methamphetamine-injured patients needed endotracheal intubation more often and required a larger fluid volume for resuscitation than the controls. The methamphetamine group was more likely to have inhalation injury and to develop pneumonia than the control group.

From Blostein PA, Plaisier B, Sheldon BM, et al: Methamphetamine production is hazardous to your health, *J Trauma* 66(6):1712-1717, 2009.

CHEMICAL BURN INJURIES

Caustic chemicals often are present in the home and workplace. Unintentional exposure is common. Three types of caustic agents often are associated with burn injuries. These are alkalis, acids, and organic compounds. Alkalis are strong bases with a high pH. Alkalis include hydroxides and carbonates of sodium, potassium, ammonium, lithium, barium, and calcium. These compounds commonly are found in oven cleaners, household drain cleaners, fertilizers, heavy industrial cleaners, and the structural bonds of cement and concrete. Strong acids are in many household cleaners, such as rust removers, bathroom cleaners, and swimming pool acidifiers (Figure 39-11).

Organic compounds are chemicals that contain carbon. Most organic compounds, such as wood and coal, are harmless chemicals. However, several organic compounds produce caustic injury to human tissue. These compounds include phenols and creosote and petroleum products such as gasoline. In addition to their role in producing chemical burns, organic compounds may be absorbed by the skin. As described in Chapter 34, absorption in turn may cause serious systemic effects. The severity of chemical injury is related to the type of chemical agent, concentration and volume of the chemical, and duration of contact.

LOOK AGAIN
See Chapter 34: Toxicology, pp. 1002-1004.

Assessment

While obtaining the patient history, the paramedic should collect facts regarding the exposure. When dealing with a chemical exposure, the paramedic should determine the following:

- Type of chemical substance. If the container is available and can be transported safely, it should be taken to the medical facility
- Concentration of chemical substance
- Volume of chemical substance
- Mechanism of injury (e.g., local immersion of a body part, injection, splash)
- Time of contamination
- First aid administered before EMS arrival
- Appearance (chemical burns vary in color)
- Pain

Management

As with all burn injuries, the safety of the rescuers must be the first priority in managing the victim of chemical injury. (Law enforcement, fire service, and special rescue personnel

may be needed to secure the scene before entry.) The paramedic must consider the use of protective gear before entering the scene. Depending on the scene and the chemical agent(s), decontamination may be required. Personal protection may include gloves, eye shields, protective garments, and appropriate breathing apparatus. A response to a hazardous materials incident requires special safety considerations and trained rescue personnel (see Chapter 57). The treatment of chemical injuries varies little from that of thermal burns during the primary survey. Treatment is directed at stopping the burning process. This can best be achieved by the following actions:

1. Remove all clothing, including shoes. These can trap concentrated chemicals.
2. Brush off powdered chemicals.
   a. Break open and irrigate under blisters that may contain chemical.[16]
3. Irrigate the affected area with vast amounts of water.
   a. In otherwise stable patients, irrigation takes priority over transport. That is the case unless irrigation can be continued en route to the emergency department.
   b. If a large body surface area is involved, a shower should be used for irrigation, if available.

CHEMICAL BURN INJURY TO THE EYES

Chemical exposure to the eyes (e.g., from mace, pepper spray, or other irritants) may cause damage ranging from superficial inflammation (*chemical conjunctivitis*) to severe burns. Patients with these conditions have local pain, visual disturbance, lacrimation (tearing), edema, and redness of surrounding tissues. Management guidelines include flushing the eyes with water. This can be done by using a mild flow from a hose, intravenous tubing, or water from a container. (The affected eye should be irrigated from the medial to the lateral aspect. This will help to avoid flushing the chemical into the unaffected eye.) Irrigation should be continued during transport. If contact lenses are present, they should be removed. When retracting the lids to irrigate the eyes, the paramedic should take care to apply pressure only to the bony structures surrounding the eye. Pressure on the globe should be avoided.

Some EMS services use nasal cannulas to irrigate both eyes simultaneously. The cannula is placed over the bridge of the nose; the nasal prongs are pointing down toward the eyes. The cannula is attached to an intravenous administration set using normal saline or lactated Ringer's solution, and the fluid is run continually into both eyes (Figure 39-12). Irrigation lenses (e.g., *Morgan therapeutic lens*) may be useful for prolonged eye irrigation in adults, provided that edema is absent and there are no lacerations or penetrating wounds of the globe or eyelids (Figure 39-13). The use of these devices in the prehospital setting is controversial. Their use requires special training and authorization from medical direction. A chemical burn to the eye can be frightening for the patient. The patient may fear loss of sight from the injury. The paramedic should attempt to calm the patient and explain the importance of thorough eye irrigation, which may be uncomfortable. This often improves the patient's cooperation.

FIGURE 39-12 Use of nasal cannula for eye irrigation.

FIGURE 39-13 Commercial irrigation lens.

USE OF ANTIDOTES OR NEUTRALIZING AGENTS

According to the American Burn Association, no agent has been found to be superior to water for treating most chemical burns.[16] Thus the use of antidotes or neutralizing agents should be avoided in initial prehospital management of most burn injuries. Many neutralizing agents produce heat. They may increase injury when applied to the wound.

In special circumstances, such as when an industrial complex within a response area is known to use a chemical agent with a specific antidote, medical direction may elect to have the EMS stock the neutralizer. In this case, paramedics should receive special training on the indications, contraindications, use, and side effects of these agents.

Specific Chemical Injuries

The main treatment for most chemical burns is copious irrigation with water. However, a number of chemical injuries necessitate further discussion and include those from petroleum, hydrofluoric acid, phenols, ammonia, and alkali metals. Personal safety is a priority when working around any of these chemicals.

PETROLEUM

In the absence of flame, products such as gasoline and diesel fuel can cause significant chemical burns if prolonged contact occurs. (This may occur, for example, with entrapment in a vehicle that is surrounded by spilled gasoline.) At first, the injury may appear to be only a superficial or partial-thickness burn. In fact, though, it may be a full-thickness injury. Systemic effects such as central nervous system depression, organ failure, and death may result from the absorption of various hydrocarbons. In addition, lead toxicity can occur if the exposure was from gasoline that contained tetraethyl lead.

HYDROFLUORIC ACID

Hydrofluoric acid is one of the most corrosive materials known. The acid is used in industry for cleaning fabrics and metals, for glass etching, and in the manufacture of silicone chips for electronic equipment. The hydrogen ion and fluoride ion are damaging to tissue. Fluoride hinders several chemical reactions that are required for cell survival. Fluoride also continues to penetrate and kill cells even when it is neutralized by binding to calcium or magnesium. Thus endogenous or exogenous hydrofluoric acid has the potential to produce deep, painful, and severe injuries. If large body surface areas are involved, the patient may experience severe hypocalcemia and even death. This is true with exposure to high concentrations of the acid also. Even the most minor-appearing wounds that involve hydrofluoric acid should be evaluated at a proper medical facility.

Irrigation of the exposed area with large amounts of water should be started immediately. On arrival in the emergency department, treatment may include subcutaneous injection of 10% calcium gluconate directly into the burn site.

PHENOL

Phenol (*carbolic acid*) is an aromatic hydrocarbon. Phenol is derived from coal tar and is used widely in industry as a disinfectant in cleaning agents. Phenol also is used in the manufacture of plastics, dyes, fertilizers, and explosives. Skin contact with phenol can result in local tissue coagulation and systemic toxicity if the agent is absorbed. A soft tissue injury from phenol exposure may be painless because of the anesthetic properties of the agent. Minor exposures may cause central nervous system depression and dysrhythmias. Patients with significant exposures (10% to 15% TBSA) may require systemic support. These patients should be observed carefully for signs of respiratory failure.

Wounds should be irrigated with large volumes of water. After irrigation, medical direction may advise that the wound be swabbed with a suitable solvent such as glycerol, vegetable oil, or soap and water to bind phenol and prevent its systemic absorption.

AMMONIA

Ammonia is a noxious, irritating gas. Ammonia also is a strong alkali that is very soluble in water. Ammonia is hazardous if introduced into the eye and may result in tissue necrosis and blindness. The patient with an ammonia burn to the eye probably will have swelling or spasm of the eyelids. These injuries must be irrigated with water or a balanced salt solution for up to 24 hours.

NOTE

Anhydrous ammonia burns may be encountered as a result of methamphetamine lab explosions (see Chapter 34).

Respiratory injury from ammonia vapors depends on two factors: the concentration and duration of exposure. For example, short-term, high-concentration exposure usually results in upper airway edema. However, long-term, low-concentration exposure may damage the lower respiratory tract. The initial care for patients with respiratory injury includes high-concentration oxygen administration, ventilatory support as needed, and rapid transport to an appropriate medical facility.

ALKALI METALS

Sodium and potassium are highly reactive metals. They can ignite spontaneously. Water generally is contraindicated when these metals are imbedded in the skin because they react with water and produce large amounts of heat. Physically removing the metal or covering it with oil minimizes the thermal injury.

ELECTRICAL BURN INJURIES

Electrical injuries account for 4% to 6.5% of admissions to burn centers and are responsible for about 500 deaths each year.[2] Good patient care and personal safety at the scene of an electrocution depend on understanding how electricity flows (current) through the body (Box 39-6).

Types of Electrical Injury

Three basic types of injury may occur as a result of contact with electrical current. These are *direct contact burns, arc injuries,* and *flash burns*. Direct contact burns occur when electrical current directly penetrates the resistance of the skin and underlying tissues. The hand and wrist are common entrance sites. The foot is a common exit site (Figure 39-14). Although the skin may initially resist current flow, continued contact with the source lessens resistance and permits

BOX 39-6 Principles of Tissue Damage Caused by Electricity

Tissue damage produced by electrical current is a function of six factors: amperage, voltage, resistance, type of current, current pathway, and duration of current flow.

1. *Amperage*. Amperage is a measure of the current flow (intensity) per unit of time. One ampere is a passage of 1 coulomb of charge per second past any point in the circuit. Thus a 10-amp flow means that 10 coulombs of electricity are passing a point per second.
2. *Voltage*. Voltage is a continuous force (tension) applied to any electrical circuit that produces a flow of electricity. Volts are the driving force for electrical current. One volt is the force needed to drive 1 amp of current in a circuit with 1 ohm of resistance. High-voltage electrical injuries result from contact with a source of 1000 volts or greater. High-tension accidents usually range from 7200 to 19,000 volts. Yet they may involve current with as high as 100,000 to 1 million volts.
3. *Ohm*. An ohm is a measure of the resistance of an electrical conductor. Electrical resistance is composed of four factors: (1) resistivity, the capacity of a material to resist current flow; (2) the size of the object pathway; (3) the length of the object pathway; and (4) temperature. Resistance to the flow of electricity varies greatly within the body because various tissues have different resistance to current flow. Tissue resistance to electrical flow in the body is highest in bone and decreases progressively through the fat, skin, muscle, blood, and nerve tissue.
4. *Type of current*. Two basic forms of electrical current are in common usage: direct current (DC) and alternating current (AC). The type of current can influence patterns and severity of injury. Direct current flows in one direction only. Direct current often is used in industry; it is the type of current produced by batteries. Direct current commonly is used in electrosurgical devices and defibrillators and is characterized by high amperage and low voltage.

   Alternating current reverses the direction of flow at regular intervals (60-cycle current has 60 reversals per second). These alterations in current direction can cause tetanic muscle contractions. These contractions may "freeze" the victim to the source until the current is terminated. Household current in the United States generally is alternating current and either 120 or 220 volts. Alternating current is a more common cause of electrical injury.
5. *Current pathway*. Electricity normally flows along a continuous pathway. This pathway is known as an electrical circuit. The current pathway can be unpredictable. However, as a rule, low-voltage current (less than 1000 volts) follows the path of least resistance. High-voltage current follows the shortest path. In either case, the greater the current flow, the greater the heat generated.

   The pathway of the current through the body is important because it gives a clue as to what anatomical structures are damaged. For example, if the current travels from one hand to the other, it may flow across the heart and provoke ventricular fibrillation or other dysrhythmias.
6. *Duration of flow*. Tissue injury results from the conversion of electrical energy into heat. The amount of heat produced is directly proportional to the square of the current strength multiplied by the resistance of the tissue multiplied by the duration of the current flow (Joule's law). Therefore injury is directly proportional to the duration of contact with the electrical source.

increased current flow. The greatest tissue damage occurs directly under and adjacent to the contact points and may include fat, fascia, muscle, and bone. Tissue destruction may be massive at the entrance and exit sites; however, injury to the area between these wounds is what poses the greatest threat to the patient's life.

Arc injuries occur when a person is close enough to a high-voltage source that the current between two contact points near the skin overcomes the resistance in the air, passing the current flow through the air to the bystander. Temperatures generated by these sources can be as high as 2000° to 4000° C (3632° to 7232° F). The arc may jump as far as 10 feet.

Flame and flash burn injuries can occur when the heat of electrical current ignites a nearby combustible source. Common injury sites include the face and eyes (*welder's flash*). Flash burns also may ignite a person's clothing or cause fire in the surrounding environment. No electrical current passes through the body in this type of burn.

Effects of Electrical Injury

Electrical injuries often are unpredictable. They vary according to the parameters that have been described. Yet certain physiological effects should be expected by the paramedic crew.

The skin is almost always the first point of contact with electrical current. Direct contact and passage of the current through tissue may cause wide areas of coagulation necrosis. The entrance site is often a bull's-eye wound. The site may appear dry, leathery, charred, or depressed. The exit wound may be ulcerated and may appear exploded. Areas of tissue may be missing.

Oral burns often are seen in children younger than 2 years of age. These wounds usually are caused by chewing or sucking on a low-tension electrical cord. Oral burns may be associated with injury to the tongue, palate, and face.

Hypertension and tachycardia associated with a large release of catecholamines is a common finding in electrical injury. Electrical current also may cause significant dysrhythmias (including ventricular fibrillation and asystole) and damage to the myocardium as it passes through the body. The patient may have suffered cardiac arrest. If early rescue and resuscitation can be initiated, success rates are high.

Nerve tissue is a good conductor of electrical current. Thus nerve tissue often may be affected in electrical injuries. Central nervous system damage may result in seizures or coma with or without focal neurological findings. Peripheral nerve injury may lead to motor or sensory deficits. These deficits may be permanent. If the current passes

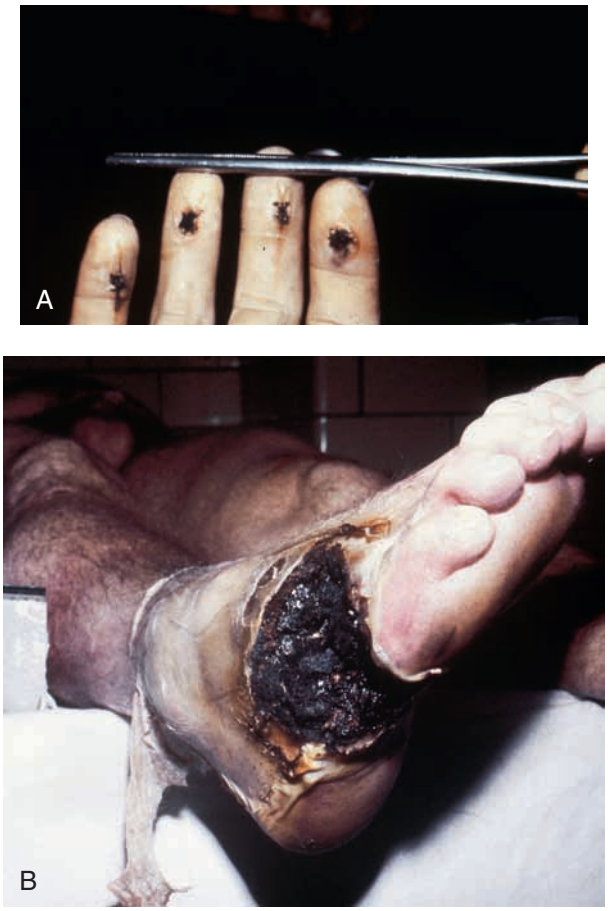

FIGURE 39-14 Direct contact burn. **A,** Entry wound (hand). **B,** Exit wound (foot).

through the brainstem, respiratory arrest or depression, cerebral edema, or hemorrhage may rapidly lead to death.

Electrical injury can cause extensive necrosis of blood vessels. This may not be evident upon the arrival of EMS. However, such injuries can cause immediate or delayed internal hemorrhage or arterial or venous thrombosis and embolism with subsequent complications.

Damage within the extremities after an electrical burn is similar to that sustained by crush injury (described in Chapter 38). Severe muscle necrosis releases myoglobin. Bursting of the red blood cells (hemolysis) releases hemoglobin. Both of these large molecules can precipitate in the renal tubules, producing acute renal failure. Some patients may require amputation of the affected extremity. This results from decreased circulation and compartment syndrome. In the electrocuted patient, severe muscle spasms can produce bony fractures. These spasms also may produce dislocations, even of major joints. A patient may fall after the electrical shock and sustain skeletal trauma (including damage to the cervical spine).

Acute renal failure can be a serious complication from significant direct contact electrical **injuries.**[17] Acute renal failure may result from a combination of myoglobin or hemoglobin sludging in the renal tubules, disseminated intravascular coagulation caused by tissue damage, hypovolemic shock, and direct current damage. Acute renal failure is not of immediate consequence in the prehospital setting. Yet prompt fluid resuscitation and management of shock may have a positive impact on a number of these patients.

Ventilation may be impaired when electrical burns produce central nervous system injury or chest wall dysfunction. If the respiratory center is disrupted, hypoventilation can lead to immediate patient death. Contact with any alternating current sources also has been known to produce respiratory arrest and death from tetany of the muscles of respiration.

Conjunctival and corneal burns and ruptured tympanic membranes may be found in some electrical injuries. Cataracts and hearing loss also may appear as late as 1 year after the event.

A number of other internal structures may be damaged from electrical injury. These structures include the abdominal organs and urinary bladder. Submucosal hemorrhage may occur in the bowel; various forms of ulceration are possible. Each patient requires a thorough physical assessment and a high degree of suspicion for associated trauma.

Assessment and Management

Patient assessment should begin by ensuring that no hazards exist for the rescuers or bystanders. If the patient is still in contact with the electrical source, the paramedic should summon the electric company, fire department, or other specially trained personnel before approaching the patient. Once the scene is safe, the patient intervention may begin.

CRITICAL THINKING

What will you do if you respond to a scene and there is a child still in contact with electrical current and having tetanic movements? A large crowd has gathered and is screaming at you to help. The fire department is 3 minutes away. How will you feel?

PRIMARY SURVEY

The primary survey should proceed as it does for all other trauma patients. The paramedic should take care to immobilize the cervical spine. If the patient is not breathing, assisted ventilation should begin immediately. The paramedic should perform intubation as soon as possible because apnea may persist for lengthy periods. A patient who is breathing should have a patent airway maintained. Respirations should be supported with supplemental high-concentration oxygen as well. If the patient is in cardiac arrest, the paramedic should initiate resuscitation efforts according to protocol. If possible, a history of the event should be obtained that includes the following:

- Patient's chief complaint (e.g., injury or disorientation)
- Source, voltage, and amperage of the electrical injury
- Duration of contact
- Level of consciousness before and after the injury
- Significant medical history

NOTE
The source, voltage, and type of current (alternating current versus direct current) are essential information for the attending physician to estimate internal damage from electrical current.

PHYSICAL EXAMINATION

The physical exam should be thorough. The paramedic should search for entrance and exit wounds or any associated trauma caused by tetany or a fall. The paramedic should recall that there may have been multiple pathways of current. This would mean multiple wounds. The paramedic should remove all of the patient's clothing and jewelry and examine the areas between the patient's fingers and toes for sites of entry or exit. Distal pulses, motor function, and sensation in all extremities should be assessed and documented to monitor for possible development of compartment syndrome. The paramedic should cover entrance and exit wounds with sterile dressings and should manage any associated trauma appropriately.

Internal damage from electrical current may be much more significant than external wounds. Frequent reassessment is necessary because of the progressive nature of electrical injury. In addition, electrocardiogram monitoring should be implemented at the scene and continued during patient transport. As previously discussed, electrical injury may cause a variety of dysrhythmias, some of which can be lethal.

MANAGEMENT

Early administration of fluids is critical for patients with severe electrical injury. Fluid administration helps to prevent hypovolemia and subsequent renal failure. If possible, the paramedic should establish two large-bore intravenous lines. These should be in an extremity without entry or exit wounds. The fluid of choice generally is lactated Ringer's solution or normal saline without glucose. The flow rate should be determined by the patient's clinical status.

In the emergency department or during interhospital transfer, the patient's intravenous fluid rates will be regulated to maintain a urine output of 1 to 1.5 mL/kg/hr.[11] This rate decreases the potential for renal damage caused by myoglobin accumulation. Emergency department management may include the administration of ***sodium bicarbonate*** to help maintain an alkaline urine. Alkalinity in turn increases the solubility of hemoglobin and myoglobin and decreases the risk of renal failure.

Lightning Injury

Lightning strikes the earth about 7.4 million times each year and accounts for about 70 deaths each year.[2] Lightning can deliver direct current of up to 200,000 amps at a potential of 100 million or more volts, with temperatures that vary between 16,000° and 60,000° F (8871° and 33,315° C). Lightning injuries can occur from a direct strike or by a side flash (splash) between a victim and a nearby object that has been struck by lightning. About 30% of those struck by lightning die.[18] Lightning strikes are most common in Florida, Texas, and North Carolina.

Lightning strikes produce tissue injuries that differ from other types of electrical injury because the pathway of tissue damage often is over rather than *through* the skin (Figure 39-15). The duration of the lightning is short ($\frac{1}{100}$ to $\frac{1}{1000}$ second). Thus skin burns are less severe than those seen with other high-voltage current (full-thickness burns are rare). Common lightning burns are linear, feathery, and punctate (pinpoint). In addition, depending on the severity of the strike, 30% of those struck by lightning suffer cardiac and respiratory arrest.[12]

Lightning injuries may be classified as minor, moderate, or severe. The patients with minor lightning injuries usually are conscious. These patients often are confused and amnesic. Burns or other signs of injury are rare. The vital signs of these patients usually are stable.

The patients with moderate injury may be combative or comatose. These patients may have associated injuries from the impact of the lightning strike. Superficial and partial-thickness burns are common, as is tympanic membrane rupture. These patients may have serious internal organ damage. They should be observed carefully for signs and symptoms of cardiorespiratory dysfunction.

Severe lightning injuries include those that cause immediate brain damage, seizures, respiratory paralysis, and cardiac arrest. The prehospital care is directed at basic and advanced life support measures and rapid transport to a proper facility.

FIGURE 39-15 Lightning injury.

ASSESSMENT AND MANAGEMENT

Like all other emergency responses, scene safety is the first priority. If the electrical storm is still in progress, all patient care should take place in a sheltered area. To prevent injury from subsequent lightning strikes, the paramedic crew should stay away from objects that project from the ground. Such objects include trees, fences, and high buildings. The crew also should avoid areas of open water. If rescue attempts in an open area are necessary, the paramedic should stay low to the ground.

The prehospital management of lightning injuries is the same as that for other severe electrical injuries. Initial patient care is directed at airway and ventilatory support; basic and advanced life support; patient immobilization; fluid resuscitation to prevent hypovolemia and renal failure; pharmacological therapy (per protocol) to manage seizures (if present), promote excretion of myoglobin, and treat dysrhythmias; wound care; and rapid transport to a proper facility.

NOTE

Cardiopulmonary resuscitation should be initiated immediately for patients who are pulseless because resuscitation is possible after lightning injury.[19]

RADIATION EXPOSURE

The most common radiation incidents involve sealed radioactive sources used in industrial radiography and nondestructive testing. The victims of these types of incidents rarely require emergency care. However, EMS may be called to building fires and crashes that may involve radioactive materials. Thus an understanding of the hazards of radiation exposure is important. As with all incidents involving hazardous materials, the paramedic crew should never enter the scene until it has been made safe by the proper authorities.

Generally, safety issues regarding radiation have been minor because of excellent adherence to radiation regulations throughout the world. However, hazards associated with radiation became well known as a result of several incidents. First, the serious potential for disaster occurred at Three Mile Island in Pennsylvania in 1979. Second, a disastrous incident occurred at the Chernobyl Nuclear Power Station in the Soviet Union in 1986. Most recently, the earthquake and tsunami that struck Japan in 2011 caused a serious radiation event when the Fukushima Daiichi nuclear power plant was damaged.

CRITICAL THINKING

What industries in your area use radioactive materials? Is there a preplan for incidents at those sites?

Characteristics of Radioactive Particles

Radioactive particles generally are classified into three types: *alpha, beta,* and *gamma*. Alpha particles are large. They travel only a few millimeters. They have little penetrating ability. In fact, alpha particles may be stopped by paper, clothing, or skin. These particles are considered the least dangerous external radiation source. However, if alpha particles enter the body through inhalation, ingestion, or absorption, they can damage internal organs and interfere with the chemical functions of the body. Alpha radiation is considered the most dangerous form of internal radiation exposure.

Beta particles are 0.017 (one seven thousandth) the size of alpha particles. Yet beta particles have much more energy and penetrating power. Beta particles can penetrate subcutaneous tissue. They usually enter the body through damaged skin, ingestion, or inhalation. Protection from alpha and beta radiation requires full protective clothing, including a positive-pressure self-contained breathing apparatus.

Gamma rays and x-rays are the most dangerous forms of penetrating radiation. They require lead shields for protection. Gamma rays have 10,000 times the penetrating power of alpha particles. They have 100 times the penetrating power of beta particles.[20] Protective clothing does not stop gamma rays. Gamma rays pose internal and external hazards. They may produce localized skin burns and extensive internal damage.

Harmful Effects From Radiation Exposure

Nonionizing radiation includes radio waves and microwaves. Nonionizing radiation usually is considered safe. Ionizing radiation is produced by nuclear weapons, reactors, radioactive material, and x-ray machines. Although rare, the exposure to ionizing radiation poses a threat to victims and rescue workers.

The amount of emitted radiation is expressed in *roentgens* and indicates the ionization produced in the air by gamma or x-ray radiation. Other units used to measure radiation are the *rad* (radiation absorbed dose) and the *rem* (roentgen equivalent man). A rad is a measure of the amount of ionized radiation being emitted and the amount that has been absorbed and is active within the body tissues. A rem is used to assess the biological effects of the various types of radiation. For emergency purposes, rescue workers should assume that 1 roentgen equals 1 rad equals 1 rem.

Doses of less than 100 rem usually do not cause significant acute problems. Doses from 100 to 200 rem may cause symptoms. Yet the doses are not life threatening. When an exposure of 200 rem is neared, nausea, vomiting, and diarrhea begin within 2 to 4 hours. After an exposure of 450 rem, 50% mortality can be expected within 30 days if no medical care is given.[21] Victims of radiation rarely show immediate signs or symptoms of exposure. Thus all victims

BOX 39-7 Types of Radiation Injury

The harmful effects from radiation may be classified as external irradiation, contamination by radioactive materials, incorporation of radioactive materials, and combined radiation injury.

External irradiation occurs when all or part of the body is exposed to penetrating radiation from an external source. An example of external irradiation is a medical x-ray. The degree of radiation injury depends on the intensity of radiation, which in turn depends on the duration of exposure. Degree of injury also depends on the distance from the source. A patient who has been exposed to large amounts of radiation may have nausea, vomiting, and diarrhea. In severe cases, additional symptoms may include weight loss, hair loss, fever, bleeding, mouth and throat sores, skin burns, lowered body resistance, vesiculation, and ulceration. The effects from this type of radiation are not contagious; there are no risks to the rescuer in providing care.

Contamination occurs when radioactive materials in the form of gases, liquids, or solids are released into the environment. These materials contaminate persons internally, externally, or both. When radioactive material remains on the patient's clothing or skin or in open wounds, a potential hazard is present for the rescuer and the patient. Patients who have been contaminated should be considered medical emergencies. They may pose significant risk to emergency providers.

Incorporation refers to the uptake of radioactive materials by body cells, tissues, and target organs such as bone, liver, thyroid, or kidney. Incorporation is impossible unless contamination has occurred.

A combination radiation injury involves external irradiation, contamination, incorporation, or some combination of these. This type of exposure usually is the result of a major incident. Exposure may be complicated by a patient's physical injury.

After exposure to radiation, a person may be at risk for delayed complications. Such complications include cell and chromosomal changes, subsequent reproductive genetic aberrations, cell death, and sterility. Diseases such as anemia and forms of cancer may develop as well.

of possible exposure should be presumed to have a radiation injury until proved otherwise (Box 39-7).

NOTE

An object or a person who has been exposed to radiation is not radioactive. Only the presence of the radioactive residue poses a threat to rescuers.

Emergency Response to Radiation Accidents

If the EMS crew has been advised that radioactive materials are present at an emergency scene, they should approach the site with caution. They should not enter the scene until it has been secured by proper authorities (see Chapter 57). Rescue personnel, emergency vehicles, and the command post should be positioned 200 to 300 feet upwind of the site. Emergency workers should not eat, drink, or smoke at the site or in any rescue vehicle. The proper local authorities should be contacted (state radiological health office, local specialists). Medical direction should be notified as well. Protective clothing suitable for other hazardous material releases should be worn by all emergency workers. In addition, dose meters should be available for all rescue personnel. Self-contained breathing apparatus should be used if fire, smoke, or gas is present.

Personal Protection From Radiation

The Federal Emergency Management Agency recommends that basic radiation protection for the rescuer and the patient include the following four factors[22]:

1. *Time:* The less time spent in a radiation field, the less radiation exposure. If adequate personnel are available, a rotating team approach can be used to keep individual radiation exposure to a minimum.
2. *Distance:* The farther a person is from the source of radiation, the lower the radiation dose. Even moving several feet away from a radioactive source greatly reduces the level of exposure.
3. *Shielding:* The general principle of shielding is that the denser the material, the greater its ability to stop the passage of radiation. Lead shields provide the best protection from exposure. However, vehicles, mounds of dirt, and pieces of heavy equipment placed between the radiation source and the rescuer and victim also can diminish exposure levels. Protective clothing and self-contained breathing apparatus may provide adequate protection from all alpha and some beta radiation, but protective clothing does not prevent penetration of gamma rays. If adequate shielding is not readily available, rescuers should use the time and distance factors to reduce radiation exposure.
4. *Quantity:* Limiting the amount of radioactive material in a specific area lessens the radiation exposure. Examples include removing contaminated clothing, bagging all contaminated items, and moving containers of radioactive material from the area.

Emergency Care for Victims of Radiation Exposure

A patient who has been irradiated is not radioactive. But when external contamination occurs and radioactive material remains on the patient's clothing and skin or in open wounds, the rescuer should consult with medical direction and follow agency protocol. The effects of radiation exposure may be instant (e.g., burns) or delayed.

With the exception of dealing with contaminants and containing their spread, there are no emergency care procedures specific to radiation injury. All external bleeding should be controlled, the spine immobilized, open wounds covered, and fractures stabilized in normal fashion. The EMS crew should move the patient away from the source of radiation as soon as possible. Lifesaving care should not

be delayed for patient transfer or decontamination procedures. Intravenous fluid replacement should be initiated if indicated. (Strict aseptic technique should be used.) If an intravenous line is not needed for specific therapy, its use should be avoided to prevent introducing contaminants into the body.

Radiation Decontamination Procedures

Radiation emergencies involving patients may be defined in two ways: clean and dirty. *Clean* means that the patient was exposed but not contaminated. *Dirty* means that the patient was contaminated. Only properly trained personnel (e.g., hazardous materials teams and qualified county, state, or federal health department personnel) should attempt to decontaminate radiation victims at the scene. A patient who is to be transported to a hospital for decontamination should be isolated from the environment (described in Chapter 57). Also, all patient effects should be transported with the patient.

SUMMARY

- Each year more than 2 million Americans seek medical attention for burns. Morbidity and mortality rates from burn injury follow significant patterns regarding gender, age, and socioeconomic status. A burn injury is caused by an interaction between thermal, chemical, electrical, or radiation energy and biological matter.
- Tissue damage from burns depends on the degree of the heat and on the duration of exposure to the thermal source. As local events occur at the injury site, other organ systems become involved in a general response to the stress caused by the burn.
- Burns are classified in terms of depth as superficial, partial-thickness, and full-thickness. The rule of nines provides a rough estimate of burn injury size (extent) and is most accurate for adults and for children older than age 10. The Lund and Browder chart is a more accurate method of determining the area of burn injury. Severity of burn injury and burn center referral guidelines are based on standards that take into account the depth, extent, and severity of the burn wound; the source of injury; the age of the patient; the presence of concurrent medical or surgical problems; and the body region that is burned.
- Shock after thermal injury results from edema and accumulation of vascular fluid. These tissue changes occur in the area of injury and can produce systemic hypovolemia if the burn area is large.
- Emergency care for a burn patient begins with the initial assessment. The goal is to recognize and treat life-threatening injuries.
- Goals for prehospital management of the severely burned patient include preventing further tissue injury, maintaining the airway, administering oxygen and ventilatory support, providing fluid resuscitation, providing rapid transport to an appropriate medical facility, using aseptic (clean) technique to minimize the patient's exposure to infectious agents, managing pain, and providing psychological and emotional support.
- Prehospital considerations in caring for patients with inhalation injury include recognition of the dangers inherent in the fire environment, awareness of the pathophysiological principles of inhalation injury, and early detection and treatment of impending airway or respiratory problems.
- The severity of chemical injury is related to three factors: the chemical agent, the concentration and volume of the chemical, and the duration of contact. Treatment is directed at stopping the burning process by using copious irrigation.
- Three types of injury may occur as a result of contact with electrical current: direct contact burns, arc injuries, and flash burns. Once the scene is safe, patient intervention may begin. Internal damage from electrical current may be much more significant than external wounds.
- Persons who are injured by radiation rarely require emergency care. Radioactive particles are classified into three types: alpha, beta, and gamma. The Federal Emergency Management Agency recommends that basic radiation protection for the rescuer and the patient include four factors: minimize time in the radiation field; maintain a safe distance from the source; place shielding between the rescuers and the source; and limit the amount of radioactive material in a specific area.

CHAPTER

40 Head, Face, and Neck Trauma

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the mechanisms of injury, assessment, and management of maxillofacial injuries.
2. Describe the mechanisms of injury, assessment, and management of ear, eye, and dental injuries.
3. Describe the mechanisms of injury, assessment, and management of anterior neck trauma.
4. Describe the mechanisms of injury, assessment, and management of injuries to the scalp, cranial vault, or cranial nerves.
5. Distinguish between types of traumatic brain injury based on an understanding of pathophysiology and assessment findings.
6. Outline the prehospital management of the patient with cerebral injury.
7. Calculate a Glasgow Coma Scale, trauma score, Revised Trauma Score, and pediatric trauma score when given appropriate patient information.

KEY TERMS

antegrade amnesia The loss of memory for events that occurred immediately after recovery of consciousness.

astigmatism An abnormal condition of the eye in which the light rays cannot be focused clearly on a point on the retina because the spherical curve of the cornea is not equal in all meridians.

barotitis An inflammation of the ear caused by changes in atmospheric pressure.

basilar skull fracture A fracture that may occur when the mandibular condyles perforate the base of the skull but that more commonly results from extension of a linear fracture into the floor of the anterior and middle fossae.

Battle's sign Ecchymosis over the mastoid process caused by a fracture of the temporal bone.

blowout fracture A fracture of the floor of the orbit caused by a blow that suddenly increases the intraocular pressure.

central vision The vision that results from images falling on the macula of the retina.

cerebral contusion Bruising of the brain in the area of the cortex or deeper within the frontal (most common), temporal, or occipital lobes.

cerebral perfusion pressure A measure of the amount of blood flow to the brain calculated by subtracting the intracranial pressure from the mean systemic arterial blood pressure.

concussion A head injury that results from violent jarring or shaking, such as that caused by a blow or explosion.

consensual movement The movement of one eye acting in concert with the other.

contrecoup An injury that occurs at a site opposite the side of impact.

corneal abrasion The rubbing off of the outer layers of the cornea.

coup Local damage that occurs at the site of impact.

Cushing's triad Increased systolic pressure, widened pulse pressure, and decrease in pulse and respiratory rates, which result from increased intracranial pressure.

decerebrate posturing A position in which a comatose patient's arms are extended and internally rotated and the legs are extended with the feet in forced plantar flexion; usually observed in patients who have compression of the brainstem.

decorticate posturing A position in which the comatose patient's upper extremities are rigidly flexed at the elbows and at the wrists; usually observed in patients who have a lesion in the mesencephalic region of the brain.

dental malocclusion A misalignment of the teeth.

depressed skull fracture Any fracture of the skull in which fragments are depressed below the normal surface of the skull.

epidural hematoma Accumulation of blood between the dura mater and the cranium.

focal injuries Specific, grossly observable brain lesions.

Glasgow Coma Scale A standardized system for assessing the degree of conscious impairment in the critically ill and for predicting the duration and ultimate outcome of coma.

hemotympanum Blood behind the tympanic membrane from fractures of the temporal bone.

intracerebral hematoma An accumulation of blood or fluid within the tissue of the brain.
Le Fort fracture A fracture pattern that can be produced in the midface region.
linear skull fracture A skull fracture that does not displace the bone tissue.
mean arterial pressure The arithmetic mean of the blood pressure in the arterial portion of the circulation.
moderate diffuse injury A head injury that results in minute petechial bruising of brain tissue.
open vault fracture A fracture that results in direct communication between a scalp laceration and cerebral substance.
pediatric trauma score An injury severity index that grades six components commonly seen in pediatric trauma patients: size (weight), airway, central nervous system, systolic blood pressure, open wound, and skeletal injury.
peripheral vision The ability to see objects that reflect light waves on areas of the retina other than the macula.
photophobia Abnormal sensitivity to light.
primary brain injury The direct trauma to the brain and the associated vascular injuries that occurred from the initial injury.
raccoon's eyes Ecchymosis of one or both orbits caused by fracture of the base of the sphenoid sinus.
retrograde amnesia The loss of memory for events that occurred before the event that precipitated the amnesia.
Revised Trauma Score An injury severity index that uses the Glasgow Coma Scale and measurements for systolic blood pressure and respiratory rate.
secondary brain injury Brain injury results from intracellular and extracellular derangements that probably were initiated at the time of the injury.
severe diffuse axonal injury Brain injury that involves severe mechanical shearing of many axons in both cerebral hemispheres extending to the brainstem.
stellate wound A star-shaped wound.
subarachnoid hematoma A collection of blood or fluid in the subarachnoid space.
subdural hematoma A collection of blood in the subdural space.
subgaleal hematomata A collection of blood beneath the strong sheet of fibrous connective tissue that joins the frontal and occipitofrontal muscles.
traumatic brain injury A traumatic insult to the brain capable of producing physical, intellectual, emotional, social, and vocational change.
traumatic hyphema A hemorrhage into the anterior chamber of the eye; it usually is a result of blunt trauma.
traumatic perforation A tear or puncture of the tympanic membrane.
visual acuity A measurement of the clarity or sharpness of vision.
vitreous humor The transparent, jellylike material that fills the space between the lens and the retina.

Each year, an estimated 1.5 million people sustain head injury in the United States, and about 52,000 patients with severe head trauma die each year from traumatic brain injury.[1] The categories of head trauma discussed in this chapter include maxillofacial trauma; ear, eye, and dental trauma; anterior neck trauma; and trauma to the skull and brain.

(Courtesy Ray Kemp, St. Charles, Mo.)

MAXILLOFACIAL INJURIES

In descending order of frequency, major causes of maxillofacial trauma are motor vehicle crashes, home injuries, athletic injuries, animal bites, intentional violent acts, and industrial injuries. Maxillofacial trauma may include soft tissue injuries and facial fractures.

Soft Tissue Injuries

The face receives its blood supply from the branches of the internal and external carotid arteries. These branches provide a rich vascular supply (Figure 40-1). As a result, soft tissue injuries to the face often appear to be serious (Figure 40-2). With the exception of a compromised upper airway and the potential for heavy bleeding, however, damage to the tissues of the maxillofacial area is seldom life threatening. Depending on the mechanism of injury, facial trauma may range from minor cuts and abrasions to more serious injuries. The more serious injuries may involve extensive soft tissue lacerations and avulsions. If possible, the

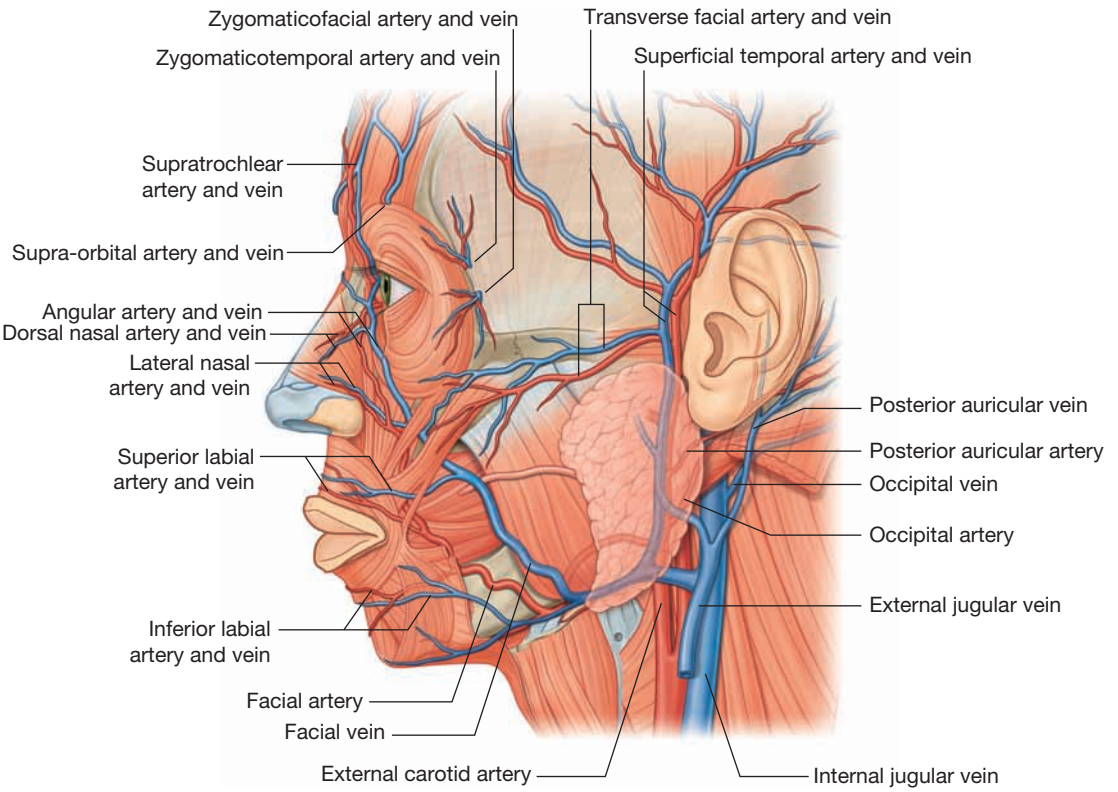

FIGURE 40-1 Arterial blood supply to the face. (From Drake R, et al: *Gray's anatomy for students,* ed 2, Philadelphia, 2010, Churchill Livingstone.)

paramedic should obtain a thorough history from the patient. The history should include mechanism of injury; events leading up to the injury; time of injury; associated medical problems; and allergies, medications, and last oral intake.

CRITICAL THINKING
Why might it be difficult to obtain a history from a patient with this type of injury?

MANAGEMENT

The management of soft tissue injuries was described in Chapter 38. The key principles of wound management include the control of bleeding with direct pressure and pressure bandages. The paramedic should use spinal precautions if indicated by mechanism of injury (described in Chapter 41). The paramedic also should pay close attention to airway management. Soft tissue injuries to the nose and mouth are common with facial injuries. The paramedic should assess the patient's airway for obstruction caused by blood, vomitus, bone fragments, broken teeth, dentures, and damage to the anterior neck. Suction may be needed to clear the patient's airway. Also, oral or nasal adjuncts, tracheal intubation, or cricothyrotomy may be required to ensure adequate ventilation and oxygenation.

Facial Fractures

Facial bones can withstand tremendous forces from the impact of energy. However, facial fractures are common after blunt trauma. The anatomical structure of the facial bones allows a stepwise fracture to absorb the impact of blunt trauma. Blunt trauma injuries may be classified anatomically as fractures to the mandible, midface, zygoma, orbit, and nose. Signs and symptoms of facial fractures include the following:

- Asymmetry of cheek bone prominences
- Crepitus
- Dental malocclusion
- Discontinuity of the orbital rim
- Displacement of the nasal septum
- Ecchymosis
- Lacerations and bleeding
- Limitation of forward movement of the mandible
- Limited ocular movements
- Numbness
- Pain
- Swelling
- Visual disturbances

FRACTURES OF THE MANDIBLE

The mandible is the single facial bone in the lower third of the face (see Chapter 10: Review of Human Systems). Because of its prominence, fractures to this bone rank

FIGURE 40-2 **A,** Appearance of a patient after being attacked. **B,** Appearance of same man after cleansing. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

second in frequency after nasal fractures. The mandible is a hemicircle of bone. It may break in multiple locations, often distant from the point of impact. Signs and symptoms specific to mandibular fractures include **dental malocclusion** (patients may complain that their teeth do not "feel right" when their mouths are closed), numbness in the chin, and inability to open the mouth. The patient also may have difficulty swallowing and may have excessive salivation. Most patients with mandibular fractures require hospitalization.

Anterior dislocation of the mandible in the absence of fracture also may occur as a result of blunt trauma to the face (rare), an abnormally wide yawn, and dental treatment requiring that the jaws remain open for long periods. In these cases, the condylar head advances forward beyond the articular surface of the temporal bone. The jaw-closing muscles spasm. As a result, the mouth becomes locked in a wide-open position. The patient usually feels severe pain from the spasm. The patient also experiences anxiety and discomfort that perpetuate the spasm. Mandibular dislocations are reduced manually in the emergency department with the aid of a muscle relaxant or sedative or in the operating room with a general anesthetic.

FIGURE 40-3 Fracture of the middle third of the face. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

CRITICAL THINKING
What will be your patient care priority with these patients?

FRACTURES OF THE MIDFACE

The middle third of the face includes the maxilla, zygoma, floor of the orbit, and nose. Fractures to this region result from direct or transmitted force. (For example, fractures may result from blunt trauma to the mandible with the energy transmitted to produce fractures to the maxilla.) These injuries often are associated with central nervous system injury and spinal trauma (Figure 40-3).

In 1901 a cadaver study done by Le Fort described three patterns of injuries (**Le Fort fractures).** These injuries occur in the midface region (Figure 40-4). The *Le Fort I fracture* involves the maxilla up to the level of the nasal fossa. The *Le Fort II* involves the nasal bones and medial orbits. The fracture line generally is shaped like a pyramid. The *Le Fort III* is a complex fracture in which the facial bones are separated from the cranial bones. Depending on

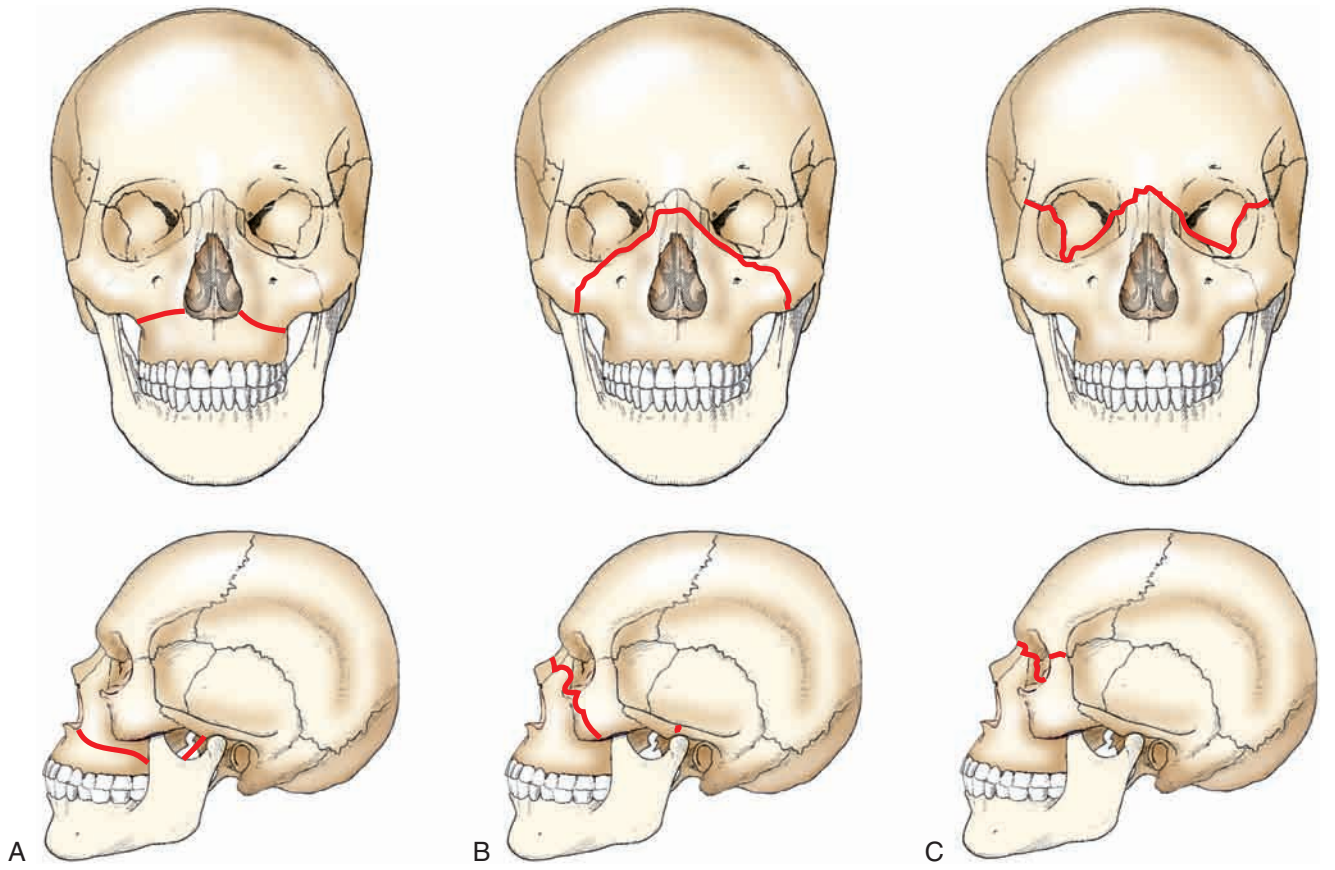

FIGURE 40-4 **A,** Le Fort I facial fractures (lateral and frontal views). **B,** Le Fort II fractures (lateral and frontal views). **C,** Le Fort III fractures (lateral and frontal views). (Modified from ENA: *Sheehy's emergency nursing,* ed 6, St Louis, 2010, Mosby.)

the severity of injury, different combinations of Le Fort fractures may be present.

Signs and symptoms specific to midface fractures include midfacial edema, unstable maxilla, lengthening of the face (donkey face), epistaxis, numb upper teeth, nasal flattening, and cerebrospinal fluid rhinorrhea (cerebrospinal fluid leakage from the nose caused by ethmoid cribriform plate fracture). Patients with midface fractures require hospitalization. These patients (particularly those with Le Fort II and III fractures) are at risk of having serious airway problems related to swelling and bleeding. Because of the extent of the fractures, placing nasogastric or even nasotracheal tubes into the brain tissue is a possibility.

NOTE
As described in Chapter 15, nasal airways, nasogastric tubes, and nasotracheal intubation are contraindicated in patients who have fractures of the basal skull or facial bones. Cerebrospinal fluid leakage from the ear or nose should be allowed to drain freely. The paramedic should make no attempts to control cerebrospinal fluid leakage with direct pressure.

FRACTURES OF THE ZYGOMA

The zygoma (malar eminence) articulates with the frontal, maxillary, and temporal bones. The zygoma commonly is called the *cheek bone*. It is rarely fractured because of its sturdy construction. When fractures occur, they usually are a result of physical assaults and vehicle crashes. Zygomatic fractures often are associated with orbital fractures and manifest similar clinical signs (Figure 40-5). The two are distinguished by x-ray exam. Signs and symptoms specific to zygomatic fractures include flatness of a usually rounded cheek area; numbness of the cheek, nose, and upper lip (particularly if an orbital fracture is involved); epistaxis; and altered vision.

FRACTURES OF THE ORBIT

The orbital contents are protected by a bony ring. The ring resembles a pyramid, with the apex pointed toward the back of the head. The bones of the walls, floor, and roof of the orbit are thin and are fractured easily by direct blows and transmitted forces. In addition, many orbital fractures are associated with other facial injuries, such as Le Fort II and III fractures.

A **blowout fracture** to the orbit can occur when an object of greater diameter than that of the bony orbital rim

strikes the globe of the eye and surrounding soft tissue (Figure 40-6). This impact pushes the globe into the orbit and in turn compresses the orbital contents. The sudden increase in intraocular pressure is transmitted to the orbital floor. The orbital floor is the weakest part of the orbital structure. If the orbital floor fractures, the orbital contents may be forced into the maxillary sinus, where soft tissue and extraocular muscles may be trapped in the defect. Signs and symptoms of blowout fractures include periorbital edema, subconjunctival ecchymosis, diplopia (double vision), enophthalmos (recessed globe), epistaxis, anesthesia in the region of the infraorbital nerve (anterior cheek), and impaired extraocular movements.

FIGURE 40-5 Fracture of the zygomatic bone. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

CRITICAL THINKING
How do you assess a patient's eye movement?

Orbital fractures often are associated with other fractures, including the Le Fort II and III injuries and those of the zygomatic complex. In addition, injury to the orbital contents is common. The paramedic should suspect such injury with any facial fracture.

FRACTURES OF THE NOSE

Of all the facial bones the nasal bones have the least structural strength. They are fractured most frequently. The external portion of the nose, formed mostly of hyaline cartilage, is supported mainly by the nasal bones and the frontal processes of the maxillary bones. Injuries to the nose may depress the dorsum of the nose, displace it to one side, or result only in epistaxis and swelling without apparent skeletal deformity. Fractures to the orbit also may be present. In children, minimal displacement of nasal bones can result in growth changes and ultimate deformity.

Management of Facial Fractures

When caring for a patient with facial fractures, the paramedic should assume that the spine has been injured and should use spinal precautions. Facial fractures are associated with a high percentage of related cervical spine

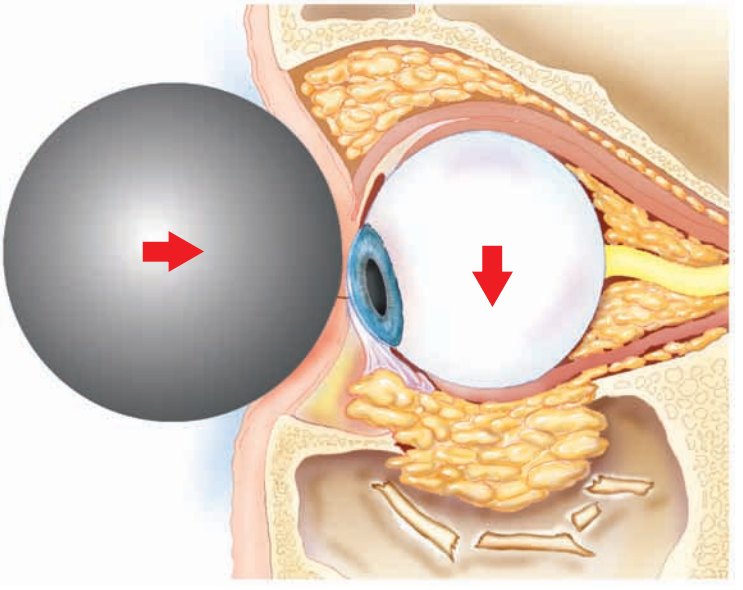

FIGURE 40-6 Artist's impression of a blowout fracture caused by the impact of a ball. (From Ragge N: *Immediate eye care,* London, 1990, Wolfe Medical Publications, Ltd.)

fractures.[1] The paramedic should assess the patient's airway for obstruction caused by blood, vomitus, bone fragments, broken teeth, dentures, and damage to the anterior neck. Suction may be needed to clear the airway of debris and fluid. The paramedic may need to maintain the airway with a nasal (in the absence of suspected midface or basal skull fracture) or oral adjunct, tracheal intubation, or cricothyrotomy if indicated.

Bleeding usually can be controlled by direct pressure and pressure bandages. Epistaxis may be severe and should be controlled by applying external pressure to the anterior nares. To prevent blood from draining down the throat, mild epistaxis is best controlled in the conscious patient by instructing the patient to sit upright or to lean forward (in the absence of spinal injury) while compressing the nares. An unconscious patient should be positioned on the side (if not contraindicated by injury). If bleeding is severe, the paramedic should evaluate the patient for hemorrhagic shock.

CRITICAL THINKING
Why should the blood not drain posteriorly?

EAR, EYE, AND DENTAL TRAUMA

The ears, eyes, or teeth may be injured separately or along with other forms of head and facial trauma. Injury to these regions may be minor. Yet such injuries may result in permanent sensory function loss and disfigurement. Regardless of the severity, the paramedic should evaluate ear, eye, and dental trauma and treat it only after identifying and managing life-threatening problems.

Ear Trauma

Trauma to the ear may include lacerations and contusions, thermal injuries, chemical injuries, traumatic perforations, and barotitis.

LACERATIONS AND CONTUSIONS

Lacerations and contusions usually result from blunt trauma. They are particularly common in victims of domestic violence (Figure 40-7). These injuries are treated by using direct pressure to control bleeding. In addition, the application of ice or cold compresses decreases soft tissue swelling. If a portion of the outer ear (pinna) has been avulsed, the paramedic should retrieve the avulsed tissue if possible. The tissue should be wrapped in moist gauze, sealed in plastic, placed on ice, and transported with the patient for surgical repair. Cartilage tears often heal poorly and are easily infected.

THERMAL INJURIES

Thermal injuries may occur from prolonged exposure to extreme cold. They also may occur from exposure of lesser duration to extreme heat. Contact with hot liquids or electrical currents also can lead to thermal injury. Prehospital treatment usually is limited to application of dressings to prevent contamination and transportation for evaluation by a physician. (Thermal injuries are discussed in Chapter 39 and Chapter 45.)

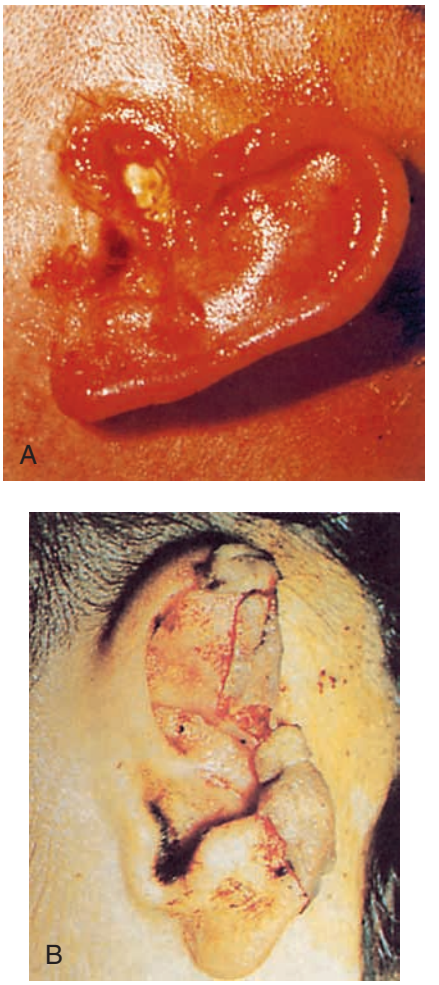

FIGURE 40-7 **A,** Partially detached pinna. **B,** Loss of rim. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

CHEMICAL INJURIES

As described in Chapter 39: Burns, strong acids or alkalis produce burns on contact. Emergency care consists of copious irrigation. After irrigation, the paramedic should bathe the ear and ear canal with saline or sterile water, allowing the irrigation liquid to remain in the ear canal for 2 to 3 minutes. This procedure should be repeated 3 or 4 times, after which the ear should be dried and covered to prevent contamination. The patient should be transported for evaluation by a physician.

TRAUMATIC PERFORATIONS

The tympanic membrane can be perforated. **Traumatic perforation** can occur by objects such as a cotton-tipped applicator and by changes in pressure. Pressure injuries

may result from explosions (blast injuries) or scuba diving (barotrauma). These injuries usually heal spontaneously without treatment. Still, evaluation by a physician is advised.

If the injury is caused by a penetrating object, the paramedic should stabilize the object in place and cover the ear to prevent further contamination. The inner or middle ear canal may have been contaminated (e.g., by swimming water or a foreign object). In that case, antibiotic therapy usually is prescribed. Serious complications that may result from perforations include facial nerve palsy (described in Chapter 23) frequently accompanied by temporal bone fractures, hearing loss, and vertigo.

BAROTITIS

Barotitis occurs when a person is exposed to changes in barometric pressure great enough to produce inflammation and injury to the middle ear. Barotitis can result, for example, from flying at high altitudes and from scuba diving.

Gas pressure in the air-filled spaces of the middle ear normally equals that of the environment. Boyle's law (further described in Chapter 45) states that at constant temperature, the volume of a gas is inversely proportional to the pressure. On ascent, gas expands. On descent, it contracts. Therefore when gases become trapped or partially trapped, they expand in direct proportion to the decrease in pressure. When trapped gas cannot reach equilibrium with environmental pressure, pain and the sensation of a blocked ear may develop. To equalize the pressure in the middle ear, the patient can be directed to bear down (Valsalva's maneuver), yawn, swallow, and move the lower jaw. These methods may cause the eustachian tube to open, which will equalize the pressure in the middle ear cavity.

Eye Trauma

More than 2000 eye and orbital injuries are estimated to occur each day in the United States.[2] Common causes of eye injury are blunt and penetrating trauma from motor vehicle crashes, sport and recreational activities, and violent altercations; chemical exposure from household and industrial accidents; foreign bodies; and animal bites and scratches.

EVALUATION

Acute eye injuries may be difficult to identify because a patient with normal vision may have a serious underlying injury. Symptoms requiring a high degree of suspicion include the following:

- Obvious trauma with eye injury
- Visual loss or blurred vision that does not improve with blinking, indicating possible damage to the globe, ocular contents, or optic nerve
- Loss of a portion of the visual field, indicating possible detachment of the retina, hemorrhage into the eye, or optic nerve injury

Evaluation of eye injury should include a thorough history and measurement of visual acuity, pupillary reaction, and extraocular movements (see Chapter 20: Secondary Assessment). Assessing the patient's vision will be a rough estimation at best. The patient's vision will be reevaluated in the emergency department under controlled circumstances.

CRITICAL THINKING

Aside from trauma, what are some other causes of visual disturbances?

History. A thorough history should include the following information:

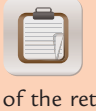
- Exact mode of injury
- Previous ocular, medical, and drug history, including cataracts, glaucoma, and presence of hepatitis or human immunodeficiency virus
- Use of eye medications
- Use of corrective glasses or contact lenses
- Presence of ocular prostheses
- Duration of symptoms and treatment interventions that may have been attempted before emergency medical services arrival

Visual Acuity. The measurement of **visual acuity** is usually the first step in any examination of the patient's eyes. (The exception is a chemical burn to the eye. In this case, irrigation should be performed before measurement of visual acuity.) Visual acuity can be measured with a handheld visual acuity chart (e.g., Snellen chart), or any printed material with small, medium, and large point sizes (e.g., an intravenous fluid bag). The paramedic should record the distance that the printed item was held from the patient's face.

The vision of each eye should be assessed separately while covering the other eye. (No pressure should be applied.) The paramedic should test the injured eye first for acuity comparison to the uninjured eye. If the patient wears corrective lenses, acuity should be measured with lenses first and then without lenses. Illiterate or non–English-speaking patients require an alternative method of evaluation. Such methods may include finger counting, hand motion, and presence or absence of light perception. Abnormal responses to any of these methods indicate significant loss of vision.

CRITICAL THINKING

The assessment of visual acuity may be difficult on some calls. What factors in the prehospital setting may make it difficult?



NOTE

The two types of vision are central and peripheral. **Central vision** results from images falling on the macula of the retina. **Peripheral vision** is the ability to see objects that reflect light waves on areas of the retina other than the macula.

PUPILLARY REACTION

Pupils should be black, round, and equal in size. The pupils also should react to light in the same way and at the same time. Both eyes should constrict in response to light and dilate in response to dark. (A *direct response to light* refers to constriction of the illuminated pupil. A *consensual response to light* refers to constriction of the opposite pupil.) Abnormal pupillary responses after blunt trauma to the eye are common and may be caused by tearing. More commonly, though, they are caused by direct trauma to the pupillary sphincter muscle. Abnormal responses also may suggest a more serious injury involving the optic nerve or globe. As described in Chapter 20, causes of pupil abnormalities in the absence of recent injury include drug use, cataracts, previous surgical procedures, ocular prosthesis, anisocoria (normal or congenital unequal pupil size), central nervous system disease, strokes, and previous injury. The paramedic should document all of the patient's pupil abnormalities.

DID YOU KNOW?

When the eyes are open, the central nervous system is exposed. This happens nowhere else in the human body. Because of this vulnerability, the brain is well wired to provide protection. A sudden movement near the face, a flash of bright light, or a loud noise will cause the eyelids to slam shut, forming a waterproof, airtight shield. Strong tarsal plates shield support and protect the eyelids. Eyelashes are rooted in nerve cells so sensitive that a particle of grit caught by one lash will close the both eyelids automatically.

EXTRAOCULAR MOVEMENTS

Extraocular muscles are responsible for movements of the globe, or eyeball. Voluntary muscles are innervated by cranial nerves III, IV, and VI. The muscles are attached to the outside of the eyeball and bones of the orbit and move the globe in any desired direction. Involuntary eye muscles are innervated by sympathetic nerves. These muscles are located within the eye. Examples of involuntary eye muscles are the iris and the ciliary muscle. These muscles dilate and constrict the pupil and change the shape of the lens, respectively.

To evaluate the extraocular movement of the eyes (described in Chapter 20), the paramedic should instruct the patient to visually track the movement of an object. (For example, the object may be a finger, pencil, or penlight.) The patient should be asked to track the object up, down, to the right, and to the left. Abnormalities in movement may indicate orbital content edema, cranial nerve injury, contusions or lacerations of extraocular muscles, or muscle entrapment in a fracture. Patients with limited or abnormal extraocular movements often complain of double vision in one or more directions of gaze. The paramedic should document all findings.

EVALUATION AND MANAGEMENT OF SPECIFIC EYE INJURIES

Few eye injuries are truly urgent. However, all victims of ocular trauma should be evaluated by a physician. Some patients need specialized care by an ophthalmologist. If the paramedic suspects a serious injury that may require specialized care, medical direction should be advised as soon as possible. That way, services will be ready when the patient arrives in the emergency department (Figure 40-8).

Foreign bodies in the cornea, conjunctiva, or eyelid usually cause the patient to complain of the sensation of something in the eye (especially when opening and closing the eyelids) and to have profuse tearing. If a foreign body is suspected, the inner surface of the upper and lower lids and conjunctivae should be inspected. The paramedic should remove the foreign body by gentle, copious irrigation with clear fluid. (For example, tap water, normal saline, or sterile water are appropriate.) Medical direction may recommend that an ophthalmic anesthetic such as ***tetracaine*** be applied for patient comfort. The paramedic should advise and remind the patient not to touch or rub the eye after the administration of ***tetracaine.*** Serious eye injury can result.

Corneal abrasion occurs when the outer layers of the cornea are avulsed. The injury often results from a foreign body scratching the cornea and is common in those who wear some types of contact lenses. Patients with a corneal abrasion usually complain of pain and foreign body sensation under the upper eyelid, **photophobia** (abnormal light sensitivity), excessive tearing, and sometimes a decrease in visual acuity. Often these signs and symptoms are delayed. The prehospital management of corneal abrasion is gentle irrigation with clear fluid. Management also involves the application of a double patch to eyes to prevent the injured eye from moving when the uninjured eye moves, causing aggravation (Figure 40-9). Corneal abrasions generally heal within 24 to 48 hours.

CRITICAL THINKING

Will the patient with a suspected corneal abrasion need to be evaluated by a physician?

Blunt trauma to the eye or its adjacent structures may result in a contusion injury, **traumatic hyphema** (bleeding into the anterior chamber), or globe or scleral rupture. Box 40-1 lists the signs and symptoms of these injuries.

Blunt injury to the eye may be associated with other serious injuries. Such injuries include orbital fracture, vitreous hemorrhage, and dislocation of the lens. The prehospital care should be limited to the control of any bleeding by application of gentle, direct pressure; protection of the eye with a metal shield or cardboard cup; and rapid transport for physician evaluation. If the paramedic suspects a traumatic hyphema or globe or scleral rupture, the paramedic should place the patient on a spine board and elevate the

FIGURE 40-8 **A,** Avulsion of lid. **B,** Hyphema. **C,** Ruptured globe. **D,** Acid burn. **E,** Alkali burn. (From Ragge N: *Immediate eye care,* London, 1990, Wolfe Medical Publications, Ltd.)

head of the spine board 40 degrees to decrease intraocular pressure. The patient should also be instructed to avoid any activity that might increase intraocular pressure. Analgesics and antiemetics may be indicated for pain relief and nausea. These drugs can reduce movement, straining, coughing, and retching that may increase intraocular pressure.

Penetrating injury to the eye may be associated with embedded foreign bodies, lid avulsions, and lacerations to the lids, sclera, or cornea. Penetrating globe injuries can damage retinal structures and can cause a loss of **vitreous humor** (the jellylike fluid in the eye that fills the space between the lens and the retina) and subsequent blindness. The paramedic should control any bleeding by applying gentle, direct pressure. The globe should be protected from dehydration or contamination from foreign material. One way is to cover the orbital area with plastic or damp, sterile dressings and an eye shield.

NOTE

Eye drops should not be used when globe rupture is suspected. Aggressive pain management is crucial to prevent or decrease expulsion of intraocular contents. If the patient is nauseated, antiemetics should be given.[3]

The paramedic should stabilize foreign bodies protruding from the eye and should cover these with a cardboard cup and secure the cup with tape. The unaffected eye should also be covered to prevent **consensual movement** (one eye acting in concert with the other). The paramedic should not attempt to remove the object. If needed, the penetrating object may be shortened for transport (*after* consulting with medical direction). Oxygen and intravenous fluids also may be recommended in these cases.

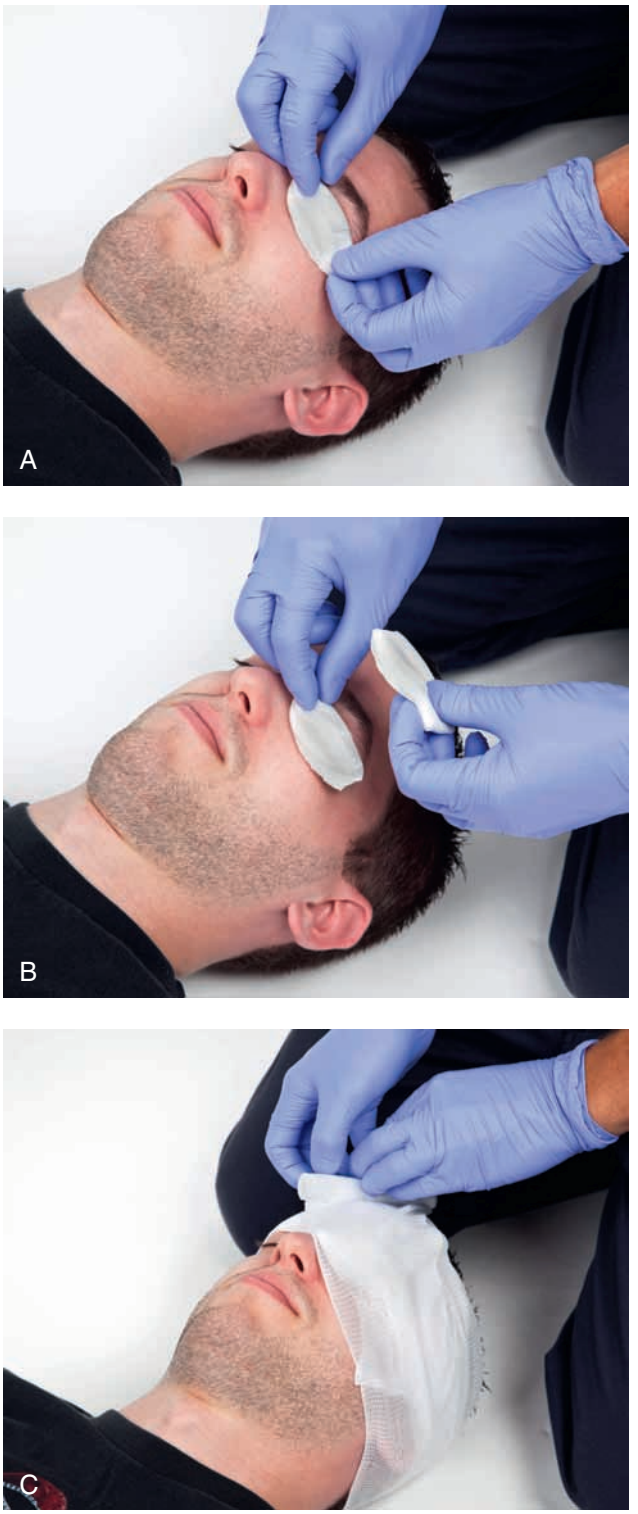


FIGURE 40-9 Application of a double patch. **A,** A folded pad is placed over the closed eye. **B,** A second unfolded pad is placed over the top of the first pad. **C,** The pads are secured firmly in place.

BOX 40-1 Signs and Symptoms of Eye Injuries

Contusion Injury

- Traumatic dilation or constriction of the pupil
- Pain
- Photophobia
- Blurred vision
- Tears of the iris (tear-shaped pupil)

Traumatic Hyphema

- Traumatic dilation or, less commonly, constriction of the pupil
- Decrease in visual acuity
- Blood in the anterior chamber (may be visible with penlight)

Globe or Scleral Rupture

- Decrease in visual acuity to hand movements or light perception
- Lowered intraocular pressure (soft eye)
- Pupil irregularity
- Hyphema

Chemical injury to the eye (described in Chapter 39) may be associated with loss of corneal epithelial tissue, globe perforation, and scarring and deformation of eyelids and conjunctivae. These injuries are true emergencies. They require immediate intervention. A chemical exposure generally mandates extensive, continuous irrigation of both eyes with a neutral fluid for 20 minutes before patient transport (if effective irrigation can be performed) and while en route to the emergency department.

LOOK AGAIN
See Chapter 39: Burns, pp. 1136-1137.

CRITICAL THINKING
Should you wait until contacting medical direction before you begin irrigation of the eye?

CONTACT LENSES

Contact lenses are of three general types: hard, soft hydrophilic, and rigid gas-permeable. Hard lenses are microlenses that sometimes are prescribed for **astigmatism** (these lenses rarely are used today). Soft (hydrophilic) lenses usually are large in diameter (extending onto the conjunctiva). Soft lenses may be designed for daily or extended wear. Rigid gas-permeable lenses are similar in size to microlenses. These lenses have a low water content and high oxygen permeability.

As a rule, paramedics should not attempt to remove contact lenses in patients with eye injuries. To do so may cause more damage and may aggravate the injury. If management of an eye injury is complicated by the presence of contact lenses (e.g., chemical burns to the eyes), medical direction may recommend that the lenses be removed. If the patient is unable to remove the lenses, the paramedic may be instructed to do so (Box 40-2).

Dental Trauma

The adult normally has 32 teeth. Each tooth consists of two sections: the *crown,* which projects above the *gingiva* (the portion of the oral mucosa surrounding the tooth), and the *root,* which fits into the bony socket (alveolus) of the maxilla or mandible. Three layers make up the hard tissues of the teeth: the *enamel,* the *dentin* (ivory), and the *cementum*. The soft tissues of the teeth include the *pulp* and the *periodontal membrane* (Figure 40-10).

The teeth and associated alveolar process may be injured alone or along with fractures of the jaw or facial bones. The two most common types of dental trauma involve fractures and avulsions of the anterior teeth. If a tooth is fractured, the paramedic should examine the oral cavity carefully for tooth fragments. Removal of fragments reduces the risk of aspiration and obstruction of the airway. Lacerations and avulsions to the tongue and surrounding mucous membranes often occur with dental trauma. These injuries often are painful and may bleed profusely. They may compromise the patient's airway as well.

BOX 40-2 Removal of Contact Lenses

Removal of Hard and Rigid Gas-Permeable Lenses

1. With gloved hands, separate the eyelids so that the margins of the lids are beyond the top and bottom edges of the lens.
2. Gently pass the eyelids down and forward to the edges of the lens.
3. Move the eyelids toward each other, forcing the lens to slide out between them.
4. Store the lens in a container with water or saline, and label the container with the patient's name. If a contact lens container is not available, store each lens in a separate container and label as left or right.
5. If lens removal is difficult, gently move the lens downward from the cornea to the conjunctiva overlying the sclera until arrival in the emergency department.

NOTE: Special suction cups are also available for the removal of hard and rigid contact lenses. This device should be moistened with saline or sterile water before contacting the lens.

Removal of Soft Lenses

1. With gloved hands, pull down the lower eyelid.
2. Gently slide the soft lens down onto the conjunctiva.
3. Using a pinching motion, compress the lens between the thumb and index finger.
4. Remove the lens from the eye.
5. Store the lens in a container (marked right or left) with water or saline, and label the container with the patient's name.

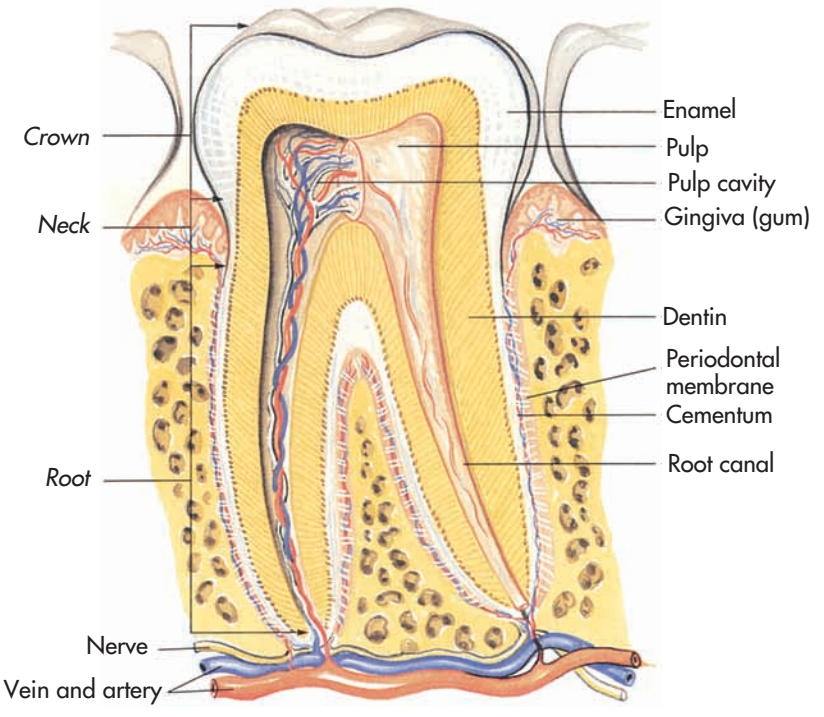

FIGURE 40-10 Longitudinal section of a tooth. (From Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

Tooth avulsions are common, and many teeth can be saved with proper emergency treatment.[4] Permanent teeth that have been avulsed have a good survival rate if reimplanted and stabilized within 1 hour. (Deciduous teeth [milk or baby teeth] generally are not reimplanted. They may become fused to the bone, delaying formation and eruption of the permanent tooth.) If the avulsed tooth has been out of the patient's mouth for less than 15 minutes, medical direction may recommend reimplanting the tooth into the original socket. The paramedic should take care not to reimplant the tooth backward and also should be alert for possible aspiration. If reimplantation is impossible, the paramedic should follow the guidelines established by the American Dental Association and the American Association of Endodontists:

1. Never place an avulsed tooth in anything that can dry or crush the outside of the tooth.
2. Do not handle the tooth roughly. Do not rinse it off or rub, scrape, or disinfect the outside of the tooth in any way. (Any adherent membrane or fibrous tissue should be left in place to avoid stripping off the periodontal membrane and ligament, which are critical to the survival of a reimplanted tooth.)
3. Place the tooth in a nurturing, break-resistant storage device (e.g., Emergency Tooth Preserving System). This device should have a tightly fitted top and soft inner walls.
4. Store the tooth in a pH-balanced, isotonic, glucose-, calcium-, and magnesium-enriched cell-preserving fluid (e.g., Hank's solution). Use refrigerated fresh whole milk as the best alternative storage medium. (Powdered milk is not suitable.) For short periods (1 hour or less), use sterile saline. Do not use tap water because it damages the periodontal ligament.
5. Advise medical direction of avulsed teeth so that appropriate services will be available when the patient arrives in the emergency department.

ANTERIOR NECK TRAUMA

Anterior neck injuries are caused by blunt and penetrating trauma (Figure 40-11). These injuries may result in damage to the skeletal structures, vascular structures, nerves, muscles, and glands of the neck. Common mechanisms of injury to the anterior neck are as follows:

- Strangulation injuries from clothing, jewelry, or personal equipment getting caught in machinery
- All-terrain vehicles and other small motor vehicles (clothesline injuries to the neck from running into wires, ropes, or fences)
- Blows to the neck
- Contact sports (boxing, karate, basketball, football, hockey)
- Hangings
- Horseback riding
- Hyperextension and hyperflexion injuries
- Industrial injuries

FIGURE 40-11 A self-inflicted stab wound that had entered the pharynx. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

- Missile injury from firearms
- Motor vehicle crashes
- Neck striking dashboard or steering column
- Snow skiing
- Sport and recreational activities
- Stab wounds (knives, screwdrivers, ice picks)
- Violent altercations
- Water sports (jet skiing, water skiing)

With blunt and penetrating neck injuries, the paramedic should assume the patient has a cervical spine injury also. The paramedic must assume such injury until ruled out by clinical examination and x-ray films (radiography) of the cervical region of the neck. Radiographic examination alone does not rule out cervical spine injury (see Chapter 41).

Evaluation

For purposes of evaluating the trauma patient, the neck can be divided into three zones defined by horizontal planes (Figure 40-12).[5] Zone I represents the base of the neck. This zone extends from the sternal notch to the top of the clavicles or the cricoid cartilage. Injuries to this zone have the highest mortality rate because of the risk of injury to major vascular and thoracic structures (subclavian vessels and jugular veins, lungs, esophagus, trachea, cervical spine, cervical nerve roots).

Zone II extends from the clavicles or cricoid cartilage cephalad to the angle of the mandible. The carotid artery, jugular vein, trachea, larynx, esophagus, and cervical spine are the vital structures in this zone. Because of the relative size of zone II, injuries to this zone are the most common. However, they have a lower mortality rate than zone I injuries.

Zone III is the part of the neck above the angle of the mandible. The risk of injury to the distal carotid artery, salivary glands, and pharynx is greatest in this zone.

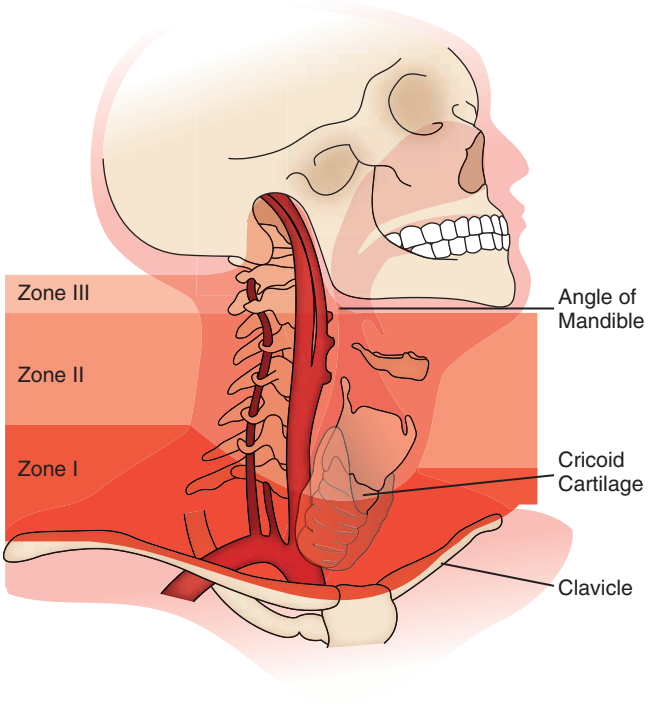

FIGURE 40-12 Zones of the neck. The junction of zone I and zone II is described variously as the cricoid cartilage or top of the clavicles.

Soft Tissue Injuries

Soft tissue injuries to the neck from blunt trauma often produce hematomata and associated edema or direct laryngeal or tracheal injury. Both of these injuries can result in airway compromise. Penetrating trauma may produce lacerations and puncture wounds with resultant vascular, laryngotracheal, or esophageal injury. Blunt trauma may cause vascular injuries as well. However, this is uncommon. As with all trauma victims, initial evaluation and resuscitation must begin with rapid assessment, control of the airway, and consideration for spinal injury.

CRITICAL THINKING
Is prehospital airway control always possible in patients with anterior neck injuries?

HEMATOMATA AND EDEMA

Edema of the pharynx, larynx, trachea, epiglottis, and vocal cords may produce enough pressure in the neck tissues to obstruct the airway completely. If the airway is compromised (evidenced by dyspnea, inspiratory stridor, cyanosis, or changes in voice quality), the paramedic should consider oral or nasal intubation with spinal precautions. Intubation stabilizes damaged areas of the neck, protects the airway, and provides a means for ventilatory support. (A slightly smaller endotracheal tube may be needed to ensure passage through the airway.)

NOTE
Crushed or severed airways can be blocked totally or partially by attempts at oral or nasal intubation. In these cases (if the patient is moving air), rapid transport with high-concentration oxygen is perhaps the most prudent course.

When direct intubation is impossible because of blood, vomitus (that cannot be removed by suction), or progressive edema, a cricothyrotomy or translaryngeal cannula ventilation (described in Chapter 15) may be indicated. Another measure that may help in treating edematous airways includes the administration of cool, humidified oxygen. Yet another measure is the slight elevation of the patient's head. (This can be done if it is not contraindicated by the injury.)

LACERATIONS AND PUNCTURE WOUNDS

Lacerations and puncture wounds may be superficial or deep. Superficial wounds usually can be managed by covering the wound. The covering helps to prevent further contamination. Deep wounds are associated with more serious injuries to underlying structures. These injuries may require aggressive airway therapy and ventilatory support, suction, hemorrhage control by direct pressure, and fluid replacement. Signs and symptoms of significant penetrating neck trauma include the following:

- Active bleeding
- Dysphagia
- Dyspnea
- Hematemesis
- Hemoptysis
- Hoarseness
- Large or expanding hematoma
- Mobility and crepitus
- Neurological deficit (stroke, brachial plexus injury, spinal cord injury)
- Pulse deficit
- Shock
- Stridor
- Subcutaneous emphysema
- Tenderness to palpation

CRITICAL THINKING
Why is rapid transport crucial when caring for a patient who has anterior neck injuries?

VASCULAR INJURY

Blood vessels are the most commonly injured structures in the neck; they may be injured by blunt or penetrating trauma. Vessels at risk of injury include the carotid,

vertebral, subclavian, innominate, and internal mammary arteries and the jugular and subclavian veins. Laceration of these major vessels can result in rapid exsanguination (death from extensive blood loss) if bleeding is not controlled.

Securing the airway (with spinal precautions) and providing adequate ventilatory support is the first priority. The next priority is to control hemorrhage. This can be achieved with constant, direct pressure. The paramedic should apply pressure only to the affected vessels. Thus blood flow to the brain will not be obstructed completely. If bleeding cannot be controlled in this manner, medical direction may advise applying direct pressure with a gloved finger to the vessel.

NOTE
Under no circumstances should cervical vessels be clamped with hemostats in the prehospital setting. Doing so may traumatize critical vascular structures and may produce permanent nerve injury.

If the paramedic suspects a venous injury, the patient should be kept supine or in a slight Trendelenburg position. This will help to prevent air embolism (a rare but lethal complication). If the paramedic suspects an air embolism (described in Chapter 14), the paramedic should turn the immobilized patient on the left side. The patient's head should be lower than the feet in an attempt to trap the air embolus in the right ventricle. Venous neck wounds should be dressed with an occlusive dressing.

Fluid replacement for hypovolemia should be guided by medical direction. Fluid replacement may include using large-bore catheters and isotonic crystalloid (lactated Ringer's solution or normal saline). If penetrating injury to the base of the neck (zone I) has occurred, upper extremity venous drainage may be compromised by the laceration. In this event, placement of at least one intravenous line in a lower extremity should be considered. Medical direction may advise that a second intravenous line be placed in the upper extremity on the side opposite the injury.

CRITICAL THINKING
Why might application of a pneumatic antishock garment be harmful with this type of injury?

LARYNGEAL OR TRACHEAL INJURY

Injury from blunt or penetrating trauma to the anterior neck may cause fracture or dislocation of the laryngeal and tracheal cartilages, hemorrhage, or swelling of the air passages. All of these injuries can compromise the airway and cause respiratory distress. Airway injury can lead to death in head and neck trauma patients. Thus rapid and judicious control of the airway and prevention of aspiration are crucial. In addition, a high degree of suspicion for associated vascular disruption and esophageal, chest, and intraabdominal injury is a critical aspect of preventing death. Injuries that may be associated with laryngeal and tracheal trauma include the following:

- Fracture of the hyoid bone resulting in laceration and distortion of the epiglottis
- Separation of the hyoid and thyroid cartilages resulting in epiglottis dislocation, aspiration, and subcutaneous emphysema
- Fractures of the thyroid cartilage resulting in epiglottis and vocal cord avulsion, arytenoid dislocation, and aspiration of blood and bone fragments
- Dislocation or fracture of the cricothyroid resulting in long-term laryngeal stenosis, laryngeal nerve paralysis, and laryngotracheal avulsion
- Fracture to the trachea resulting in tracheal avulsion, complete airway obstruction, and subcutaneous emphysema

The management of laryngeal and tracheal trauma is controversial. Some medical direction agencies recommend oral or nasal intubation. Other agencies believe that intubation attempts may contribute to the potential for injury resulting from lack of oxygen during the procedure. These attempts also may damage the airway structures further. Alternative methods of airway management include use of bag-mask ventilation, cricothyrotomy, and translaryngeal cannula ventilation.

NOTE
Airway procedures that involve entry through the neck generally are avoided in the field because of the associated risks. As a rule, these patients should be well ventilated with a bag-mask device. They should be transported rapidly to the receiving facility for surgical tracheotomy as well. As described in Chapter 15, translaryngeal cannula ventilation is hazardous in the presence of complete airway obstruction. Incorrectly used, this technique does not provide adequate exhalation of gases and air. The technique may result in carbon dioxide retention and significant injury from high pressure developing in the chest and airways (barotrauma).

If penetrating trauma causes complete disruption of the laryngotracheal structure, medical direction may recommend dissection through the wound. That way, the exposed distal trachea can be cannulated directly with a cuffed endotracheal tube. Regardless of the method chosen, emergency care is directed at securing the airway with spinal precautions, providing adequate ventilatory support, controlling hemorrhage, treating for shock, and providing rapid transport to an appropriate medical facility for definitive surgical care.

ESOPHAGEAL INJURY

Esophageal injuries should be suspected in patients with trauma to the neck or chest. Specific injuries that require a high degree of suspicion for associated esophageal injury include tracheal fractures, penetrating trauma from stab or gunshot wounds, and ingestion of caustic substances.

Esophageal injury is difficult to diagnose. It may be overlooked as the paramedic focuses on more obvious injuries that pose a threat to life. Signs and symptoms may include subcutaneous emphysema, neck hematoma, and bleeding from the mouth and nose.

Esophageal perforation is associated with a high mortality rate. Death results from mediastinitis caused by the release of gastric contents into the thoracic cavity. If not contraindicated by mechanism of injury, the paramedic should place the patient with a suspected esophageal tear in a semi-Fowler position. (This is an inclined position. The upper half of the body is raised by elevating the head or stretcher about 30 degrees.) This position will help to prevent reflux of gastric contents.

CRITICAL THINKING

Are these signs and symptoms so unique that you will be able to distinguish esophageal injury as the cause, versus other kinds of traumatic conditions?

HEAD TRAUMA

As described in Chapter 10: Review of Human Systems, the anatomical components of the skull are the scalp followed by the cranial vault, under which are the dural membrane, the arachnoid membrane, the pia mater, and brain substance. Injuries to the skull may be classified as soft tissue injuries to the scalp and as skull fractures.

LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 171-176.

NOTE

All patients with head or neck trauma must be assumed to have a spinal injury. This must be the case until injury is ruled out by clinical examination and x-ray films in the emergency department. (Spinal precautions [including helmet removal] are presented in Chapter 41.) This text assumes that spinal precautions will be used for all patients with a significant mechanism of injury.

Soft Tissue Injuries to the Scalp

The most common scalp injury is an irregular linear laceration. Like the face, the scalp is very vascular. Thus scalp lacerations may bleed heavily (Figure 40-13). They also may result in hypovolemia, particularly in infants and children. Other, less frequent scalp injuries include **stellate wounds** (ballistic wounds that are star-shaped), avulsions, and **subgaleal hematomata** (bleeding in the potential space between the skull and scalp).

FIGURE 40-13 Even small wounds from the scalp can bleed profusely. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

Management of soft tissue injuries to the scalp includes efforts to prevent contamination of open wounds, use of direct pressure or pressure dressings to decrease blood loss, and replacement of fluids if needed. The potential for underlying skull fracture and brain and spinal trauma also exists with these injuries. Scalp lacerations that are the only injury rarely produce life-threatening complications. However, such lacerations can result in excessive blood loss. If not contraindicated by injury, the paramedic should position all patients with head or facial trauma on a stretcher or spine board with the head elevated 30 degrees (semi-Fowler position).

Skull Fractures

Skull fractures may be classified as *linear fractures, basilar fractures, depressed fractures,* and *open vault fractures* (Figure 40-14). Complications associated with these injuries are cranial nerve injury, vascular involvement (e.g., meningeal artery and dural sinuses), infection, underlying brain injury, and dural defects caused by depressed bone fragments. As with all injuries to the head, the paramedic should consider the possibility of a spinal injury. Proper spinal precautions should be maintained.

LINEAR FRACTURES

Linear fractures (seen as straight lines on x-ray film) account for 80% of all fractures to the skull.[6] Such fractures usually are not depressed. Often linear fractures occur without an overlying scalp laceration. As an isolated injury, these fractures usually have a low rate of complication. But if the fracture is associated with scalp laceration, infection is possible. Linear fractures that cross the meningeal groove

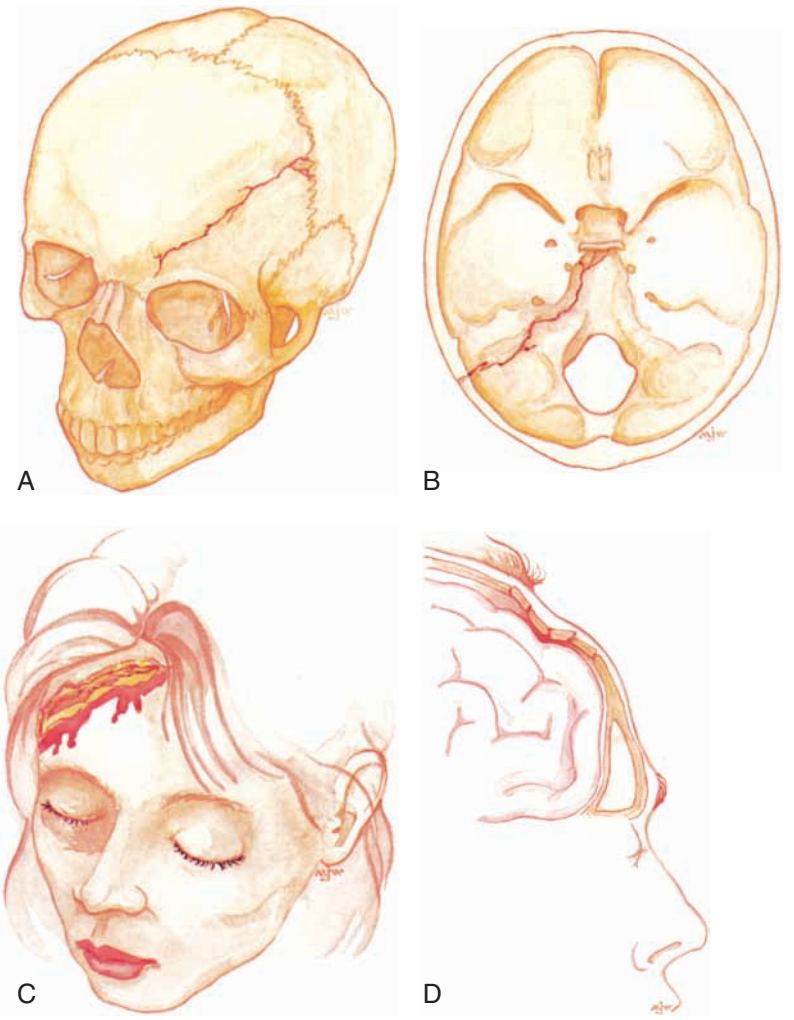

FIGURE 40-14 Skull fractures. **A,** Linear skull fracture. **B,** Basilar skull fracture. **C,** Open vault fracture. **D,** Depressed skull fracture.

in the temporal-parietal area, midline, or occipital area may lead to epidural bleeding from the middle cerebral artery.

CRITICAL THINKING
Will you be able to detect linear skull fractures during a physical examination in the prehospital setting?

BASILAR SKULL FRACTURES

Basilar skull fractures usually are associated with major impact trauma. These injuries may occur when the mandibular condyles perforate into the base of the skull. More commonly, though, they result from an extension of a linear fracture into the floor of the anterior and middle fossae. Basilar skull fractures can be difficult to see on x-ray films. They usually are diagnosed clinically by the following signs and symptoms:

- Ecchymosis over the mastoid process resulting from fracture to the temporal bone **(Battle's sign)** (Figure 40-15, *A*)
- Ecchymosis of one or both orbits caused by fracture of the base of the sphenoid sinus **(raccoon's eyes)** (Figure 40-15, *B*)
- Blood behind the tympanic membrane caused by fractures of the temporal bone (**hemotympanum**)
- Cerebrospinal fluid leakage, which can result in bacterial meningitis

NOTE
Battle's sign and raccoon's eyes usually do not occur until some time after the injury. If they are present on the arrival of emergency medical services, the bruising is most likely the result of a prior injury.

Other complications associated with basilar skull fractures include cranial nerve injuries and massive hemorrhage from vascular involvement of the carotid artery. Treatment for basilar skull fractures includes bed rest, in-hospital observation, and evaluation for hearing loss caused by acoustic nerve injury.

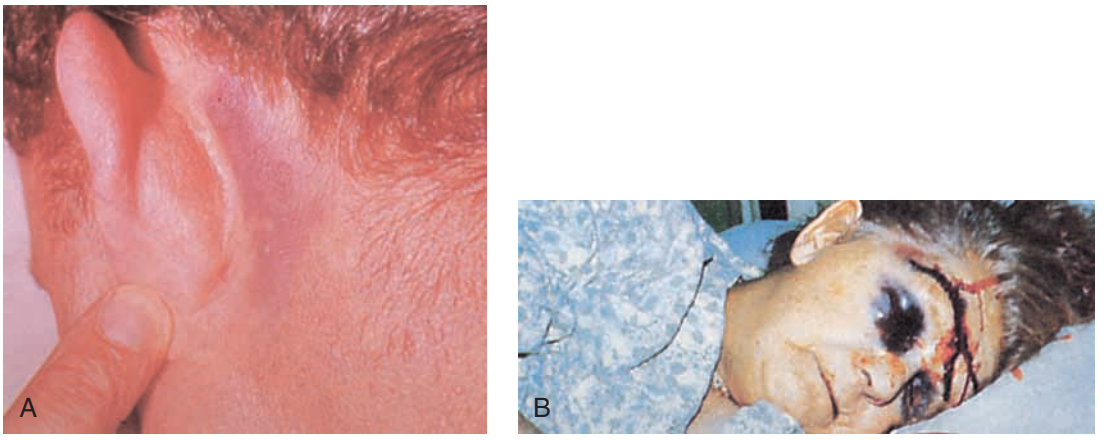

FIGURE 40-15 **A,** Battle's sign. **B,** Raccoon's eyes. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

DEPRESSED SKULL FRACTURES

Depressed skull fractures usually result from a relatively small object striking the head at high speed. Thus they commonly are associated with scalp lacerations (Figure 40-16). The frontal and parietal bones most often are affected by these fractures. Thirty percent of patients with depressed skull fractures are estimated to have associated hematomata and cerebral contusions.[7] If the depression is greater than the thickness of the skull, dural laceration also is likely. Patients with depressed skull fractures often require surgical removal of the bone fragments (craniectomy).

OPEN VAULT FRACTURES

Open vault fractures result when an opening exists between a scalp laceration and brain tissue (Figure 40-17). Because of the nature of these injuries and the force required to produce them, they often are associated with multiple trauma to other systems. They have a high mortality rate. Exposure of brain tissue to the external environment may lead to infection (meningitis). Open vault fractures require surgical repair. Prehospital management usually is limited to spinal immobilization, ventilatory support, efforts to prevent contamination, and rapid transportation to an appropriate medical facility.

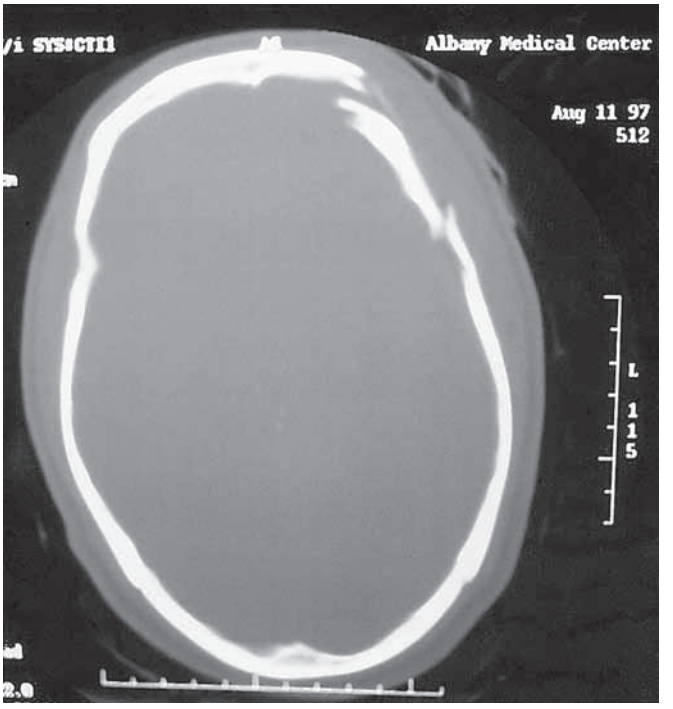

FIGURE 40-16 Head computed tomography scan showing a depressed skull fracture. (From Ferrera PC, Colucciello SA, Marx J, et al: *Trauma management: an emergency medicine approach,* St Louis, 2001, Mosby.)

Cranial Nerve Injuries

As described in Chapter 10, 12 pairs of cranial nerves leave the brain and pass through openings in the skull called *foramina.* Injury to cranial nerves usually is associated with skull fractures. Signs and symptoms of common cranial nerve injuries are as follows:

Cranial nerve I (olfactory nerve)
- Loss of smell
- Impaired taste (dependent on food aroma)
- Hallmark of basilar skull fracture

Cranial nerve II (optic nerve)
- Blindness in one or both eyes
- Visual field defects

Cranial nerve III (oculomotor nerve)
- Ipsilateral (same side), dilated, fixed pupil
- Especially compression by the temporal lobe
- Mimics direct ocular trauma

Cranial nerve VII (facial nerve)
- Immediate or delayed facial paralysis
- Basilar skull fracture

Cranial nerve VIII (auditory nerve)
- Deafness
- Basilar skull fracture

FIGURE 40-17 Severe fracture of the base of the skull. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

TRAUMATIC BRAIN INJURY

A **traumatic brain injury** (TBI) is defined by the Brain Injury Association as "a traumatic insult to the brain capable of producing physical, intellectual, emotional, social, and vocational change"[8] (Box 40-3). Traumatic brain injury can be divided into two categories: **primary brain injury** and **secondary brain injury.** Primary brain injury refers to direct trauma to the brain and to the associated vascular injuries that occurred from the initial injury. Secondary brain injury results from intracellular and extracellular derangements that probably were initiated at the time of the injury. These derangements may include hypoxia, hypocapnia, and hypercapnia from airway compromise, aspiration of gastric contents, and thoracic injury; anemia and hypotension from external and internal hemorrhage; and hyperglycemia or hypoglycemia that can further injure ischemic brain tissue. The adverse effects of secondary brain injury can be minimized. They perhaps can be reversed, if they are recognized and properly managed in the prehospital setting. Brain injuries can be classified as *diffuse* (moderate or severe) or *focal*. (The two forms are commonly found together.[9])

Diffuse injuries (usually caused by acceleration-deceleration forces)
- Diffuse axonal injury (DAI)
- Hypoxic-ischemic damage
- Meningitis
- Vascular injury

Focal injuries (generally caused by contact)
- Scalp injury
- Skull fracture
- Surface contusions
- Brain hemorrhage

BOX 40-3 Brain Injury Facts[10]

According to the Centers for Disease Control and Prevention's National Center for Injury Prevention and Control, the following annual statistics apply in the United States:

- At least 1.4 million people sustain a TBI.
- Approximately 50,000 people die from a TBI.
- Approximately 475,000 TBIs occur among infants, children, and adolescents 14 years and younger.
- About 80,000 to 90,000 people experience the onset of a long-term disability attributable to a TBI.

The following groups are at particular risk for TBI[11]:

- Males are about twice as likely as females to sustain a TBI.
- Infants and children ages 4 years and younger and adolescents ages 15 to 19 years are the two age groups at highest risk for a TBI.
- Adults ages 75 years or older have the highest rates of TBI-related hospitalization and death.

A TBI is caused by an excessive force, blow, or penetrating injury to the head. The leading causes of TBI are as follows:

- Falls (28%)
- Motor vehicle crashes (20%)
- Being struck by or against objects (19%)
- Assaults (11%)

Diffuse Injuries

Diffuse injuries include concussion and diffuse axonal injury. The major cause of damage in diffuse injury is the disruption of axons—the neural processes that allow one nerve to communicate with another.

CONCUSSION

Concussion is sometimes called a *mild diffuse axonal injury*. Concussion is caused by a mild to moderate impact to the skull, movement of the brain within the cranial vault, or

both. Concussion occurs when the function of the brainstem (particularly the reticular activating system) or both cerebral cortices is temporarily disturbed. This results in a brief altered level of consciousness, but not always a loss of consciousness. (If a loss of consciousness occurs, it is usually less than 5 minutes in duration.) A concussion may be a serious injury (*no concussion is minor*). Concussions can be assigned into one of three grades as defined by the American Academy of Neurology (AAN)[12]:

- Grade 1:
  - Transient confusion
  - **No** loss of consciousness
  - Concussion symptoms **clear in less than 15 minutes**
- Grade 2:
  - Transient confusion
  - **No** loss of consciousness
  - Concussion symptoms or mental status abnormalities **last longer than 15 minutes**
- Grade 3:
  - Any loss of consciousness, either brief (seconds) or prolonged (minutes)

NOTE

According to the American Academy of Neurology (AAN), permanent brain injury can occur with either grade 2 or grade 3 concussion. A concussion may have permanent consequences if the acute symptoms of the concussion continue for more than 15 minutes.[12]

The altered level of consciousness or loss of consciousness usually is followed by periods of drowsiness, restlessness, and confusion, with a fairly rapid return to normal behavior. The patient may have no recall of the events before the injury **(retrograde amnesia).** In addition, amnesia may exist after recovery of consciousness **(antegrade amnesia).** This short-term memory loss may produce anxiety. The patient may ask repetitive questions (e.g., "Where am I? What happened?"). Other signs and symptoms of concussion are vomiting; combativeness; transient visual disturbances (e.g., light flashes and wavy lines); defects in equilibrium and coordination; and changes in blood pressure, pulse rate, and respiration (rare). After physician evaluation, treatment usually consists of in-hospital or home observation by a reliable observer for 24 to 48 hours.

CRITICAL THINKING

Consider the patient with a new onset of retrograde or antegrade amnesia. Why should the patient not be considered a reliable historian?

A concussion injury affects the patient most severely at the time of impact but is followed by improvement. Concussion is the most common type of brain injury. *Any patient whose condition worsens over time or whose level of consciousness deteriorates rather than improves must be suspected of having a more serious injury.* Therefore documentation of baseline measurements of level of consciousness, memory status, and neurological function (e.g., Glasgow Coma Scale or AVPU scale) in any victim of head injury is important. If a patient with a concussion has a loss of consciousness more than 5 minutes, the paramedic should suspect a more serious injury caused by contusion or hemorrhage.

MODERATE DIFFUSE AXONAL INJURY

A moderate diffuse injury is a head injury that results in minute petechial bruising of brain tissue. The involvement of the brainstem and reticular activating system leads to unconsciousness. These injuries account for 20% of all severe head injuries and 45% of all cases of diffuse injury.[13] Often these patients will have basilar skull fracture. Most patients will survive the injury, yet permanent neurological impairment is common.

A patient with moderate diffuse injury initially will be unconscious, followed by persistent confusion, disorientation, and amnesia of the event. During recovery, these patients often experience an inability to concentrate, frequent periods of anxiety, uncharacteristic mood swings, and sensorimotor deficits (e.g., an altered sense of smell). Patients with moderate diffuse injury are managed similar to those patients with concussion: frequent reassessments of the level of consciousness and assurance of an adequate airway and tidal volume are necessary. If possible, patients with head injury should be moved to a quiet, calm area. Exposure to bright lights should be avoided. (Patients often are photophobic.) Also, constant reorientation of the patient may be necessary.

SEVERE DIFFUSE AXONAL INJURY

As the name implies, a **severe diffuse axonal injury** is the severest form of brain injury. Severe DAI was once known as a *brainstem injury*. Severe DAI involves severe mechanical shearing of many axons in both cerebral hemispheres extending to the brainstem. Severe DAI occurs in approximately 16% of patients with severe head trauma.[6] These patients often are unconscious for prolonged periods. They may exhibit abnormal posturing and other signs of increased intracranial pressure (ICP), described later in this chapter. The prehospital care for these patients is focused on ensuring an adequate airway and tidal volume. Hypoxia must be prevented in all patients with head injury. (This helps to avoid secondary injury to brain tissue.)

CRITICAL THINKING

Can a patient with a diffuse axonal injury die as a result of that injury?

Focal Injury

Focal injuries are specific, grossly observable brain lesions. Included in this category are lesions that result from skull fracture (previously described), contusion, edema with associated increased ICP, ischemia, and hemorrhage. As described in Chapter 10, the brain occupies 80% of the intracranial space. The brain is divided into four areas: the brainstem (consisting of the medulla, pons, and midbrain), the diencephalon (including the thalamus and hypothalamus), the cerebrum, and the cerebellum. The intracranial contents consist of brain water (58%), brain solids (25%), cerebrospinal fluid (7%), and intracranial blood (10%).

CEREBRAL CONTUSION

A **cerebral contusion** is bruising of the brain in the area of the cortex or deeper within the frontal (most common), temporal, or occipital lobes (Figure 40-18). This bruising produces a structural change in the brain tissue. Bruising results in greater neurological deficits and abnormalities than are seen with concussions. These abnormalities may include seizures, hemiparesis, aphasia, and personality changes. If the brainstem also is contused, the patient may lose consciousness. In some cases, the comatose state may be prolonged. It may last hours to days or longer. Of the patients who die from head injury, the majority have cerebral contusions at autopsy.

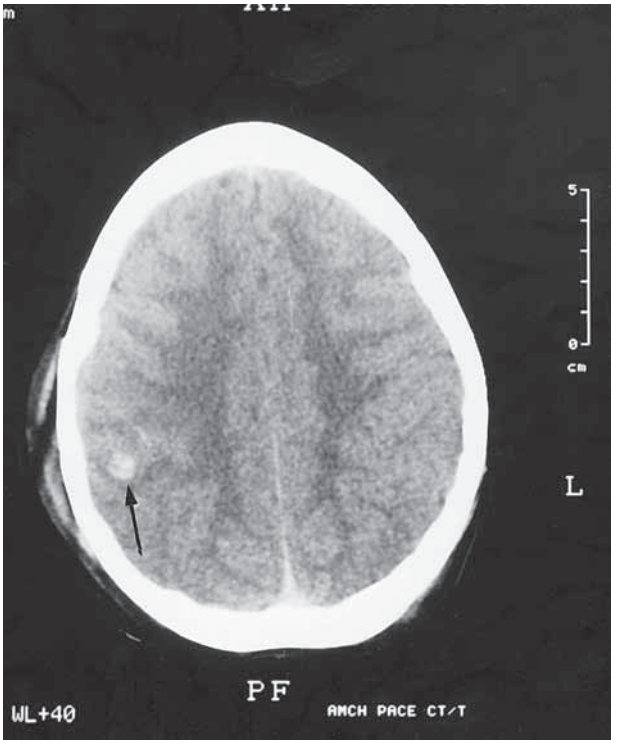

FIGURE 40-18 Head CT scan demonstrating a cerebral contusion (*arrow*). (From Ferrera PC, Colucciello SA, Marx J, et al: *Trauma management: an emergency medicine approach,* St Louis, 2001, Mosby.)

If applied force is enough to cause the brain to be displaced against the irregular surfaces of the skull, tiny blood vessels in the pia mater may rupture. The brain substance may be damaged locally at the site of impact **(coup).** Or the brain may be damaged on the opposite, or contralateral, side **(contrecoup).** Contrecoup injuries often are caused by deceleration of the head. This may occur, for example, in a fall or motor vehicle crash.

As a rule, cerebral contusions usually heal without intervention. As with patients with concussion, these patients usually improve. However, the time to heal and level of improvement differ in these two conditions. The most important complication associated with cerebral contusion is increased ICP manifested by headache, nausea, vomiting, seizures, and a declining level of consciousness. These signs usually are delayed responses to the injury. Therefore they usually are not seen in the prehospital emergency setting.

EDEMA

Major injuries to the brain often result in swelling of the brain tissue with or without associated hemorrhage. The swelling results from humoral and metabolic responses to injury. Swelling leads to considerable increases in ICP. This in turn can lead to decreased cerebral perfusion (described later) or herniation.

ISCHEMIA

Ischemia can result from vascular injuries, secondary vascular spasm, or increased ICP. In any case, focal or more global infarcts can result.

HEMORRHAGE

The same forces that result in concussion and contusion also may cause serious vascular damage. This damage may result in hemorrhage into or around brain tissue. These injuries may cause epidural or subdural hematomata. The hematomata compress the underlying brain tissue, or produce intraparenchymal hemorrhage (bleeding directly into the brain tissue). This bleeding often results from cerebral contusions and skull fractures.

Cerebral Blood Flow. Although the brain accounts for only 2% of adult weight, 20% of total body oxygen use and 25% of total body glucose use are devoted to brain metabolism. Oxygen and glucose delivery are controlled by cerebral blood flow.

As described in Chapter 25, cerebral blood flow is a function of cerebral perfusion pressure (CPP) and resistance of the cerebral vascular bed. Cerebral blood flow is determined by the mean arterial pressure (MAP) (the diastolic pressure plus one third pulse pressure) minus the intracranial pressure (CPP = MAP − ICP). Normal mean arterial pressure ranges from 85 to 95 mm Hg. Intracranial pressure is normally 10 to 15 mm Hg or less. Thus normal CPP is between 70 and 80 mm Hg. (A cerebral perfusion pressure of 60 mm Hg is the critical minimum threshold

to adequately perfuse the brain.) As ICP approaches mean arterial pressure, the gradient for flow decreases and cerebral blood flow decreases. That is, when ICP increases, CPP decreases. As CPP decreases, vessels in the brain dilate (cerebral vasodilation). This results in increased cerebral blood volume (increasing ICP) and further cerebral vasodilation. In most emergency medical services systems, CPP is not calculated because mean arterial pressure and ICP are not measured in the prehospital setting. However, maintaining a systolic blood pressure of at least 90 mm Hg also may help maintain adequate mean arterial pressure.[1,14]

CRITICAL THINKING

What happens to the flow of oxygen to the brain, and carbon dioxide from the brain to the capillaries, when intracranial pressure is increasing and cerebral perfusion pressure is decreasing?

Vascular tone in the normal brain is regulated by carbon dioxide pressure (PCO_2), oxygen pressure (PO_2), and autonomic and neurohumoral control; PCO_2 has the greatest effect on intracerebral vascular diameter and subsequent resistance. For example, if PCO_2 is increased from 40 to 80 mm Hg, cerebral blood flow is doubled. This results in increased brain blood volume and ICP.

Intracranial Pressure. The normal range of ICP is 10 to 15 mm Hg or less. When ICP rises above this level, the body has difficulty maintaining adequate CPP, usually because of an expanding mass or diffuse swelling. Cerebral blood flow is diminished when the CPP is not adequate. As the cranial vault continues to fill (because of brain edema or expanding hematoma), the body tries to compensate for the decline in CPP by an increase in mean arterial pressure (*Cushing reflex*). Yet this increase in cerebral blood flow further elevates the ICP. As pressure continues to increase, cerebrospinal fluid is displaced to make up for the expansion. If unresolved, the brain substance may herniate over the edge of the tentorium. (This is one of three extensions of the dura mater that separates the cerebellum from the occipital lobe of the cerebrum.) Alternatively, it may herniate through the foramen magnum (Figure 40-19).

Early signs and symptoms of increased ICP include headache, nausea and vomiting, and altered level of consciousness (Box 40-4). These signs and symptoms eventually are followed by increased systolic pressure, widened pulse pressure, and decreased pulse rate and irregular respiratory pattern **(Cushing's triad).** As the volume continues to expand in the cranial vault, herniation of the temporal lobe of the brain through the tentorium may occur. The herniation causes compression of cranial nerve III. This produces a dilated pupil and loss of the light reflex on the

BOX 40-4 Levels of Increasing Intracranial Cerebral Pressure

Cortex and Upper Brainstem

- Blood pressure rises; pulse rate slows.
- Pupils remain reactive.
- Cheyne-Stokes respirations may be present.
- Patient initially will try to localize and remove painful stimuli (eventually withdraws and flexion occurs).
- All effects are reversible at this stage.

Middle Brainstem

- Wide pulse pressure and bradycardia are present.
- Pupils become nonreactive or sluggish.
- Central neurogenic hyperventilation develops.
- Abnormal posturing (extension) occurs.
- Few patients function normally with injury at this level.

Lower Portion of Brainstem/Medulla

- Pupil is "blown" (fixed and dilated) on same side of injury.
- Respirations become ataxic.
- Patient will be flaccid.
- Pulse rate is irregular.
- QRS, S-T, and T wave changes will be present.
- Blood pressure will fluctuate.
- These patients generally do not survive.

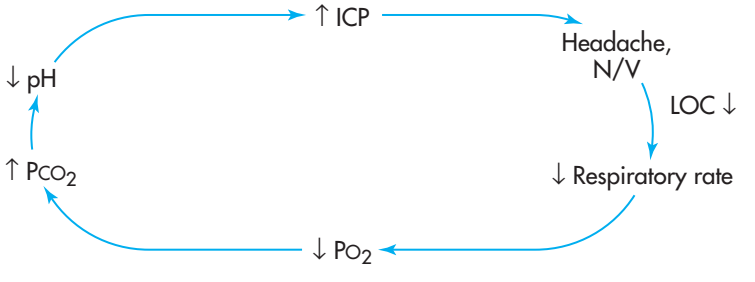

FIGURE 40-19 Effects of increased intracranial pressure.

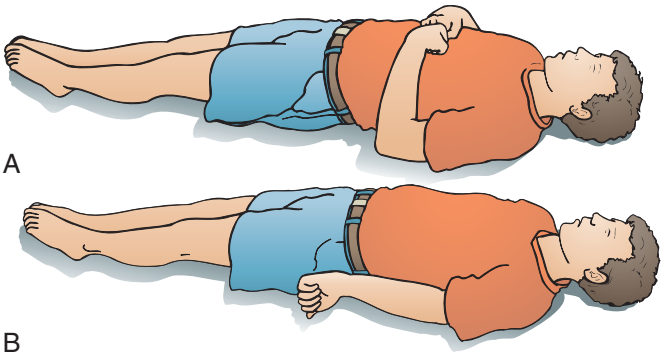

FIGURE 40-20 **A,** Abnormal flexion (decorticate posturing). **B,** Abnormal extension (decerebrate posturing). (Modified from ENA: *Sheehy's emergency nursing,* ed 6, St Louis, 2010, Mosby.)

side of compression. The patient rapidly becomes unresponsive to verbal and painful stimuli. The patient may exhibit the ominous sign of **decorticate posturing**. (This is characterized by extension of the legs and flexion of the arms at the elbows.) Or the patient may exhibit **decerebrate posturing**. (This is characterized by extension of all four extremities [Figure 40-20].)

CRITICAL THINKING
Why is cranial nerve III affected by this shift in brain tissue?

Respiratory Patterns. As ICP continues to rise, abnormal respiratory patterns (described in Chapter 15) may develop. Respiratory abnormalities associated with increased ICP and significant brainstem injury include hypoventilation, *Cheyne-Stokes breathing* (which may accompany decorticate posturing), *central neurogenic hyperventilation* (which may accompany decerebrate posturing), and *ataxic breathing.* The presence of decorticate (flexion) or decerebrate (extension) posturing and abnormal respiratory patterns is not of major clinical importance other than to identify the need for intervention and treatment (intubation and consideration of immediate neurosurgical intervention).

NOTE
Some motion of the limbs, albeit abnormal, is better than no motion of the limbs. (No motion indicates a worse level of neurological function.)

TYPES OF BRAIN HEMORRHAGE

Traditionally, brain hemorrhages are classified according to their location as epidural, subdural, subarachnoid, or cerebral (intraparenchymal) (Figure 40-21).

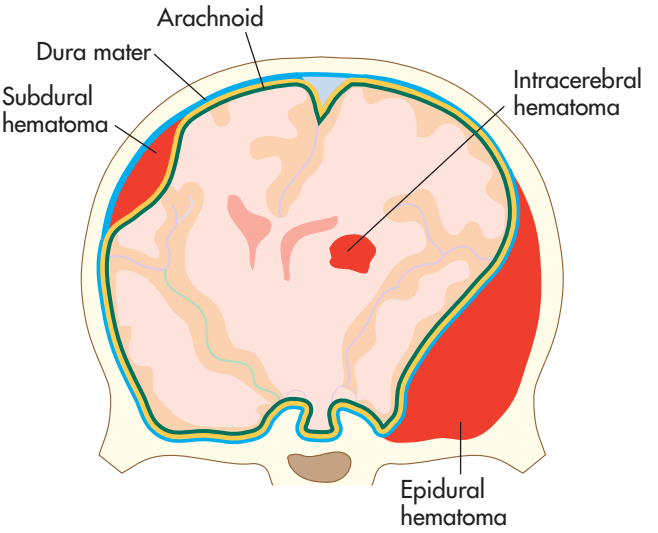

FIGURE 40-21 Varieties of intracranial hemorrhage.

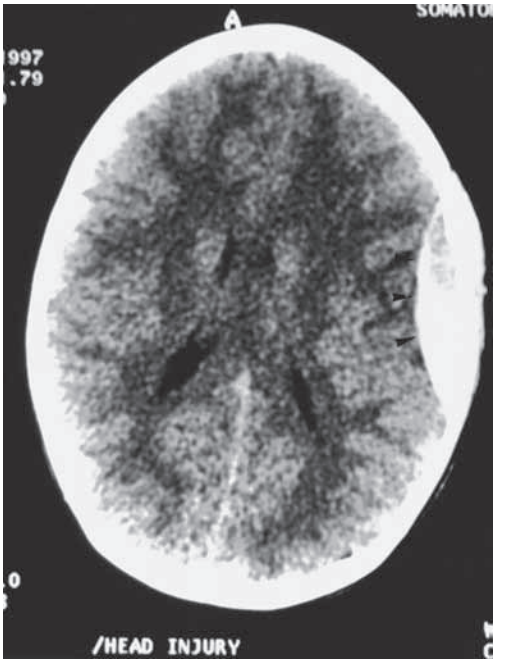

FIGURE 40-22 Head computed tomography scan showing an epidural hematoma. (From Ferrera PC, Colucciello SA, Marx J, et al: *Trauma management: an emergency medicine approach,* St Louis, 2001, Mosby.)

Epidural Hematoma. An **epidural hematoma** (accounting for 0.5% to 1% of all head injuries[1]) is a collection of blood between the cranium and the dura in the epidural space (Figure 40-22). The hematoma usually is a rapidly developing lesion. Usually the hematoma is associated with a laceration or tear of the middle meningeal artery. This hemorrhage often occurs as a result of a linear or depressed skull fracture in the temporal bone. Yet bleeding from

other sites can produce epidural hemorrhage as well. If the source of hemorrhage is mostly venous, deterioration usually is not as rapid because low-pressure vessels bleed more slowly.

Fifty percent of patients with epidural hematoma have a transient loss of consciousness, followed by a lucid interval in which neurological status returns to normal. (The remaining 50% of patients with acute epidural hematoma never recover consciousness.) The lucid interval usually lasts between 6 and 18 hours. During this time the hematoma enlarges. As ICP rises, the patient develops a headache with lethargy, decreasing level of consciousness, and contralateral hemiparesis. In the early stages of an epidural hematoma, the patient may complain only of headache and drowsiness. Definitive treatment includes immediate recognition and rapid transport to a proper facility for surgery. Common causes of epidural hematoma include low-velocity blows to the head, violent altercations, and deceleration injuries. About 20% of these patients who are comatose die.[1]

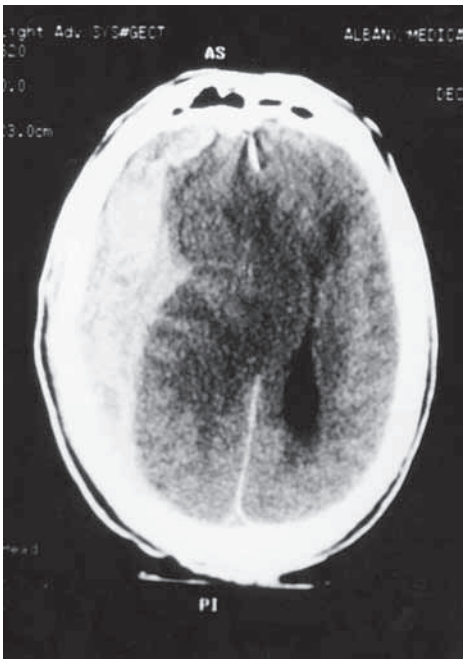

FIGURE 40-23 Head computed tomography scan showing an acute subdural hematoma. (From Ferrera PC, Colucciello SA, Marx J, et al: *Trauma management: an emergency medicine approach,* St Louis, 2001, Mosby.)

CRITICAL THINKING

What could account for delays in surgical treatment, causing subsequent death, in patients who have an epidural hematoma?

Subdural Hematoma. A **subdural hematoma** is a collection of blood between the dura and the surface of the brain in the subdural space (Figure 40-23). This injury usually results from bleeding of the veins that bridge the subdural space. Associated contusion or laceration of the brain often is present. The hematoma often results from blunt head trauma. Commonly the hematoma is associated with skull fracture. Subdural hematomata are classified as *acute, subacute,* and *chronic*. Classification depends on the time lapse between the injury and development of symptoms. As a general rule, if symptoms occur within 24 hours, the hematoma is considered acute; between 2 and 10 days, subacute; and after 2 weeks, chronic.[1] Subdural hematomata are more common than epidural hematomata.

Signs and symptoms of subdural hematoma are similar to those of epidural hematoma and include headache, nausea and vomiting, decreasing level of consciousness, coma, abnormal posturing, paralysis, and, in infants, bulging fontanelles. These findings may be subtle because of the slow development of the hematoma in the subacute and chronic phases. Definitive care consists of surgery to remove the blood from the hematoma. Individuals at increased risk of developing subdural hematoma include older adults, patients with clotting deficiencies (e.g., alcoholics, hemophiliacs, and persons who take anticoagulants), and patients with cortical atrophy (older adults, alcoholics).

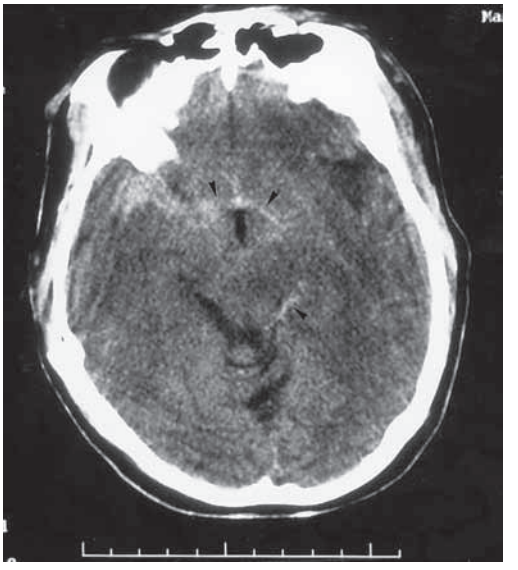

FIGURE 40-24 Head computed tomography scan showing a traumatic subarachnoid hemorrhage. (From Ferrera PC, Colucciello SA, Marx J, et al: *Trauma management: an emergency medicine approach,* St Louis, 2001, Mosby.)

Subarachnoid Hematoma. A **subarachnoid hematoma** refers to intracranial bleeding into the cerebrospinal fluid. This results in bloody cerebrospinal fluid and meningeal irritation (Figure 40-24). Bleeding that results from trauma, rupture of an aneurysm, or arteriovenous anomaly may extend into the brain if the force of the bleeding from the broken vessel is sudden and severe. Patients with this injury often complain of a sudden and severe headache. The

headache initially may be localized. Then the headache spreads (from meningeal irritation) and becomes dull and throbbing. Other characteristics of a subarachnoid hemorrhage include dizziness, neck stiffness, unequal pupils, vomiting, seizures, and loss of consciousness. Severe hemorrhage may result in coma and death. Permanent brain damage is common in those who survive.

CRITICAL THINKING

What causes the vomiting, seizures, and loss of consciousness in a patient with subarachnoid hemorrhage?

Cerebral Hematoma. An **intracerebral hematoma** may be defined as a collection of more than 5 mL of blood somewhere within the substance of the brain, most commonly in the frontal or temporal lobe.[15] This injury can result from multiple lacerations produced by penetrating head trauma (gunshot wound). The injury also may result from a high-velocity deceleration injury (automobile crash) in which vessels are torn as the brain moves across rough surfaces of the skull. Increased ICP can produce an intracerebral hematoma as the result of the brain being compressed.

Cerebral hematoma often is associated with subdural hemorrhage and skull fracture. Signs and symptoms may be immediate or delayed. This depends on the size and location of the hemorrhage. Once symptoms appear, the patient usually deteriorates rapidly. The mortality rate after surgical evacuation of the hematoma (if possible) approaches 45%.[1]

PENETRATING INJURY

Penetrating injuries to the brain usually are caused by missiles fired from handguns and stab wounds caused by sharp objects. Such objects include knives, scissors, screwdrivers, and nails. Less often, penetrating trauma may result from falls and high-velocity vehicle crashes. Associated injuries include skull fracture; damage to cerebral arteries, veins, or venous sinuses; and intracranial hemorrhage. Complications include infection and posttraumatic epilepsy. Definitive care for these injuries requires neurosurgical intervention.

ASSESSMENT AND NEUROLOGICAL EVALUATION

Prehospital management of the patient with a head injury is determined by a number of factors, including the mechanism and severity of injury and the patient's level of consciousness. Associated injuries affect the priorities of emergency care.

Airway and Ventilation. The initial step in treating all patients with head trauma is to ensure an open airway with spinal precautions. The next step is to provide adequate ventilation with high-concentration oxygen. Airway management may include oral or nasal adjuncts, multilumen devices, or nasal or tracheal intubation to maintain and protect the airway. Tracheal intubation and ventilatory support usually are recommended in all patients with head injuries who have a Glasgow Coma Scale (GCS) score ≤8[11](described later in the chapter).

CRITICAL THINKING

Imagine the appearance of a patient with a Glasgow Coma Scale score of 8 or less. Why should these patients be intubated? What if the Glasgow Coma Scale score improves rapidly?

Patients with head injuries are likely to vomit. If the patient has a decreased level of consciousness after the airway is secured, a nasogastric tube should be inserted to empty the stomach. In the presence of facial fractures, rhinorrhea (cerebrospinal fluid discharge from the nose), or otorrhea (cerebrospinal fluid discharge from the ear), an orogastric tube rather than a nasogastric tube should be inserted. Use of this tube helps to avoid possible intubation of the cranial cavity through the fracture site. In addition, the patient should be well stabilized on a long spine board for safe repositioning. Suction equipment with large-bore suction catheters should be available as well.

Ventilatory support should be focused on maintaining adequate oxygenation and optimizing cerebral perfusion. Capnography and pulse oximetry should be used to ensure that oxygen saturation is at a level of 95% or greater. Aggressive hyperventilation reduces carbon dioxide concentration; it can lead to secondary brain injury through cerebral vasoconstriction and a decrease in cerebral blood flow. (Routine prophylactic hyperventilation should be avoided.) Thus in the absence of capnography to guide ventilatory support, normal ventilations should be provided at 10 breaths/min for adults, 20 breaths/min for children, and 25 breaths/min for infants. With evidence of herniation (Box 40-5), the patient should be hyperventilated at the

BOX 40-5 Indicators of Herniation for Hyperventilation

Cushing's triad: increased systolic blood pressure, widened pulse pressure, and decrease in the pulse rate and irregular respiratory pattern

Or

An unresponsive patient with the following:

Bilateral, dilated, unresponsive pupils or asymmetrical pupils (>1 mm)

And

Abnormal extension (decerebrate) posturing or no motor response to painful stimuli

following rates: 20 breaths/min for adults, 30 breaths/min for children, and 35 breaths/min for infants. These rates should yield a P_{CO_2} of about 35 mm Hg.[14,16]

Circulation. After the airway has been secured (maintaining spinal protection), support of the patient's cardiovascular function becomes the next priority. The paramedic should control major external bleeding and should assess the patient's vital signs. Assessment establishes a baseline for future evaluations. A cardiac monitor will detect changes in rhythm (particularly bradycardia and tachycardia) that can occur with increasing ICP and brainstem injury. The blood pressure of every patient should be maintained at normal levels with fluid replacement (per medical direction). A single episode of hypotension doubles mortality and increases morbidity in the patient with traumatic brain injury.[14] Therefore the paramedic should administer intravenous fluids to support oxygen delivery and to avoid hypertension or limit hypotension to the shortest duration possible. Systolic blood pressure thresholds that can be used to define hypotension in head-injured patients are listed in Box 40-6.

Persistent hypotension from an isolated head injury is a rare and terminal event. The exception is head injury in infants and small children. *Closed head injury in the adult does not produce hypovolemic shock.* Thus a patient with head injuries who also is hypotensive should be evaluated for other injuries that could cause hemorrhage. The paramedic also should evaluate the patient for the possibility of neurogenic shock from spinal cord trauma. Infusion of isotonic fluids (lactated Ringer's solution or normal saline) may be indicated for hemorrhagic shock. However, these fluids probably should be used cautiously in patients with hypotension caused by neurogenic shock. In the latter patient group, vasopressors also may be helpful in maintaining blood pressure. Neurogenic shock may be distinguished from hemorrhagic shock by the following:

- A relatively bradycardic response (e.g., a pulse rate of 80 beats/min with a blood pressure of 80 mm Hg)
- Skin that often is warm and dry (not cool and clammy)
- No evidence of significant blood loss or hypovolemia
- Paralysis and loss of spinal reflexes

Neurological Examination. Conscious patients should be interviewed to determine their memory status before and after the injury and establish significant medical history (e.g., heart disease, hypertension, diabetes, epilepsy, medication use, alcohol or other drug use, and allergies). The history also should include the mechanism of injury and the events that led up to the injury. (For example, the history may detail a loss of consciousness before or after the injury incident.)

The paramedic should evaluate the motor skills of conscious patients. Evaluation determines the patient's ability to follow commands and helps the paramedic to note any paralysis. (Hemiparesis or hemiplegia, especially with a sensory deficit on the same side, indicates brain damage rather than spinal trauma.) If the patient is unconscious on emergency medical services arrival, the paramedic should interview bystanders about the history of the event. The paramedic also should ask bystanders about the length of time the patient has been unconscious. The most important indicator of increasing ICP is deterioration in the patient's sensorium. Thus the paramedic should evaluate the level of consciousness using the GCS every 5 minutes. A decrease of 2 points with a GCS score of 9 or lower is significant; it indicates significant injury.[14]

NOTE

When assessing and managing an adult with a severe head injury, remember the Brain Trauma Foundation's "90-90-9 rule"[17]:

- A single drop in the patient's arterial oxygen saturation (SaO_2) to less than 90% doubles his or her chance of death.
- A single drop in the patient's systolic blood pressure to less than 90 mm Hg doubles his or her chance of death.
- A single drop in the patient's GCS score to less than 9 doubles his or her chance of death. A drop in the GCS score of 2 or more points, at any time, also doubles mortality.

CRITICAL THINKING

How reliable will the patient be regarding the duration of his or her loss of consciousness?

After the patient has been resuscitated and stabilized, the paramedic should assess the patient's pupils for symmetry, size, and reactivity to light. Abnormal pupillary responses may indicate an increase in ICP and cranial nerve involvement. *Asymmetrical pupils* differ more than 1 mm in size. *Dilated pupils* are greater than or equal to 4 mm in adults. A *fixed pupil* shows less than 1-mm change in response to bright light. (The paramedic should evaluate pupil size every 5 minutes.) Alcohol and some other drugs can cause abnormal pupillary reactions, but the reactions commonly are bilateral (except for certain eye drops, if placed in one eye). If the patient is conscious, the paramedic also should evaluate extraocular movement (see Chapter 20: Secondary Assessment).

BOX 40-6 Systolic Blood Pressure Thresholds Defining Hypotension in Head-Injured Patients

<65 mm Hg in patients from birth to 1 year of age
<75 mm Hg in patients 2 to 5 years of age
<80 mm Hg in patients 6 to 12 years
<90 mm Hg in patients 13 years or older

From Brain Trauma Foundation: *Guidelines for the management of severe head injury*, ed 3, New York, 2007.

NOTE
The initial pupil evaluation and the Glasgow Coma Scale score establish the baseline against which all subsequent neurological evaluations are compared.[14]

Fluid Therapy. In the absence of hypotension, fluid therapy normally should be restricted in a patient with head injury to minimize cerebral edema. If the patient is hemodynamically stable, the paramedic should establish an intravenous line of crystalloid fluid to keep the vein open. If significant hypovolemia is present from another injury, the paramedic should give the patient an isotonic fluid bolus. (This should be guided by medical direction.) The patient also should be transported rapidly to a proper facility. In this case, the injury causing hypovolemia usually is more immediately life threatening than the head injury. As a rule, hypotension in the presence of head injury initially should be managed with fluid boluses to maintain a systolic blood pressure of at least 90 mm Hg.[1]

Drug Therapy. Prehospital use of drugs for the treatment of head injuries is controversial. Drugs that may be prescribed by medical direction to decrease cerebral edema or circulating blood volume may include ***mannitol*** and hypertonic saline. (Both are controversial.) Medical direction may require the insertion of an indwelling urinary catheter for careful monitoring of urine output before starting diuretic therapy. Hypotension leading to hypoperfusion may occur as a complication of diuretic use in patients with head injuries.

NOTE
The administration of glucose (dextrose 50%) is contraindicated in patients with head injuries unless hypoglycemia is confirmed. Intravenously administered dextrose 50% may worsen cerebral damage.

Anticonvulsant agents such as ***lorazepam*** and ***diazepam*** are used to control seizure activity in head-injured patients. As a rule, these drugs are not used in the initial management of head injuries because of their sedating effects. Prevention of seizures avoids the rise in ICP that often accompanies sudden seizure activity. Intravenously administered ***lidocaine*** has been shown to control increases in ICP that normally occur during endotracheal intubation.[1]

In addition, the use of sedatives and paralytics for some patients with head injuries may be indicated for airway management. These drugs also may be used to aid in the transport of combative patients (especially in aeromedical transport). The paramedic should follow local protocol and consult with medical direction regarding the use of these drugs.

INJURY RATING SYSTEMS

Several injury rating systems are used to triage, guide patient care, predict patient outcome, identify changes in patient status, and evaluate trauma care in epidemiological studies and quality assurance reviews. (These also are known as *indexes* or *scales*.) These indexes are important to prehospital personnel. They aid in determining patient care needs with reference to hospital resources. Rating systems commonly used in emergency care include the Glasgow Coma Scale, trauma score, Revised Trauma Score, and pediatric trauma score.

SHOW ME THE EVIDENCE
This international research study compared outcomes of children treated with hypothermia within 8 hours of traumatic brain injury to those who were not treated. The researchers enrolled 225 children in the study. Six months after the injury 31% of the children treated with hypothermia had an unfavorable outcome as opposed to 22% of the children in the normothermic group. Also, 23 children in the hypothermic group died versus 14 in the control group. The authors concluded that hypothermia did not improve outcomes in children with traumatic brain injury and may increase deaths.

From Hutchison JS, Ward RE, Lacroix J, et al: Hypothermia therapy after traumatic brain injury in children, *N Engl J Med* 358(23):2447-2456, 2008.

Glasgow Coma Scale

The **Glasgow Coma Scale** (GCS) evaluates eye opening, verbal and motor responses, and brainstem reflex function. The scale is considered one of the best indicators of eventual clinical outcome[11] and should be part of any neurological examination for patients with head injury (Table 40-1). A GCS score of 9 to 13 indicates moderate traumatic brain injury; a GCS score of 8 or less indicates a severe traumatic brain injury. (*NOTE:* The lowest possible score is 3; the highest possible score is 15.) Hypoxemia and hypotension have been shown to affect GCS scoring negatively. Thus GCS should be measured after the primary survey. The score should be measured after a clear airway is established. Also, the GCS should be measured after necessary ventilation and circulatory resuscitation have been performed. Unresponsive patients with a GCS score of 3 to 8 should be transported to a trauma center with traumatic brain injury capabilities.[14]

Trauma Score/Revised Trauma Score

The trauma score was developed in 1980 to predict outcome for patients with blunt or penetrating injuries. This score has limited use in the prehospital setting. The trauma score does not predict adequately the mortality for isolated, severe head injury.

The **Revised Trauma Score** was published in 1989. The Revised Trauma Score uses the GCS with measurements for systolic blood pressure and respiratory rate that are

TABLE 40-1 Glasgow Coma Scale*

Criteria	Points Assigned to Score
Eye Opening	
Spontaneous eye opening	4
Eye opening on command	3
Eye opening to painful stimulus	2
No eye opening	1
Best Verbal Response	
Answers appropriately (oriented)	5†
Gives confused answers	4
Gives inappropriate response	3
Makes unintelligible noises	2
Makes no verbal response	1
Best Motor Response	
Follows commands	6
Localizes painful stimuli	5
Withdraws from pain	4
Responds with abnormal flexion to painful stimuli (decorticate)	3
Responds with abnormal extension to painful stimuli (decerebrate)	2
Gives no motor response	1
TOTAL	—

From National Association of Emergency Medical Technicians: *PHTLS basic and advanced prehospital trauma life support,* St Louis, 2006, Mosby.
**Example:* A head-injured patient with an eye opening response to pain would be assigned 2 (E2); with no verbal response would be assigned 1 (V1); and with decerebrate posturing would be assigned 2 (M2). The Glasgow Coma Scale score for this patient would be 5.
†It generally is agreed that a full verbal score of 5 should be assigned to a child less than 2 years of age who cries after stimulation.

TABLE 40-2 Revised Trauma Score*

Variable	Score (Points)	Start of Transport	End of Transport
A. Ventilatory Rate			
10-29 breaths/min	4		
>29 breaths/min	3		
6-9 breaths/min	2		
1-5 breaths/min	1		
0	0		
B. Systolic Blood Pressure			
>89 mm Hg	4		
76-89 mm Hg	3		
50-75 mm Hg	2		
1-49 mm Hg	1		
No pulse	0		
C. Glasgow Coma Scale Score			
13-15	4		
9-12	3		
6-8	2		
4-5	1		
<4	0		
Trauma score total = A + B + C	—		

Adapted from Champion HR, et al: A revision of the trauma score, *J Trauma* 29(5):624, 1989.
**Example*: At the start of transport, a head-injured patient has spontaneous ventilations at 30 breaths/min (score of 3), a systolic pressure of 80 mm Hg (score of 3), and a Glasgow Coma Scale score of 12 (score of 3), providing a Revised Trauma Score of 9. At end of transport, the patient has spontaneous ventilations of 18 breaths/min (score of 4), a systolic pressure of 62 (score of 2), and a Glasgow Coma Scale score of 7 (score of 2), providing a Revised Trauma Score of 8.

TABLE 40-3 Pediatric Trauma Score

Component	+2	+1	−1
Size	Child/adolescent >20 kg	Toddler 11-20 kg	Infant <10 kg
Airway	Normal	Assisted: O_2 mask, cannula	Intubated: endotracheal tube, cricothyroidotomy
Consciousness	Awake	Obtunded, lost consciousness	Coma, unresponsive
Systolic blood pressure	90 mm Hg	51-90 mm Hg	<50 mm Hg
	Good peripheral pulses, perfusion	Carotid, femoral pulse palpable	Weak or no pulse
Fracture	None seen or suspected	Single closed fracture anywhere	Open or multiple fractures
Cutaneous	No visible injury	Confusion, abrasion, laceration <7 cm through fascia	Tissue loss, any gunshot wound or stab through fascia

From National Association of Emergency Medical Technicians: *PHTLS basic and advanced prehospital trauma life support,* ed. 7, St Louis, 2011, Mosby.

divided into five intervals. A range of values for these physiological measurements is assigned a number between 0 and 4. These numbers then are added to give a total between 0 and 12. (A score of 0 indicates the most critical. A score of 12 indicates the least critical [Table 40-2].) Calculating the Revised Trauma Score en route to the receiving hospital provides baseline measurements. This can be helpful to the physician in managing the patient's care. In some emergency medical services systems, this score is calculated after arrival at the emergency department using data from radio reports and the prehospital care report.

Pediatric Trauma Score

The **pediatric trauma score** grades six characteristics commonly seen in pediatric trauma patients. These are size (weight), airway, consciousness, systolic blood pressure, fracture, and cutaneous injury (Table 40-3). The pediatric trauma score has a significant inverse linear relationship with patient mortality. A child with a pediatric trauma score less than 8 should be cared for in an appropriate pediatric trauma center.[14]

Patient size (weight) is one of the first parameters to assess. The smaller the child, the greater the risk for severe injury because of an increased ratio of body surface to volume. The risk also is greater because of the potential for limited physiological reserve.

The child's airway is scored by potential difficulty in management. Scoring also is by the type of care required to ensure adequate ventilation and oxygenation. Respiratory failure is the main cause of death in most pediatric patients. Aggressive management to control the airway should be started without delay.

As with adult patients, the most critical factor in assessing the central nervous system of a child is a change in the level of consciousness. Any change in the level of consciousness will reduce this score—no matter how brief the time.

The assessment of systolic blood pressure in the pediatric patient is critical because the circulating volume is notably less than that of the adult. Because of a normal child's healthy heart and excellent reserve capacity, children often do not show classic signs of shock until they have lost about 25% of their circulating volume. Any child who has a systolic blood pressure less than 50 mm Hg is in obvious jeopardy.[18]

A child's skeleton is more pliable than that of the adult. It allows traumatic forces to be sent through the body and to the organs. Thus a fracture in the pediatric patient is a sign that serious injury likely has occurred.

Like fractures, cutaneous injury in the pediatric patient is a potential contributor to mortality and disability. These injuries include open and visible wounds and penetrating trauma.

For example, a head-injured child who is 8 years of age weighs 34 kg (+2); has spontaneous respirations (+1); is unresponsive (+1); has a systolic pressure of 86 mm Hg with palpable femoral pulses (+1); has no visible fractures (+2); and has an abrasion on the head with minimal bleeding (+1). The pediatric trauma score for this patient is 8.

SUMMARY

- Major causes of maxillofacial trauma are motor vehicle crashes, home accidents, athletic injuries, animal bites, intentional violent acts, and industrial injuries.
- With the exception of compromised airway and the potential for significant bleeding, damage to the tissues of the maxillofacial area is seldom life threatening. Some facial fractures are associated with basilar skull fracture. Blunt trauma injuries may be classified as fractures to the mandible, midface, zygoma, orbit, or nose.
- Injury to the ears, eyes, or teeth may be minor or may result in permanent sensory function loss and disfigurement. Trauma to the ear may include lacerations and contusions, thermal injuries, chemical injuries, traumatic perforation, and barotitis. Evaluation of the

eye should include a thorough history. Assessment also should include measurement of visual acuity, pupillary reaction, and extraocular movements.

- Anterior neck injuries may result in damage to the skeletal structures, vascular structures, nerves, muscles, and glands of the neck. The patient should be assessed for airway compromise, bleeding, and cervical spine injury.
- Injuries to the skull may be classified as soft tissue injuries to the scalp and skull fractures. Skull fractures may be classified as linear fractures, basilar fractures, depressed fractures, and open vault fractures.
- The categories of brain injury include DAI and focal injury. Diffuse axonal injury may be mild (concussion), moderate, or severe. Focal injuries are specific, grossly observable brain lesions. Included in this category are lesions that result from skull fracture, contusion, edema with associated increased ICP, ischemia, and hemorrhage.
- The prehospital management of a patient with head injuries is determined by a number of factors. One factor is the mechanism of injury. A second factor is the severity of injury. A third factor is the patient's level of consciousness. Associated injuries affect the priorities of care.
- Several injury rating systems are used to triage, guide patient care, predict patient outcome, identify changes in patient status, and evaluate trauma care. Rating systems commonly used in emergency care include the Glasgow Coma Scale, trauma score/Revised Trauma Score, and pediatric trauma score.

CHAPTER

41 Spine and Nervous System Trauma

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the incidence, morbidity, and mortality related to spinal injury.
2. Predict mechanisms of injury that are likely to cause spinal injury.
3. Describe the anatomy and physiology of the spine and spinal cord.
4. Outline the general assessment of a patient with suspected spinal injury.
5. Distinguish between types of spinal injury.
6. Describe prehospital evaluation and assessment of spinal cord injury.
7. Identify prehospital management of the patient with spinal injuries.
8. Distinguish between spinal shock, neurogenic shock, and autonomic hyperreflexia syndrome.
9. Describe selected nontraumatic spinal conditions and the prehospital assessment and treatment of them.

KEY TERMS

anterior cord syndrome A spinal cord injury usually seen in flexion injuries; caused by pressure on the anterior aspect of the spinal cord by a ruptured intervertebral disk or fragments of the vertebral body extruded posteriorly into the spinal canal.

autonomic hyperreflexia syndrome Overactivity of the autonomic nervous system that causes an abrupt onset of extremely high blood pressure.

axial loading Vertical compression of the spine that results when direct forces are transmitted along the length of the spinal column.

Brown-Séquard syndrome A hemitransection of the spinal cord. In the classic presentation, pressure on half of the spinal cord results in weakness of the upper and lower extremities on the ipsilateral (same) side and loss of pain and temperature sensation on the contralateral (opposite) side.

central cord syndrome A spinal cord injury commonly seen with hyperextension or flexion cervical injuries; characterized by greater motor impairment of the upper than lower extremities.

degenerative disk disease A condition caused by the deterioration of the tissue of the intervertebral disk that occurs with aging.

dermatome The skin surface area supplied by a single spinal nerve.

distraction A spinal injury that occurs if the cervical spine is stopped suddenly while the weight and momentum of the body pull away from it.

herniated intervertebral disk Occurs when all or part of a spinal disk is forced through a weakened part of the disk.

mechanism of injury The means by which an injury event occurs.

neurogenic hypotension Hypotension following spinal shock; caused by a loss of sympathetic tone to the vessels.

quadriplegia A weakness or paralysis of all four extremities and the trunk.

spinal cord injury Damage to the spinal cord; may result from direct injury to the cord itself or indirectly from damage to surrounding bones, tissues, or blood vessels.

spinal shock A temporary loss of all types of spinal cord function distal to a cord injury.

spondylosis A condition of the spine characterized by fixation or stiffness of the vertebral joint.

subluxation A partial dislocation.

transection A complete or incomplete lesion to the spinal cord.

*More than 250,000 victims of **spinal cord injury** (SCI) currently are living in the United States, and more than 12,000 new spinal cord injuries will occur this year.[1] Of these, more than 4800 persons will die before they are admitted to a hospital.[2] Education in injury prevention, prehospital assessment, and proper handling and transportation of these patients can decrease morbidity and mortality.*

(Courtesy Ray Kemp, St. Charles, Mo.)

SPINAL TRAUMA: INCIDENCE, MORBIDITY, AND MORTALITY

Most spinal cord injuries (SCIs) result from motor vehicle crashes (42.1%). The next largest cause is falls (26.7%). Penetrating injuries from acts of violence (15.1%) and injuries from sports (7.6%) follow (Figure 41-1). The median age of spinal injury victims is 38 years; about 80% of victims are male.[3]

CRITICAL THINKING
Why do you think this group is at increased risk for spinal injuries?

Forty percent of trauma patients with neurological deficit will have a temporary or permanent SCI. In addition to the devastating emotional and psychological impact on victims and their families, the annual cost to society exceeds $5 billion. The average yearly costs that can be attributed to SCI vary greatly by the severity of injury. The cost of lifelong care for a 25-year-old victim with a permanent and severe SCI is estimated at more than $3.1 million.[1] Injury prevention strategies can have a positive effect on incidence, morbidity, and mortality associated with spinal trauma (see Chapter 3).

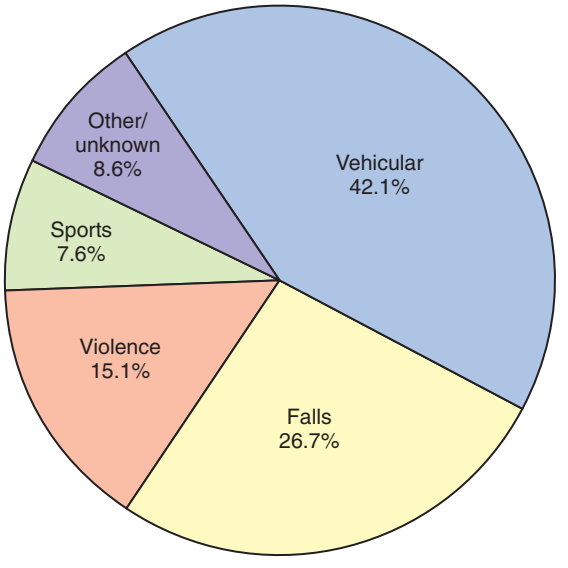

FIGURE 41-1 Mechanism of spine injury.[1]

REVIEW OF SPINAL ANATOMY

Anatomy of the spine was presented in Chapter 10. The following discussion will serve as a brief review.

The Spinal Column

The spinal column is composed of 33 bones (vertebrae). These bones are divided into five sections. The sections include 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused), and 4 coccygeal (fused) vertebrae. The anterior elements of the spine include vertebral bodies, intervertebral disks, and anterior and posterior longitudinal ligaments that connect the vertebral bodies anteriorly and inside the canal (Figure 41-2).

Each vertebra consists of a solid body (bearing most of the weight of the vertebral column), a posterior and anterior arch, a posterior spinous process, and, in some vertebrae, a transverse process. Ligaments between the spinous processes provide support for the movements of flexion and extension. Those between the laminae provide support during lateral flexion. The spinal cord lies in the spinal canal.

The Spinal Cord and Spinal Nerves

The spinal cord runs from the base of the brain down through the cervical and thoracic spine. The cord ends at about L2. Below that area, a collection of nerve roots continues, looking somewhat like a horse's tail (*cauda equina*)

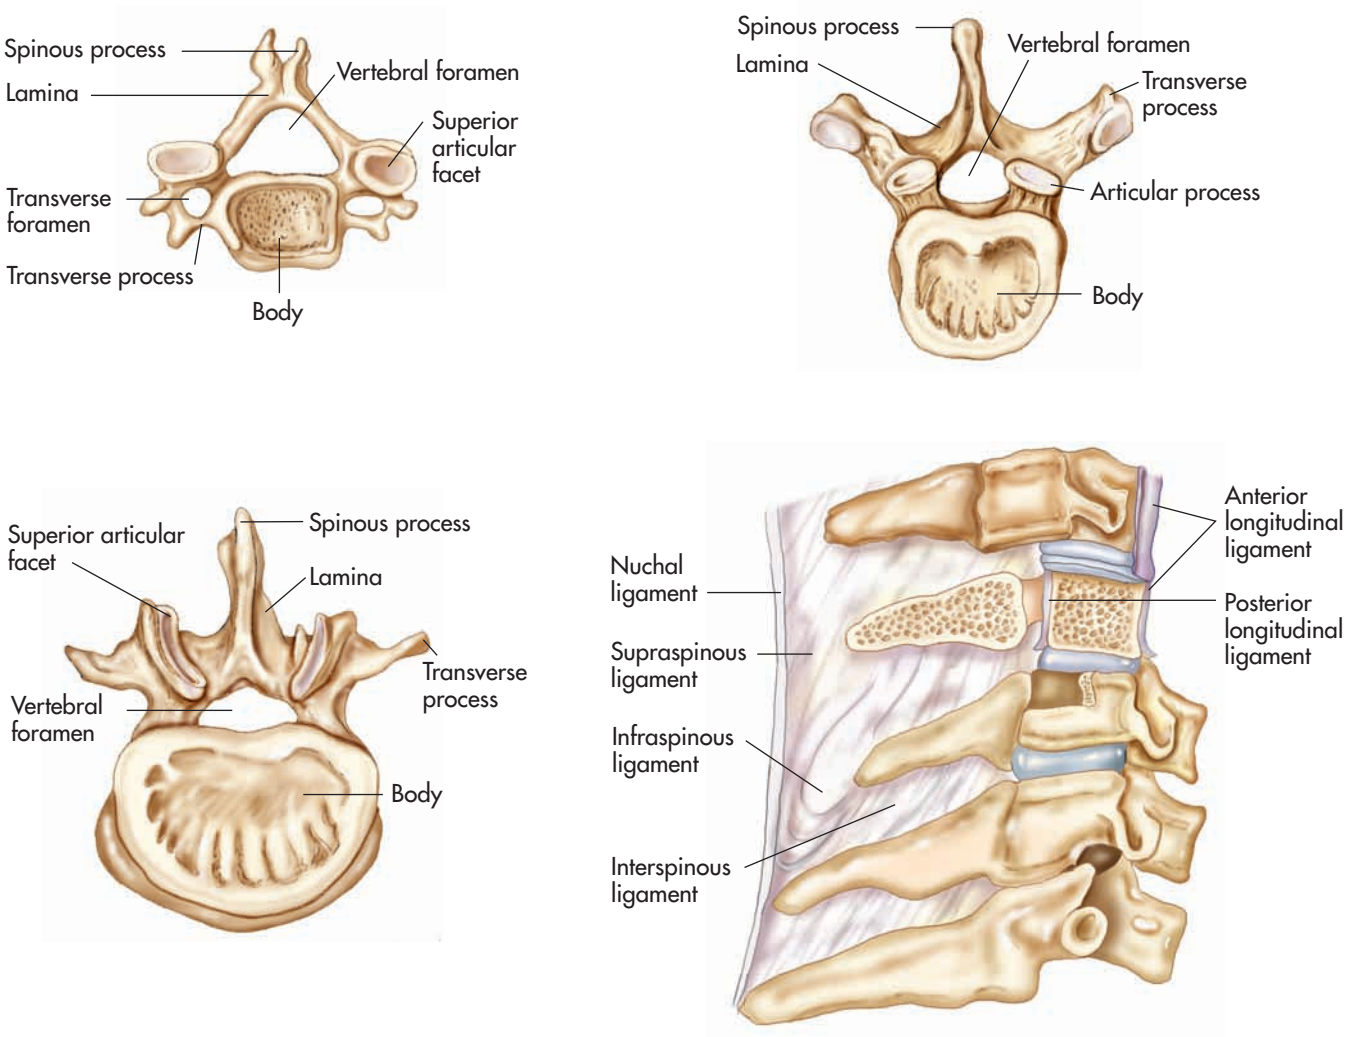

FIGURE 41-2 Vertebral bodies and elements of the spine. (From Marx J, et al: *Rosen's emergency medicine: concepts and clinical practice,* ed 6, St Louis, 2006, Mosby.)

(Figure 41-3). The nerve roots pass out of the spinal canal through the intervertebral foramen, where they innervate the body either anteriorly (motor) or posteriorly (sensory). *Ascending nerve tracts* carry sensory impulses from various parts of the body through the cord up to the brain. *Descending nerve tracts* carry motor impulses from the brain through the spinal cord and down to the body. As described in Chapter 10, the levels of nerve functions in the spinal cord are represented by **dermatomes** (the sensory area on the body innervated by a nerve root). The anterior divisions of the nerves supply the front of the spine including the limbs. The posterior divisions of the nerves are distributed to the muscles behind the spine. The spinal cord provides a means of communication between the brain and peripheral nerves. Figure 41-4 shows the relationship between the spinal column, the spinal nerves, and areas of the body that can be affected by injury or disease.

LOOK AGAIN
See Chapter 10: Review of Human Systems pp. 176-178.

TRADITIONAL SPINAL ASSESSMENT CRITERIA

Assessment of suspected SCIs traditionally has focused on **mechanism of injury** (MOI). Spinal immobilization was required for two specific patient groups: (1) unconscious injury victims and (2) any patient with a motion injury. This MOI standard covers all patients with a potential for

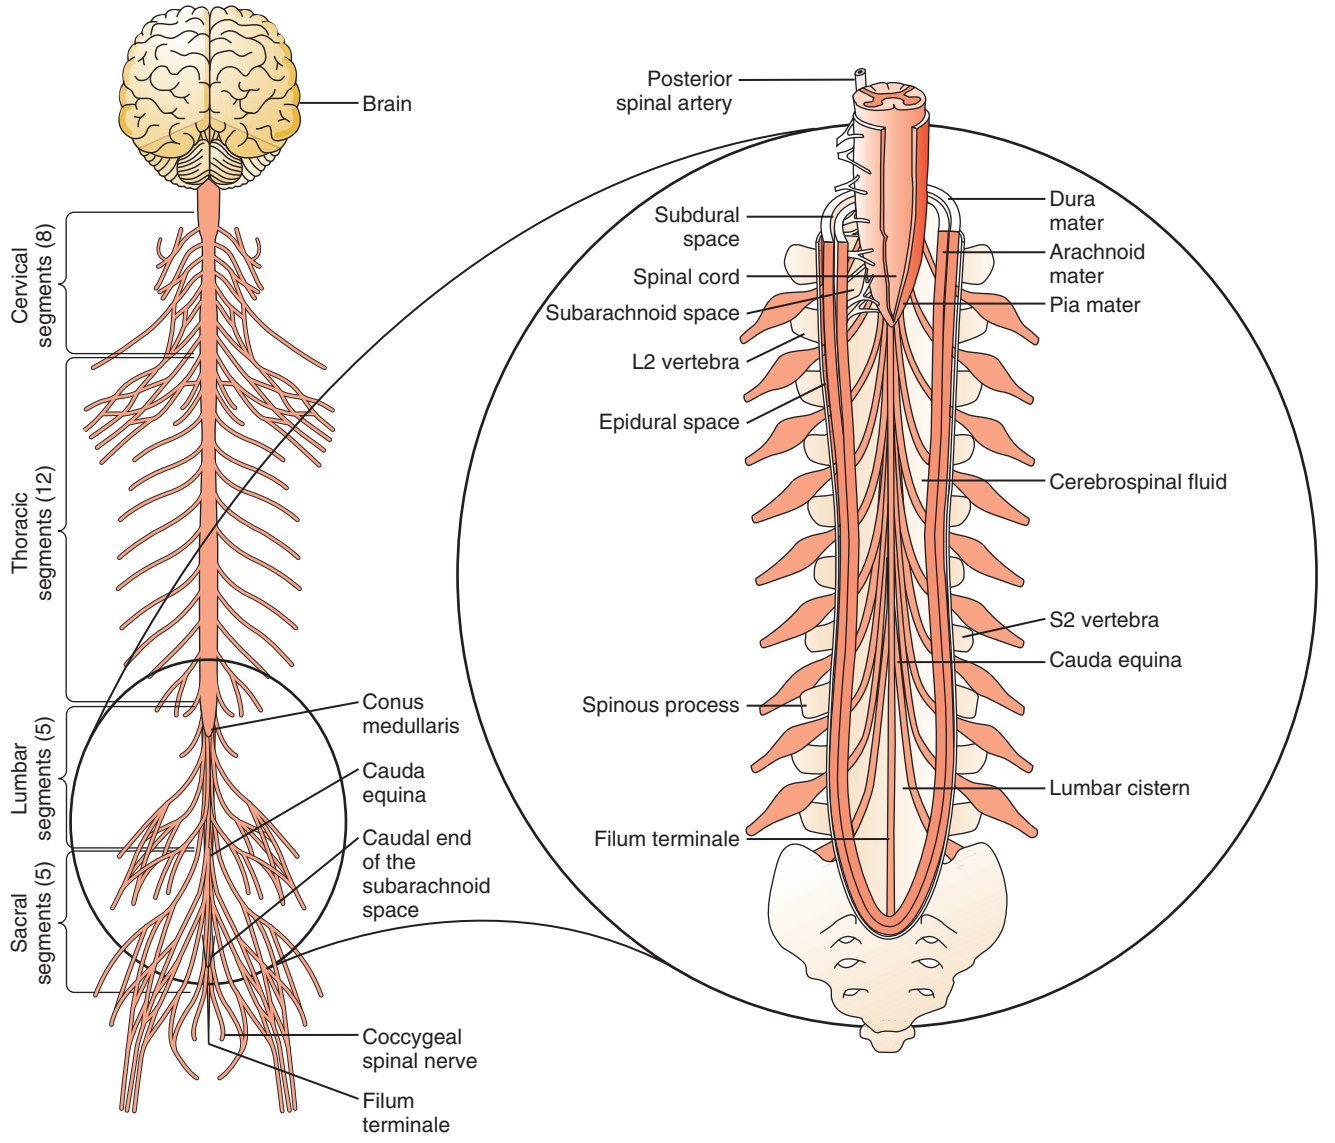

FIGURE 41-3 The spinal cord, spinal nerves, and meninges. Spinal meninges are similar to cranial membranes. Spinal meninges end at S2, creating a cerebrospinal fluid (CSF)–filled cistern below the spinal cord. The cauda equina (horse tail) is formed by the lumbar and sacral nerves, which protrude from the end of the spinal cord. (From Copstead-Kirkhorn LE, Banasik JL: *Pathophysiology,* ed 4, St Louis, 2010, Saunders.)

spinal injury, yet the standard is not always practical in the prehospital setting. The accuracy of prehospital assessment can be strengthened by applying clear, clinical guidelines (clinical criteria) for evaluating SCI, which includes the following signs and symptoms[4]:

- Altered level of consciousness (Glasgow Coma Scale score less than 15)
- Spinal pain or tenderness
- Neurological deficit or complaint
- Anatomical deformity of spine
- Evidence of alcohol or other drugs
- Distracting injury
- Inability to communicate

Mechanism of Injury

When determining MOI in a patient who may have spinal trauma, the paramedic can classify the MOI as *positive, negative,* or *uncertain*.[5] This method, combined with the clinical criteria for spinal injury listed previously, can help the paramedic identify situations in which spinal immobilization is appropriate. When in doubt, the paramedic should use full spinal precautions (Figure 41-5).

CRITICAL THINKING
What are the disadvantages of immobilizing a patient on a long spine board?

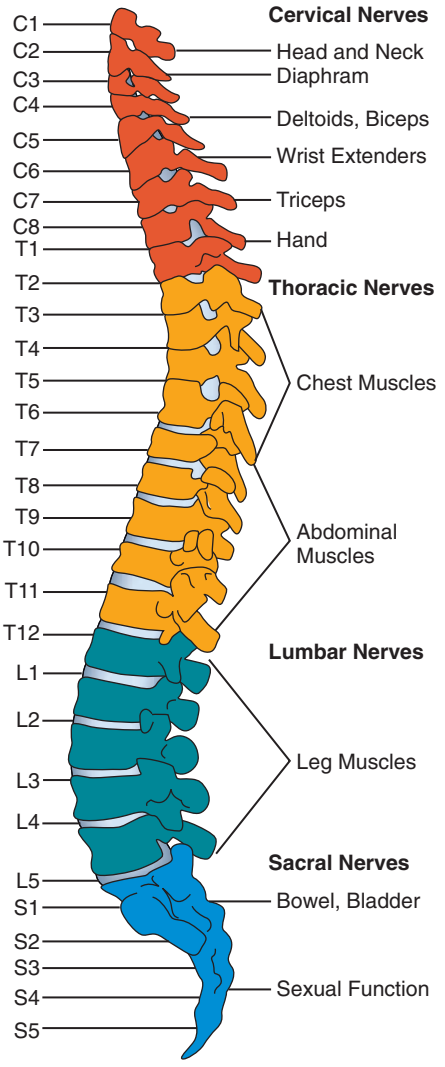

FIGURE 41-4 Nerve tracts.

POSITIVE MECHANISM OF INJURY

In a positive MOI, the forces exerted on the patient are highly suggestive of SCI. A positive MOI with physiological findings for spinal injury requires full spinal immobilization. Examples of positive MOIs include the following:

- High-speed motor vehicle crashes
- Falls from greater than 3 times the patient's height
- Violent situations occurring near the patient's spine (e.g., blunt and penetrating injuries)
- Sports injuries
- Other high-impact situations

In the absence of signs and symptoms of SCI, some medical direction agencies may recommend that a patient with a positive MOI not be immobilized.[4] Medical direction bases this action on the paramedic's assessment, a reliable patient history, and the absence of distracting injuries (described later in this chapter).

BOX 41-1 Clinical Criteria Versus Mechanism of Injury

Initial management is based solely on the mechanism of injury.

- *Positive* mechanism of injury requires spinal immobilization.
- *Negative* mechanism of injury (without signs and symptoms) requires no spinal immobilization.
- *Uncertain* mechanism of injury requires further clinical assessment and evaluation to determine need for spinal immobilization.

NEGATIVE MECHANISM OF INJURY

A negative MOI includes events in which force or impact does not suggest a likely spinal injury. In the absence of SCI signs and symptoms, negative MOI injuries do not require spinal immobilization. Examples of negative MOIs include the following:

- Dropping an object on the foot
- Twisting an ankle while running
- Isolated soft tissue injury

UNCERTAIN MECHANISM OF INJURY

At times, the impact or force involved in the injury is unknown or uncertain. Thus clinical criteria must be the basis used to determine the need for spinal immobilization (Box 41-1).

Examples of uncertain MOIs include the following:

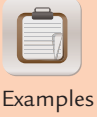
- Tripping or falling to the ground and hitting the head
- Falls from 2 to 4 feet
- Low-speed motor vehicle crashes ("fender benders")

Assessment of Uncertain Mechanism of Injury. When evaluating the need for spinal immobilization in which the MOI is uncertain, the paramedic must ensure that the patient is reliable. A reliable patient is one who is calm, cooperative, sober, alert, and oriented. Patients who would be considered unreliable include those who:

- Have acute stress reactions from sudden stress of any type
- Have brain injury
- Are intoxicated
- Have abnormal mental status
- Have distracting injuries
- Have problems communicating

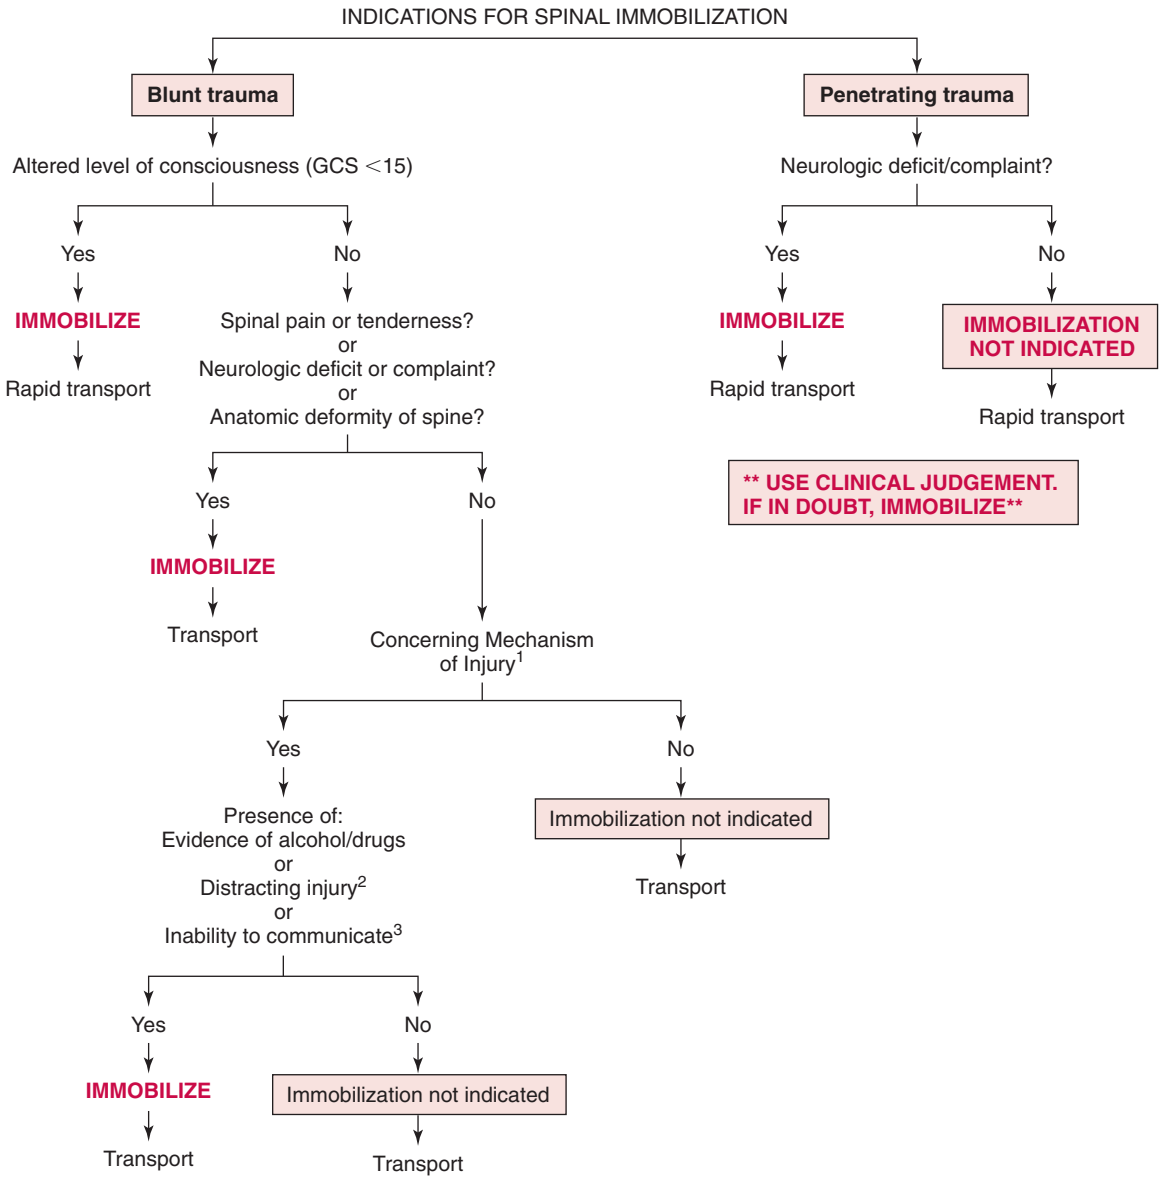
CRITICAL THINKING

The reliability of a patient is not always easy to assess quickly in the prehospital setting. Why is this?



NOTE

Any patient who has altered mental status or altered pain perception should be considered unreliable. Examples include patients with Alzheimer's disease, a psychiatric illness, and those under the influence of alcohol or other drugs.



Notes:

[1]Concerning Mechanisms of Injury

- Any mechanism that produced a violent impact to the head, neck, torso, or pelvis (e.g., assault, entrapment in structural collapse, etc.)
- Incidents producing sudden acceleration, deceleration, or lateral bending forces to the neck or torso (e.g., moderate- to high-speed MVC, pedestrian struck, involvement in an explosion, etc.)
- Any fall, especially in the elderly
- Ejection or fall from any motorized or human-powered transportation device (e.g., scooters, skateboards, bicycles, motor vehicles, motorcycles or recreational vehicles)
- Victim of shallow-water diving incident

[2]Distracting Injury

Any injury that may have the potential to impair the patient's ability to appreciate other injuries. Examples of distracting injuries include a) long bone fracture; b) a visceral injury requiring surgical consultation; c) a large laceration, degloving injury, or crush injury; d) large burns, or e) any other injury producing acute functional impairment.
(Adapted from Hoffman JR, Wolfson AB, Todd K. Mower WR: Selective cervical spine radiography in blunt trauma: methodology of the National Emergency X-Radiography Utilization Study [NEXUS], *Ann Emerg Med* 461, 1998.)

[3]Inability to communicate. Any patient who, for reasons not specified above, cannot clearly communicate so as to actively participate in their assessment. Examples: speech or hearing impaired, those who only speak a foreign language, and small children.

FIGURE 41-5 Indications for spinal immobilization. (From National Association of Emergency Medical Technicians: *PHTLS: prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

GENERAL ASSESSMENT OF SPINAL INJURY

Spinal injury most often results from the spine being forced beyond its normal range and limits of motion (Figure 41-6). The adult skull weighs 16 to 22 lb. The skull sits on top of the first cervical vertebra (C1), or the *atlas*. The second cervical vertebra (C2), or the *axis,* and its odontoid process allow the head to move with about a 180-degree range of motion. Because of the weight and position of the head in relation to the thin neck and cervical vertebrae, the cervical spine is particularly susceptible to injury (27% to 33% of all SCIs occur in the C1 to C2 region).[1] Other spinal components that affect physiological limits of motion are the posterior neck muscles and the sacrum. The posterior neck muscles allow up to 60 degrees of flexion and 70 degrees of extension without stretching of the spinal cord. The sacrum is joined to the pelvis by immovable joints.

The specific MOIs that often cause spinal trauma are axial loading; extremes of flexion, hyperextension, or hyperrotation; excessive lateral bending; and distraction. These mechanisms may result in stable and unstable injuries. This is based on the extent of damage to spinal structures and the relative strength of the structures remaining intact.

Axial Loading

Axial loading (vertical compression) of the spine results when direct forces are sent down the length of the spinal column. Examples include striking the head against the windshield of a car, shallow diving injuries, vertical falls, and being struck on the head or a helmet with a heavy object. These forces may produce compression fracture or a crushed vertebral body without SCI and most commonly occur from T12 to L2.[3]

Flexion, Hyperextension, and Hyperrotation

Extremes in flexion, hyperextension, or hyperrotation may result in fracture, ligament injury, or muscle injury. Spinal cord injury is caused when one or more of the cervical vertebrae dislocate **(subluxation)** and are forced into the spinal canal. This injures the spinal cord. Examples of these motion extremes include rapid acceleration or deceleration forces from motor vehicle crashes, hangings, and midfacial skeletal or soft tissue trauma. Serious injuries often are the result of a combination of loading and rotational forces. These forces produce displacement or fracture of one or more vertebrae.

Lateral Bending

Excessive lateral bending may result in dislocations and bony fractures to the cervical and thoracic spine. The injury occurs as a sudden lateral impact moves the torso sideways. Initially, the head tends to remain in place. Then the head is pulled along by the cervical attachments. Examples of lateral bending include side or angular collisions from motor vehicle crashes and injuries from contact sports. The mechanism of this lateral force requires less movement to produce an injury than flexion or extension forces in frontal or rear impacts.

Distraction

Distraction may occur if the cervical spine is stopped suddenly while the weight and momentum of the body pull away from it. This force or stretching may result in tearing and laceration of the spinal cord. Examples of distraction injuries include intentional or unintentional hangings (e.g., suicide or school yard or playground injuries).

Other Mechanisms

Other less common mechanisms of spinal injury include blunt and penetrating trauma and electrical injury. The spinal cord, like the brain, may suffer concussions, contusions, and lacerations. The spinal cord may develop hematomata and edema in response to blunt trauma. Examples include spinal injuries that result from direct blows such as from falling tree limbs or other heavy objects.

Penetrating trauma to the spine may be caused by missile-type injuries or stab wounds to the neck, chest, or abdomen. These forces may result in laceration of the spinal cord or nerve roots over a wide area. At times penetrating trauma may produce a complete **transection** (lesion). In addition, areas of edema or contusion adjacent to the laceration may disrupt cord tissue.

Spinal trauma may occur from direct electrical injury. Trauma also may occur from the violent muscle spasms that accompany electrical shock (described in Chapter 39: Burns).

CLASSIFICATIONS OF SPINAL INJURY

Spinal injuries may be classified as sprains and strains, fractures and dislocations, sacral and coccygeal fractures, and cord injuries. Regardless of the specific injury, all patients with suspected spinal trauma and signs and symptoms of SCI should be immobilized. Unnecessary movement should be avoided until injury to the spine or spinal cord can be excluded by clinical examination and radiography. An unstable spine can be ruled out only by radiography or lack of any potential mechanism for the injury. As a guideline, the paramedic should assume the presence of spine injury and an unstable spine with the following[4]:

- Any mechanism that produced a violent impact on the head, neck, torso, or pelvis (e.g., assault, entrapment in a structural collapse)
- Incidents that produce sudden acceleration, deceleration, or lateral bending forces to the neck or torso (e.g., moderate- to high-speed motor vehicle collisions; pedestrian struck by a vehicle; involvement in an explosion)
- Any fall, especially in elderly persons
- Ejection or a fall from any motorized or otherwise powered transportation device (e.g., scooters, skateboards, bicycles, motor vehicles, motorcycles, recreational vehicles)

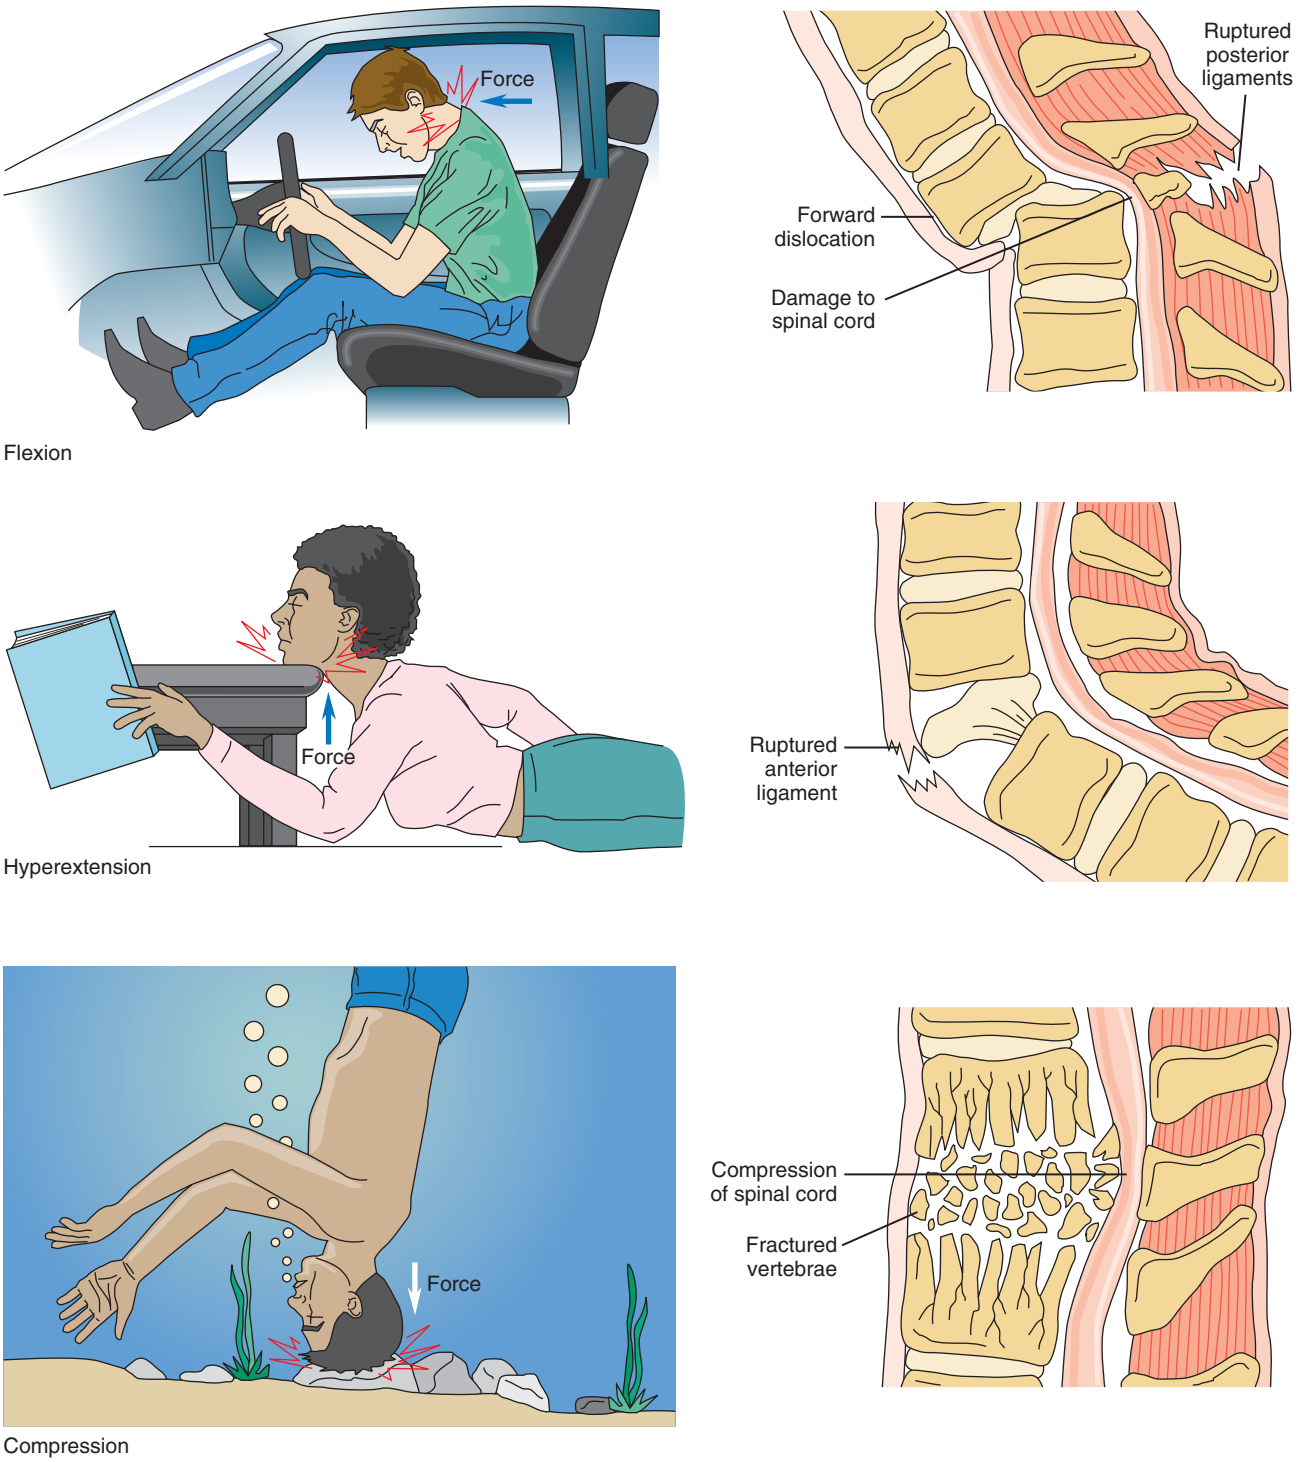


FIGURE 41-6 Mechanisms of spinal cord injury. Many situations may produce these consequences. This figure shows examples only. **A,** Flexion injury of the cervical spine ruptures the posterior ligaments. **B,** Hyperextension injury of the cervical spine ruptures the anterior ligaments. **C,** Compression fractures crush the vertebrae and force bony fragments into the spinal canal. (From Copstead-Kirkhorn LE, Banasik JL: *Pathophysiology*, ed 4, St Louis, 2010, Saunders.)

- Any victim of a shallow-water incident (e.g., diving, body surfing)
- Head injuries with any alteration in level of consciousness
- Significant helmet damage
- Significant blunt injury to the torso
- Impact or other deceleration fractures of the legs or hips
- Significant localized injuries to the area of the spinal column

Spinal injury (bony injury) can occur with or without SCI. Likewise, a patient may have SCI without bony injury. *Spinal cord injury without radiological abnormality* is a more common finding in children.[6]

The damage produced by the injury forces can be complicated further by the patient's age (calcification from the aging process), preexisting bone diseases (osteoporosis, spondylosis, rheumatoid arthritis, Paget's disease), and congenital spinal cord anomalies (e.g., fusion or narrow spinal canal). Spinal cord neurons do not regenerate to any great extent. Thus any injury to the central nervous system that causes destruction of tissue often results in irreparable damage and permanent loss of function. The role of the paramedic in protecting this critical area cannot be overemphasized.

Sprains and Strains

Sprains and strains usually result from hyperflexion and hyperextension forces. A *hyperflexion sprain* occurs when the posterior ligamentous complex tears at least partially. This sprain also can result in tears of the joint capsules. The sprain may allow partial dislocation (subluxation) of the intervertebral joints. *Hyperextension strains* are common in low-speed, rear-end car crashes. They are known commonly as whiplash. Injury occurs as the person is thrown backward against the posterior thorax during impact. This action damages anterior soft tissues of the neck.

CRITICAL THINKING
How can the paramedic distinguish between cervical sprain/strain and spinal fracture in the prehospital setting?

With sprains and strains, local pain may be produced by spasms of the neck muscles and injury to the vertebrae, intervertebral disks, and ligamentous structures. The pain usually is described as a nonradiating, aching soreness of the neck or back muscles. The discomfort often varies in intensity and with changes in posture.

On examination, a deformity of the spine may be palpable if dislocation (subluxation) has occurred. The patient may complain of associated point tenderness and swelling. Until the SCI is ruled out by x-ray exam, the paramedic should treat these patients as having unstable cervical spine injuries with a potential for damage to the spinal cord. After the diagnosis is confirmed, treatment of cervical sprain or strain usually is symptomatic. Following physician evaluation, treatment occasionally may include a cervical collar to decrease neck movement, heat application, and analgesics.

Fractures and Dislocations

The most frequently injured spinal regions in descending order are C5 to C7, C1 to C2, and T12 to L2.[3] Of these injuries, the most common are wedge-shaped compression fractures and teardrop fractures or dislocations. Neurological deficits associated with these fractures and dislocations vary with the location. They also vary with the extent of injury. Although the spine and spinal cord are close to each other, the spine can be fractured without SCI and vice versa. In addition, spinal injuries at multiple levels are common.

CRITICAL THINKING
Look at an illustration of the spinal column. Why do you think these areas are susceptible to fractures?

Wedge-shaped fractures (Figure 41-7) are hyperflexion injuries. They usually result from compressive force applied to the anterior portion of the vertebral body. This results in stretching of the posterior ligaments. (These injuries often result from injuries and falls in industrial settings.) These fractures usually occur in the mid or lower cervical segments or at T12 and L1. They generally are considered stable because the posterior ligaments rarely are disrupted totally.

Teardrop fractures and dislocations (Figure 41-8) are unstable injuries. They result from a combination of severe hyperflexion and compression forces and often are seen in motor vehicle crashes. During impact, the vertebral body is fractured. The anterior-inferior corner of the vertebral body is pushed forward. Unlike simple wedge fractures, these

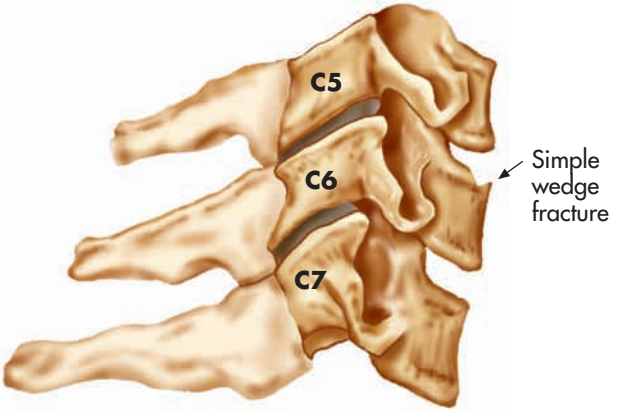

FIGURE 41-7 Lateral view of simple wedge fracture. (From Marx J, et al: *Rosen's emergency medicine: concepts and clinical practice,* ed 6, St Louis, 2006, Mosby.)

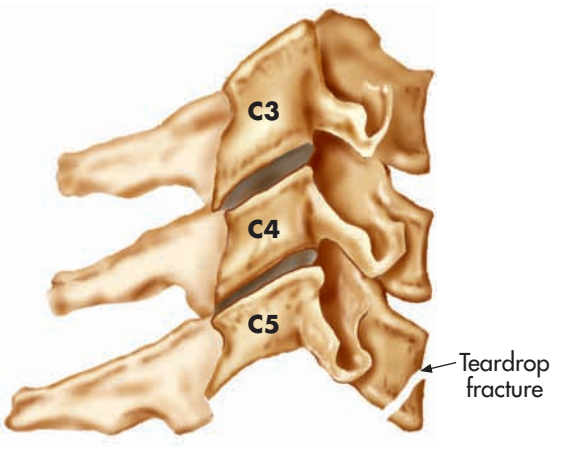

FIGURE 41-8 Lateral view of teardrop fracture. (From Marx J, et al: *Rosen's emergency medicine: concepts and clinical practice,* ed 6, St Louis, 2006, Mosby.)

fractures may be associated with neurological damage. These are among the most unstable injuries of the spine. A number of other spinal injuries are associated with the mechanisms of flexion, extension, rotation, and axial loading. Most of these are unstable and require careful immobilization.

Sacral and Coccygeal Fractures

The majority of serious spinal injuries occur in the cervical, thoracic, and lumbar regions. One reason for this is the location of the spinal cord and its termination in the adult spine at about L2. Another reason is the protection provided by the ring structure of the pelvis and the musculature of the buttocks and lower back. However, fractures through the foramina of S1 and S2 are fairly common. They may compromise several sacral nerve elements. Such fractures may result in loss of perianal sensory motor function. They also may result in damage to the bladder and bladder sphincters.

The sacrococcygeal joint also may be injured as a result of direct blows and falls. Patients often complain that they have "broken their tailbone." They often experience moderate pain from the mobile coccyx. Diagnosis usually is confirmed by a physician through a rectal examination.

Cord Injuries

Spinal cord injuries may be classified further as *primary* and *secondary* injuries.[1] Primary injuries occur at the time of impact. Secondary injuries occur after the initial injury. This type of injury can include swelling, ischemia, and movement of bony fragments. Like other tissues, the spinal cord can be concussed, contused, compressed, and lacerated. All of these mechanisms can cause temporary or permanent loss of cord-mediated functions distal to the injury from compression or ischemia. Bleeding from damaged blood vessels also can occur in the tissue of the spinal cord. Bleeding can cause an obstruction to spinal blood supply.

BOX 41-2 Complete Cord Lesions[7]

C1-C4 tetraplegia* (high tetraplegia): Individuals with complete C1-C4 (high) tetraplegia have little or no movement of upper and lower extremity muscles. They have movement of the head and neck, as well as, possibly, shoulder elevation (shrug). Persons with an injury at the C4 level have innervation of the diaphragm (the primary muscle for respiratory inspiration). They should not need long-term ventilatory assistance, although it is not uncommon to receive ventilation support initially after injury.

C5-C6 tetraplegia: Individuals with C5-C6 tetraplegia have functional use of elbow flexion and wrist extension. With the help of specialized assistive devices (such as wrist or hand orthotics to allow them to hold objects), these persons can achieve independence in feeding and grooming.

C7-C8 tetraplegia: Individuals with C7-C8 tetraplegia have the functional ability to extend their elbow and functional finger flexion, which greatly enhances their mobility and self-care skills. (C7 is usually the highest level at which patients can have an injury and still be able to live independently.) These patients can achieve independence in feeding, grooming, upper and lower extremity dressing, bathing, bed-mobility transfers, manual wheelchair propulsion, and bladder and bowel care, as well as in typing, writing, answering phones, and using computers. These persons can also drive independently using a van or a car adapted with hand controls.

Thoracic and lumbar paraplegia (below T1): Individuals with paraplegia have innervation and function of all upper extremity muscles, including those for hand function. They can achieve functional independence in self-care (including light housekeeping and meal preparation), in bladder and bowel skills, and, at the wheelchair level, in all mobility needs. Patients with this injury can drive independently by using a car adapted with hand controls.

*Tetraplegia is also known as **quadriplegia** (paralysis of four limbs).

The severity of these injuries depends on the amount and type of force that produced them and the duration of the injury.

CORD LESIONS

Lesions (transections) to the spinal cord are classified as *complete* or *incomplete*. Complete lesions usually are associated with spinal fracture or dislocation. Patients have total absence of pain, pressure, and joint sensation. They also have complete motor paralysis below the level of injury (Box 41-2). Autonomic nervous system dysfunction may be associated with complete cord lesions. This depends on the level of cord involvement. Manifestations of autonomic dysfunction include the following:

- Bradycardia caused by loss of sympathetic autonomic activity
- Hypotension caused by loss of vasomotor control and peripheral vascular resistance
- Priapism

- Loss of sweating and shivering
- Poikilothermy (body temperature varying with ambient temperature)
- Loss of bowel and bladder control

CRITICAL THINKING

Why should you immobilize a patient who already is showing signs and symptoms of a complete cord lesion?

NOTE

The 31 pairs of spinal nerves are numbered according to the vertebra at which they exit the spinal column. From the first thoracic vertebra downward, all spinal nerves exit *below* their equivalent numbered vertebrae. For example, the spinal nerve T4 exits the spinal column through the foramen in the fourth thoracic vertebra; the spinal nerve L5 exits the spinal cord through the foramen in the fifth lumbar vertebra. In the cervical region of the spinal cord, the spinal nerves exit *above* the vertebrae. A change occurs at the C7 vertebra, however, where the C8 spinal nerve exits the vertebra below the C7 vertebra. Therefore, there is an eighth cervical spinal nerve, even though there is no eighth cervical vertebra. In descending order, the cervical nerves supply feeling and movement to the arms, neck, and upper trunk; thoracic nerves supply the trunk and abdomen; and lumbar and sacral nerves supply the legs, bladder, and sexual organs.

The paramedic should be familiar with signs and symptoms of several incomplete spinal cord syndromes. Knowledge of these rare syndromes helps the paramedic to understand the potential for further injury. The three syndromes indicating incomplete lesions of the spinal cord are as follows:

1. **Central cord syndrome:** Central cord syndrome commonly occurs with hyperextension or flexion cervical injuries. The syndrome is characterized by greater motor impairment of the upper than lower extremities. Signs and symptoms of central cord syndrome are as follows:
   - Paralysis of the arms
   - *Sacral sparing* (the preservation of sensory or voluntary motor function of the perineum, buttocks, scrotum, or anus)
2. **Anterior cord syndrome:** Anterior cord syndrome usually is seen in flexion injuries. The syndrome is caused by pressure on the anterior aspect of the spinal cord by a ruptured intervertebral disk or fragments of the vertebral body forced posteriorly into the spinal canal. Signs and symptoms include the following:
   - Decreased sensation of pain and temperature below the level of the lesion (including lesions of the sacral region)
   - Intact light touch and position sensation
   - Paralysis
3. **Brown-Séquard syndrome:** Brown-Séquard syndrome is a hemitransection of the spinal cord. This syndrome may result from a ruptured intervertebral disk or the pushing of a fragment of vertebral body on the spinal cord. This often occurs after knife or missile injuries. In the classic presentation, pressure on half of the spinal cord results in weakness of the extremities on the ipsilateral (same) side. Pressure also results in loss of pain and temperature sensation on the contralateral (opposite) side.

CRITICAL THINKING

How will the prehospital care differ for a patient who has signs or symptoms of one of these syndromes?

PHARMACOLOGICAL THERAPY FOR INCOMPLETE CORD INJURY

The benefits of pharmacological agents (glucocorticoids, ***naloxone,*** calcium channel blockers, GM-1 ganglioside, and others) in the management of incomplete cord injury are controversial. These drugs are thought to provide some type of damage control following some SCIs. Some of the drugs are thought to work by reducing the toxicity of excitatory amino acids that cause cells to die; others, by encouraging the growth of new neurons or by reducing inflammation of the injured spinal cord and the bursting open of damaged cells.[1] Of these, only ***methylprednisolone*** currently is used routinely for human victims of SCI.[3]

Methylprednisolone is a synthetic steroid that is sometimes given to reduce posttraumatic spinal cord edema and inflammation. Studies have found that patients treated with large doses of this drug (30 mg/kg IV bolus, followed by a maintenance drip) within 8 hours of injury had improved recovery.[8] ***Methylprednisolone*** and other steroids have known adverse effects and complications, including suppression of adrenal glands and immune functioning.[4] Therefore the use of these drugs in managing SCI is controversial. Paramedics should consult with medical direction and follow local protocol.

EVALUATION AND ASSESSMENT OF SPINAL CORD INJURY

Spinal cord trauma should be evaluated only after all injuries that pose a threat to life have been assessed and treated. As with any scenario of serious illness or injury, the paramedic's first priority must be scene survey, including ensuring personal safety. The primary survey and assessment and management of the patient's airway, breathing, and circulation must be performed in a way that minimizes further damage. The second priority is to preserve spinal cord function and avoid secondary injury to the spinal cord.

The primary injury to the spine occurs at impact. Thus the critical role of paramedics is to prevent secondary injury. A secondary injury could result from unnecessary movement of an unstable spinal column, hypoxemia,

edema, or shock (which may reduce perfusion of the injured cord). These goals are best met by maintaining a high degree of suspicion for the presence of spinal trauma (based on scene survey, kinematics, and history of the event), providing early spinal immobilization, and rapidly correcting any volume deficit through fluid replacement, pneumatic antishock garment application (per protocol), and oxygen administration.

After any life-threatening problems found in the initial assessment are treated, the paramedic should perform a neurological examination. This examination may be done in the field. The exam also may be done en route to the receiving hospital if the patient's condition requires rapid transport. Any movement of the patient for performing a general or neurological examination must be accompanied by continuous, manual protection and in-line stabilization of the spine. Once the spine is stabilized, the paramedic should palpate the entire spine. Any report of pain on palpation indicates the need to immobilize the spine. Full documentation of the paramedic's findings provides an important baseline. This information will be useful for further assessment and evaluation of the patient in the emergency department. The components of the neurological examination include evaluation of motor and sensory findings and reflex responses.

Motor Findings

The paramedic should question conscious patients about pain in the neck or back with and without palpation. The paramedic also should ask patients about their ability to move their arms and legs. If possible, the paramedic should test the strength and motion of all four extremities. This can be done by asking the patient to flex the elbows (biceps, C6), extend the elbows (triceps, C7), and abduct/adduct the fingers (C8, T1). In unconscious patients, painful stimuli in the hands and lower extremities may initiate an involuntary muscle reflex unless the patient is in profound coma.

UPPER EXTREMITY NEUROLOGICAL FUNCTION ASSESSMENT

To test interosseous muscle function (controlled by T1 nerve roots), the paramedic should instruct the patient to spread the fingers of both hands. Then the patient should be instructed to keep the fingers apart while the paramedic squeezes the second and fourth fingers. Normal resistance should be springlike and equal on both sides.

To test the extensors of the hands and fingers (controlled by C7 nerve roots), the paramedic should instruct the patient to hold his or her wrists or fingers straight out and to keep them out while the paramedic presses down on the fingers. (The arm should be supported at the wrist to avoid testing arm function and other nerve roots.) Moderate resistance will normally be felt with moderate pressure. Both sides of the patient should be evaluated if not contraindicated by injury.

LOWER EXTREMITY NEUROLOGICAL FUNCTION ASSESSMENT

To test plantar flexors of the foot (controlled by S1 and S2 nerve roots), the paramedic should place his or her hands at the sole of each foot and instruct the patient to push against the hands. Both sides should feel equal and strong.

To test dorsal flexors of the foot and great toe (controlled by L5 nerve roots), the paramedic should hold the patient's foot (with fingers on toes) and instruct the patient to pull the feet back or toward the nose. Both sides should feel equal and strong.

Sensory Findings

In conscious patients, sensory examination should be performed with light touch on each hand and each foot (while the patient's eyes are closed) to evaluate the ability to feel this type of stimulus. (Light touch is carried by more than one nerve tract.) Sensation should be equal on both sides. The paramedic also should question the patient about weakness, numbness, paresthesia, or radicular pain (shooting pain that travels along a nerve).

If the patient cannot feel light touch or is unconscious, the paramedic may evaluate sensation by gently pricking the hands and soles of the feet. A sharp object that will not penetrate the skin is useful. (For example, the end of a pen or broken cotton-tipped applicator can be used.) One method of evaluation moves from head to toe, recording the level at which sensation stops or the unconscious patient ceases to respond to a painful stimulus by marking that location on the patient's skin with ink or a marker. Another method is to begin the sensory assessment by moving from an area of no sensation to an area where sensation begins. The paramedic would note the area where sensation begins with ink or marker. (These marks make it possible to compare sensory level accurately after repeated examinations.) Lack of response to stimulation in the upper extremities indicates cord damage in the cervical region; failure of only the lower extremities to respond indicates cord injury in the thoracic region, lumbar region, or both.

CRITICAL THINKING

How will you respond to the patient who fearfully asks you, "Why can't I move or feel my arms or legs?"

Dermatomes (described in Chapter 10) correspond to spinal nerves (Table 41-1), so the following four landmarks may be useful for a quick sensory evaluation in the prehospital setting:

1. C2 to C4 dermatomes provide a collar of sensation around the neck and over the anterior chest to below the clavicles.
2. T4 dermatome provides sensation to the nipple line.

TABLE 41-1 Common Nerve Root and Motor/Sensory Correlation

Nerve Root	Motor	Sensory
C3, C4	Trapezius (shoulder shrug)	Top of shoulder
C3 to C5	Diaphragm	Top of shoulder
C5, C6	Biceps (elbow flexion)	Thumb
C7	Triceps (elbow extension), wrist/finger extension	Middle finger
C8, T1	Finger abduction/adduction	Little finger
T4	Nipple	
T10	Umbilicus	
L1, L2	Hip flexion	Inguinal crease
L3, L4	Quadriceps	Medial thigh/calf
L5	Great toe/foot dorsiflexion	Lateral calf
S1	Knee flexion	Lateral foot
S1, S2	Foot plantar flexion	
S2 to S4	Anal sphincter tone	Perianal

FIGURE 41-9 Babinski's sign: dorsiflexion of the great toe with or without fanning of the toes. (Courtesy Gary Quick, MD.)

3. T10 dermatome provides sensation to the umbilicus.
4. S1 dermatome provides sensation to the soles of the feet.

Reflex Responses

Reflex responses seldom are evaluated in the prehospital setting. However, some abnormal responses are observed easily. These responses may indicate autonomic nerve injury. These responses include loss of temperature control, hypotension, bradycardia, and priapism. Another pathological reflex includes the presence of Babinski's sign (the plantar reflex). This is a reflex movement in which the great toe bends upward when the outer edge of the sole of the foot is scratched (Figure 41-9). Babinski's sign (which may indicate a spinal cord lesion in the older child or adult) is a normal and expected response in children younger than 2 years of age.

Other Methods of Evaluation

A visual inspection of the spine may reveal the presence of injury and its level. For example, transection of the cord above C3 often results in respiratory arrest. Lesions that occur at C4 may result in paralysis of the diaphragm. However, transections that occur at C5 to C6 usually spare the diaphragm, allowing diaphragmatic breathing. This occurs because the intercostal muscles are innervated sequentially between C4 to C5 and T12. As a result, intercostal muscle groups may be paralyzed with cervical or thoracic spinal cord lesions below the level where diaphragmatic nerves are located. (The higher the lesion, the greater the loss of intercostal muscle function.)

The patient's body position also may offer clues about neurological injury. For example, a patient with a SCI at C6 may lie with the arms flexed at the elbows and wrists (the "holdup" position).

GENERAL MANAGEMENT OF SPINAL INJURIES

A significant spinal injury still may be present, even though the patient may not show signs of spinal injury.[9] Some patients with cervical spinal injuries have normal responses to motor, sensory, and reflex examinations. Thus if the paramedic suspects a spinal injury for any reason, the paramedic must protect the patient's spine. In addition, the patient's ability to walk does not rule out the need for spinal precautions. As previously stated, an unstable spine can be ruled out only by clinical examination, radiography, and the lack of any potential mechanism for spinal injury. General principles of spinal immobilization include the following:

1. The primary goal is to prevent further injury.
2. The spine should be treated as a long bone with a joint at either end (the head and pelvis).
3. The paramedic should always use complete spinal immobilization. (Splinting and isolation of a specific injury site is impossible. Having spine fractures in more than one location also is common.)
4. Spinal immobilization begins in the initial assessment and must be maintained until the spine is immobilized completely on a long spine board.
5. The patient's head and neck must be placed in a neutral, in-line position unless contraindicated by condition or MOI. (Neutral positioning allows for the most space for the spinal cord, thereby reducing cord hypoxia and excess pressure.)

SHOW ME THE EVIDENCE

Researchers performed a prospective cohort study from 2002 to 2006 in three Canadian provinces. Paramedics assessed alert, stable, adult blunt trauma patients (with some exclusions) at risk for spine injury using a screening tool and then immobilized and transported them. At the emergency department, the patients were examined for spine injury. The study enrolled 1949 patients with mechanisms of injury that included motor vehicle collisions (62.5%) and falls (19.9%). Of this group 12 clinically important spine injuries were identified at the hospital. Paramedics correctly classified all of these patients. The authors concluded that, using the Canadian C-spine rule, 731 (37.7%) patients of the study group did not need immobilization.

From Vaillancourt C, Stiell I, Beaudoin T, et al: The out-of-hospital validation of the Canadian C-spine rule by paramedics, *Ann Emerg Med* 54(5):663-671, 2010.

Spinal Stabilization/Immobilization Techniques

As soon as a potential spine injury is recognized, the paramedic should manually protect the patient's head and neck. The basic principle to follow is that the head and neck must be maintained in line with the long axis of the body. If other injuries need treatment, the paramedic must maintain the patient's head and neck position without interruption.

A number of devices for immobilizing the spinal column are designed for prehospital use. When properly applied to patients who are sitting, standing, or lying, these devices can provide adequate spinal protection. However, no device should be considered for use until the head and neck have been stabilized with manual in-line immobilization.

NOTE

All spinal immobilization techniques discussed in this text follow the guidelines recommended by the Prehospital Trauma Life Support Committee of the National Association of Emergency Medical Technicians in cooperation with the Committee on Trauma of the American College of Surgeons.[4]

MANUAL IN-LINE IMMOBILIZATION

Manual in-line immobilization can be done from almost any patient position. It should be applied without traction on the head. Only enough tension should be applied to relieve the weight of the head from the cervical spine. After manual immobilization has been initiated, it must be continued without stopping until the head and spine are immobilized to a proper device (short spine board or vest, long spine board).

Contraindications for moving the patient's head to an in-line position follow. If any of these contraindications exist, all manual movement of the patient's head should stop. At that point, the head and neck should be stabilized in the position found. Contraindications include:

- Resistance to movement
- Neck muscle spasm
- Increased pain
- The presence or increase in neurological deficits during movement (e.g., numbness, tingling, and loss of motor function)
- Compromise of the airway or ventilation
- Severe misalignment of the head away from the midline of the shoulders and body axis (rare)

Manual Immobilization From the Sitting or Standing Patient's Side

1. Stand alongside the patient, holding the back of the head with one hand. Place the thumb and first finger of the other hand on each cheek, just below the zygomatic arch (Figure 41-10).
2. Tighten the position of both hands without moving the head or neck.
3. Move the head to an in-line position if needed. Maintain this position by bracing the elbows against your torso for support.

Manual In-Line Immobilization From the Front of the Sitting or Standing Patient

1. Stand in front of the patient and place the thumb of each hand on the patient's cheeks, just below the zygomatic arch.
2. Place the little fingers of each hand on the posterior aspect of the patient's skull.
3. Spread the remaining fingers of each hand on the lateral planes of the head and increase the strength of the grip (Figure 41-11).
4. Move the head to an in-line position if needed. Maintain this position by bracing the elbows against your torso for support.

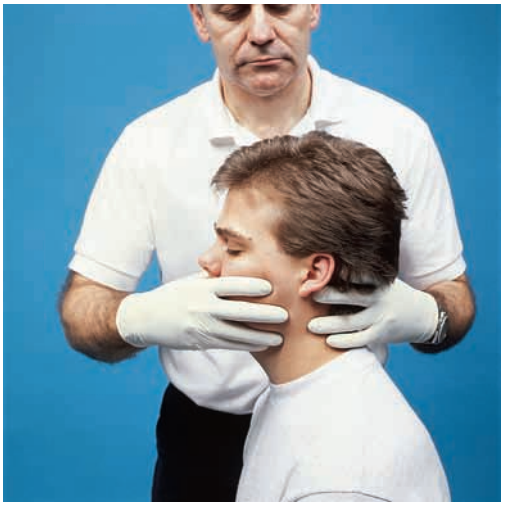

FIGURE 41-10 Manual in-line immobilization from the side.

FIGURE 41-11 Manual in-line immobilization from the front.

FIGURE 41-12 Manual in-line immobilization with a supine patient.

Manual In-Line Immobilization With a Supine Patient

1. Kneel or lie at the patient's head and place the thumbs of each hand just below the zygomatic arch of each cheek (Figure 41-12).
2. Place the little fingers of each hand on the posterior aspect of the patient's skull.
3. Spread the remaining fingers of each hand on the lateral planes of the head and increase the strength of the grip.
4. Move the head to an in-line position if needed. Maintain this position by bracing the elbows against your torso or ground surface for support.

Logroll With Spinal Precautions. Logrolling methods are used to move patients with a possible spinal injury. Examples include moving patients onto a mechanical immobilization device and turning patients from a prone to a supine position. Logrolling maneuvers require at least four rescuers for adequate spinal protection. The position of the patient's arms during a logrolling maneuver may affect thoracic-lumbar motion and further compromise the stability of the spine. One method that may minimize lateral motion and help to maintain neutral alignment of the pelvis and legs is to position the patient with arms extended at the side. The patient's palms should be on the lateral thighs.

Logroll of the Supine Patient. The following steps should be used for logrolling of patients in the supine position (Figure 41-13).

1. Rescuer 1 should be positioned at the patient's head. Rescuer 1 should provide in-line manual stabilization. Another rescuer should apply a rigid cervical collar and place a long spine board at the patient's side. (If a spinal injury with paralysis is obvious or if shock is suspected, the pneumatic antishock garment should be prepared on the spine board per protocol.)
2. Rescuers 2 and 3 should be positioned at the patient's midthorax and knees. The patient's arms should be extended at the sides, palms on lateral thighs. The legs should be brought together for neutral alignment.
3. Rescuer 2 grasps the far side of the patient at the shoulder and wrist. Rescuer 3 grasps the hips (just distal of the wrists) and both lower extremities at the ankles.
4. In one organized move, the rescuers slowly logroll the patient onto his or her side. At the same time, they slide the spine board under the patient. In-line support of the patient's head must be maintained. This is done by rotating the head exactly with the torso to avoid flexion or hyperextension. In addition, the ankles must be elevated slightly to maintain lateral and anterior-posterior alignment.
5. Rescuer 4 positions the long spine board by placing the device flat on the ground or at a 30- to 40-degree angle against the patient's back.
6. In one organized move, the rescuers slowly logroll and center the patient on the long spine board.

Logroll of the Prone Patient. The basic principles used in logrolling supine patients can be applied to a patient who is in a prone or semiprone position. The procedure uses the same initial alignment of the patient's arms and legs. The rescuers have the same responsibilities for maintaining alignment. There are two major differences in this logroll maneuver. These are Rescuer 1's hand position during the logroll and the application of the rigid cervical collar, which can be applied only after the patient is in a supine position (Figure 41-14).

1. Rescuer 1 places his or her hands in a position that provides in-line stabilization and that accommodates rotation of the patient with the torso.
2. In one organized move, the rescuers rotate the patient away from the direction of the initial prone position.
3. A rescuer places the long spine board on a flat surface or positions it between the patient's back and the rescuers at the patient's side.

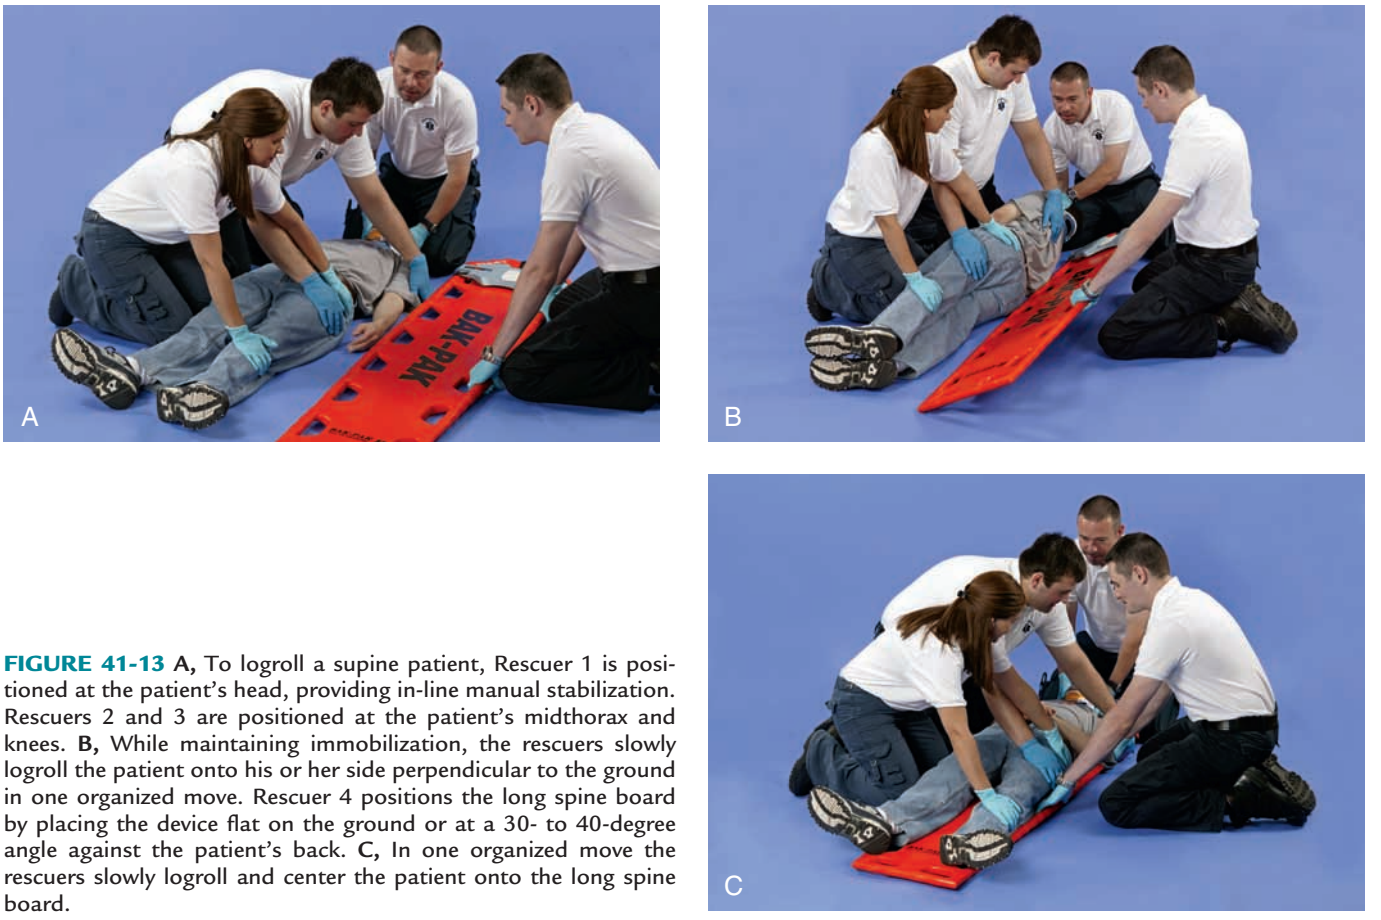

FIGURE 41-13 **A,** To logroll a supine patient, Rescuer 1 is positioned at the patient's head, providing in-line manual stabilization. Rescuers 2 and 3 are positioned at the patient's midthorax and knees. **B,** While maintaining immobilization, the rescuers slowly logroll the patient onto his or her side perpendicular to the ground in one organized move. Rescuer 4 positions the long spine board by placing the device flat on the ground or at a 30- to 40-degree angle against the patient's back. **C,** In one organized move the rescuers slowly logroll and center the patient onto the long spine board.

4. In one organized move, the rescuers slowly logroll and center the patient on the long spine board.
5. A rescuer applies a rigid cervical collar.

MECHANICAL DEVICES

Spinal immobilization equipment covered includes rigid cervical collars, short spine boards, and long spine boards. This text presents only general principles of spinal immobilization by mechanical devices. The specific methods of application vary by device. Paramedics should become familiar with the equipment used in their locale. They also should follow the application guidelines of the manufacturer.

Rigid Cervical Collars. Rigid cervical collars are designed to protect the cervical spine from compression. These devices may reduce movement and some range of motion of the head. However, they do not by themselves provide adequate immobilization of the spine. These devices must always be used along with manual in-line stabilization or immobilization by a suitable device (e.g., vest, short spine board, or long spine board). An effective rigid collar sits on the chest, posterior thoracic spine and clavicle, and trapezius muscles where tissue movement is at a minimum.[4] The collar also must be correctly sized for the patient. To apply a rigid cervical collar, the paramedic should follow these general steps, which demonstrate the application of the Stifneck™ collar (Figure 41-15):

1. Rescuer 1 applies manual in-line immobilization from behind the patient and maintains this position throughout the procedure.
2. Rescuer 2 properly angles the collar for placement.
3. Rescuer 2 positions the collar bottom.
4. Rescuer 2 sets the collar in place around the patient's neck.
5. Rescuer 2 secures the collar with the Velcro straps.
6. Rescuer 1 spreads his or her fingers and maintains support until the patient is secured to a short or long spine board.

Rigid cervical collars are available in a number of sizes (or they are adjustable). They can accommodate the range of physical characteristics of patients. Choosing the proper size reduces flexion or hyperextension of the neck. These movements may occur during patient extrication and packaging. These movements also may result from acceleration and deceleration forces that normally occur during patient transport. The following guidelines apply to the use of rigid cervical collars[4]:

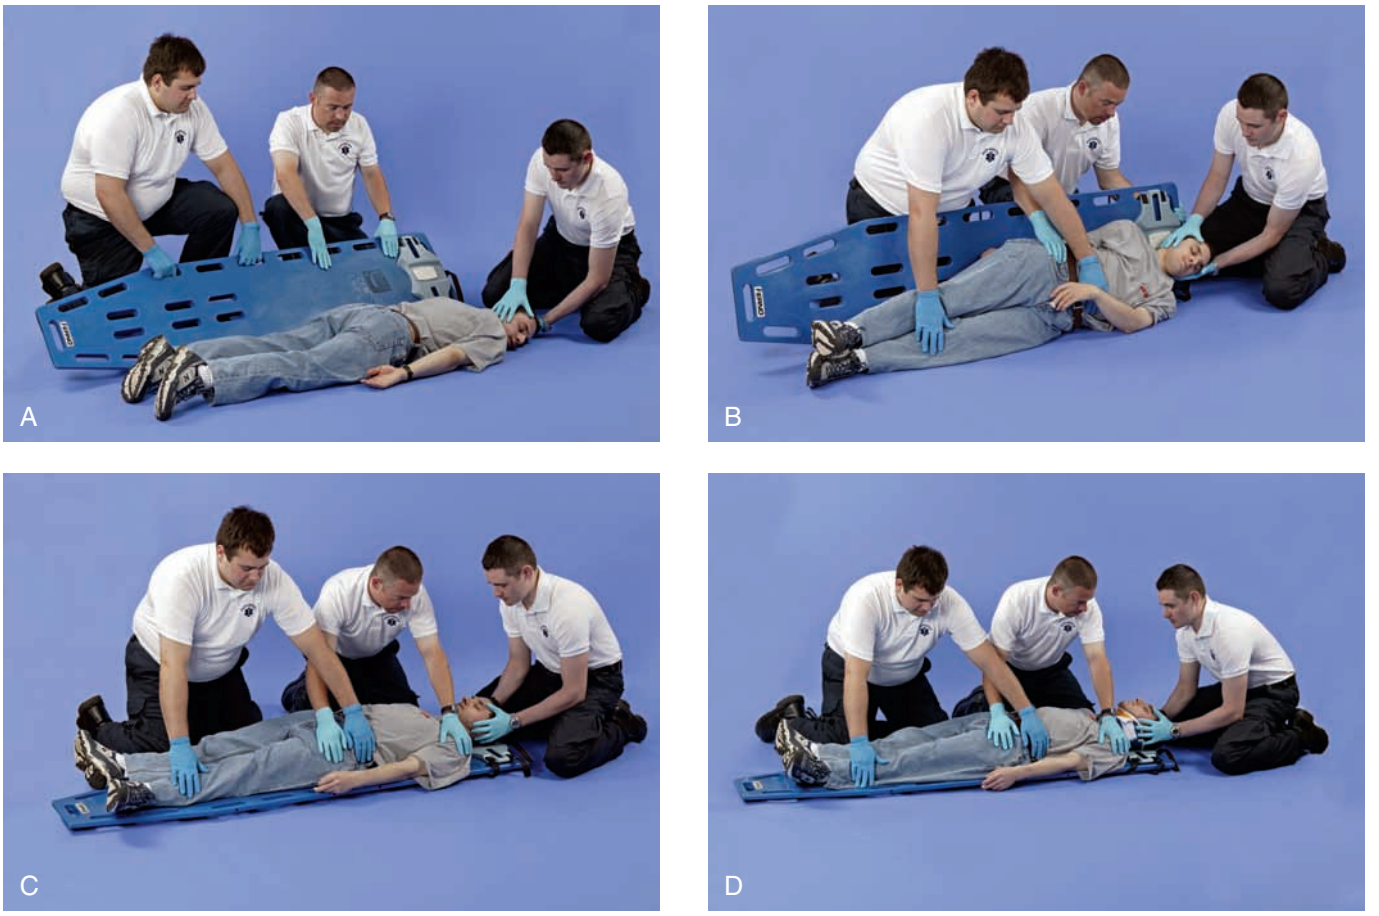

FIGURE 41-14 **A,** Rescuer 1 places his or her hands in a position that provides in-line stabilization and that accommodates the rotation of the patient with the torso. Rescuer 2 positions the long spine board. **B,** In one organized move the rescuers rotate the patient away from the direction of his or her initial prone position. **C,** In one organized move the rescuers slowly logroll and center the patient onto the long spine board. **D,** Another rescuer then applies a rigid cervical collar.

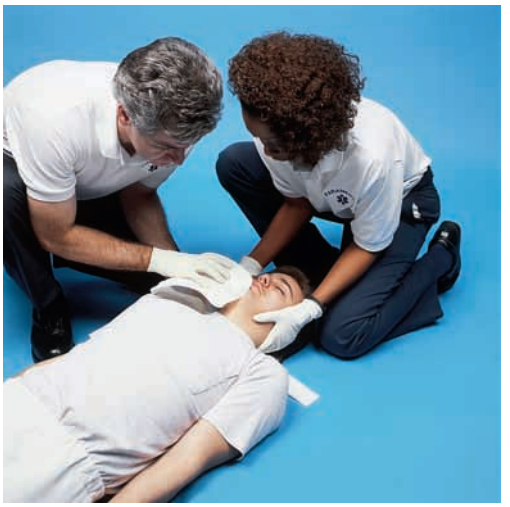

FIGURE 41-15 Rescuer 2 positions the collar and secures it with Velcro straps.

- They do not adequately immobilize by their use alone.
- They must be properly sized to the patient.
- They must not inhibit the patient's ability to open the mouth or the paramedic's ability to open the patient's mouth if vomiting occurs.
- They must not obstruct or hinder ventilation in any way.

Short Spine Boards. Short spine boards or other short spine extrication devices are used to splint the cervical and thoracic spine. These devices vary in design. They are available from a number of manufacturers. In general, short spine boards are used to provide spinal immobilization when the patient is sitting or is in a confined space. After short spine board immobilization, the patient is moved to a long spine board device for complete spinal immobilization. Examples of short spine boards include the plastic or synthetic half backboard, the Kendrick extrication device, the Oregon Spine Splint II, and the Hare extrication device. General principles of short spine board application,

FIGURE 41-16 Application of the Kendrick extrication device.

demonstrated with the Kendrick extrication device, are as follows (Figure 41-16):

CRITICAL THINKING
When would the use of the short board *not* be indicated for spinal column immobilization?

1. After manual in-line immobilization and the application of a rigid cervical collar, place the short spine board device behind the patient. The board should be positioned snugly beneath the patient's axillae; this will prevent it from moving up the torso.
2. Immobilize the upper and middle torso by fastening the chest straps, starting with the middle chest straps and followed by the lower chest straps. The upper chest strap (if used) should not be so tight that it impedes patient ventilation.[4] The middle and lower straps should be snug so that fingers cannot be slipped beneath the straps. Readjust as needed.
3. Position and fasten each groin strap separately, forming a loop. These straps prevent the Kendrick extrication device from moving up and the lower end from moving laterally.
4. Pad the device as needed and secure the head to the short spine board.
5. Carefully move the patient as a unit to a long spine board by rotating the patient and Kendrick extrication device onto the board. Hold the legs proximal to the knees and lift them during the transition.
6. Center the patient on the long spine board, release the leg straps, and slowly lower the patient's legs to an in-line position.
7. Secure the patient and Kendrick extrication device to the long spine board, maintaining a neutral in-line position with the long axis of the body. Then slightly loosen the Kendrick extrication device leg straps.

NOTE
The use of a short spine board should be considered only if the patient's condition allows. If the patient is unstable because of life-threatening injury or the need for immediate resuscitation or if the time required to apply the device would jeopardize the patient's life (e.g., a patient with a carotid pulse, but absent radial pulse), the patient's head and neck should be stabilized with manual, in-line support, and the patient should be moved as a unit to a long spine board.

RAPID EXTRICATION

The steps required for rapid extrication may vary depending on the size and make of the vehicle. They also may vary based on the patient's location inside the vehicle. A general description of the steps required for rapid extrication are listed:

Three or More Rescuers (Figure 41-17)

1. Rescuer 1 supports the patient's head and neck. Rescuer 1 uses manual in-line stabilization from behind the patient or from the patient's side. Rescuer 1 maintains this stabilization throughout the extrication process.
2. After a rapid initial assessment, Rescuer 2 applies a rigid cervical collar and positions a long spine board near the vehicle.
3. Rescuer 3 manually stabilizes and controls movement of the patient's upper and lower torso and legs during extrication.
4. The rescuers then rotate the patient in a series of short, controlled movements so that the patient's back faces the open doorway. Rescuer 2 exits the vehicle. Rescuer 2 assumes control of manual stabilization from outside the vehicle. Rescuer 1 assumes control of the patient's lower torso and legs. Each movement during the rotation of the patient should be coordinated, stopping so that the rescuers and the patient can be repositioned as needed to limit unwanted patient movement.
5. A rescuer should insert the foot end of the long spine board on the car seat at the patient's buttocks and should position the head end on the ambulance stretcher. Rotation of the patient continues until the patient can be positioned onto the long spine board.
6. The rescuers center and secure the patient on the long spine board as described later.

Two Rescuers (Figure 41-18)

1. Rescuer 1 supports the patient's head and neck. Rescuer 1 uses manual in-line stabilization from behind the patient or from the patient's side. Rescuer 1 maintains this stabilization throughout the extrication process.
2. After a rapid initial assessment, Rescuer 2 applies a rigid cervical collar and places a prerolled blanket around the patient. Rescuer 2 places the center of the blanket roll at the patient's midline on the rigid

FIGURE 41-17 **A,** Rescuer 1 supports the patient's head and neck and uses manual in-line stabilization throughout the procedure. **B,** After a rapid primary assessment, Rescuer 2 helps support the patient's midthorax while Rescuer 3 frees the patient's lower extremities for extrication. **C,** The rescuers carefully lower the patient onto the long spine board. **D,** The rescuers center and secure the patient on the long spine board.

cervical collar. Rescuer 2 then wraps the ends of the blanket roll around the cervical collar and places them under the patient's arms. Rescuer 2 positions a long spine board near the vehicle.

3. Using the ends of the blanket roll, the rescuers rotate the patient in a series of short, controlled movements so that the patient's back faces the open doorway. Each movement during the rotation of the patient should be coordinated, stopping so that the rescuers and the patient can be repositioned as needed to limit unwanted patient movement.
4. Rescuer 1 takes control of the blanket ends, moving them under the patient's shoulders, and moves the patient by the blanket while Rescuer 2 controls the patient's lower torso, pelvis, and legs.
5. The rescuers center and secure the patient on the long spine board as described next.

Long Spine Board With Supine Patient. Like short spine boards, long spine boards are available in a variety of configurations. These include plastic and synthetic spine boards, metal alloy spine boards, vacuum mattress splints, and split litters (scoop stretchers) that must be used along with a long spine board. The following description of securing patients on a long spine board may be applied to any long spinal immobilization device.

Immobilization of the torso to a long spine board must be done before immobilization of the head. This will prevent angulation of the cervical spine. The torso must not be allowed to move up, down, or to either side. Straps should be placed at the shoulders or upper chest below the axillae to avoid compression and lateral movement of the thorax, around the midtorso, and across the iliac crest to prevent movement of the lower torso. The paramedic should take care not to tighten the straps to the point of reducing chest wall movement.

After immobilization of the torso, the head and neck should be immobilized in a neutral, in-line position. When most adults are placed on a long or short spinal device, a large space is produced between the back of the head and the spine board. Therefore noncompressible padding (e.g.,

FIGURE 41-18 **A,** Rescuer 1 supports the patient's head and neck and uses manual in-line stabilization throughout the procedure. **B,** After assessment and application of a cervical collar, a rescuer positions the center of a blanket roll at the patient's midline on the cervical collar. The rescuer wraps the ends of the blanket roll around the cervical collar and places them under the patient's arms. **C,** The rescuers rotate the patient using the ends of the blanket roll until the patient's back faces the open doorway. (From National Association of Emergency Medical Technicians: *PHTLS: prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

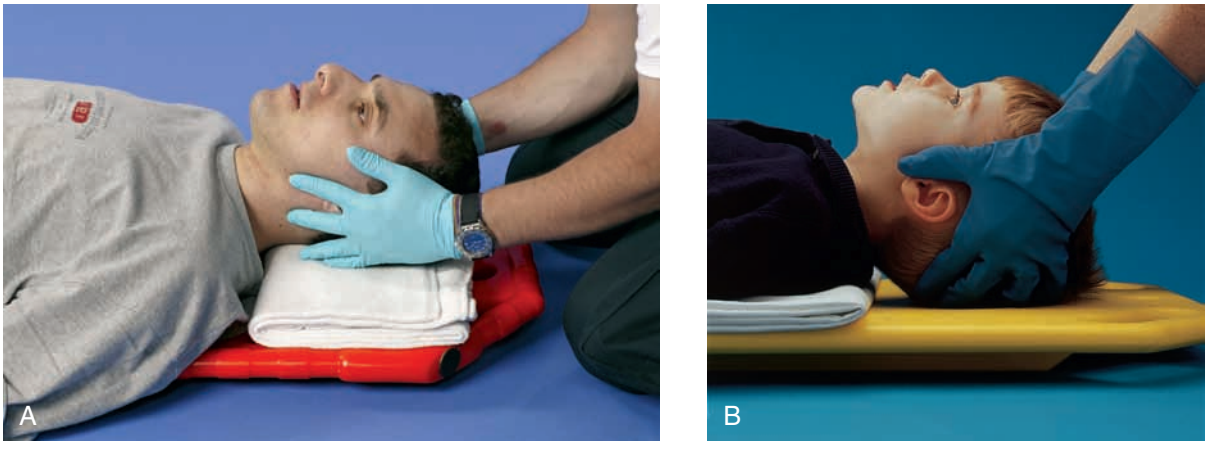

FIGURE 41-19 Padding requirements for adult (A) and pediatric (B) patients.

commercial padding or folded towels) should be added (body shims). This can be done before securing the head (Figure 41-19, *A*). The amount of padding required for in-line immobilization varies by patient and must be evaluated on an individual basis. Too little padding may cause hyperextension of the head, and too much padding may cause flexion; both may increase spinal cord damage. Children have proportionally larger heads than adults and may require padding under the torso to allow the head to lie in a neutral position on the board (Fig. 41-19, *B*). The padding (if needed) should be firm and should extend the full length and width of the torso from the buttocks to the top of the

shoulders to prevent movement and misalignment of the spine. In addition to providing enhanced stabilization, padding also improves patient comfort during transport.

The head is secured to the spinal device by placing commercial pads or rolled blankets on both sides of the head and securing them with the included straps, 2- to 3-inch tape strips, or a self-adhering firm wrap (e.g., Coban, Medi-Rip, or Elastoplast). (Elastic or gauze bandages do not prevent movement.) The upper forehead should be secured across the supraorbital ridge. The lower portion of the head should be secured across the anterior portion of the rigid cervical collar. Chinstraps, sandbags, and intravenous bags are considered less optimal in immobilizing the head to a spinal device.

The patient's legs should be secured to the long spine board. Two or more straps can be applied above and below the knees. Towels, blankets, or suitable padding may be placed on both sides of the patient's lower legs. This will minimize movement and will help to maintain the patient's central position on the spinal device (Figure 41-20).

Before moving the patient, the patient's arms should be secured to the spinal device for safety. This is best achieved by placing the patient's arms at his or her side. (The patient's palms should be facing the body.) The arms should be secured with a separate strap placed across the forearms and torso.

Long Spine Board with Standing Patient. Patients who are standing also may be secured to a long spine board using the following technique (Figure 41-21):

1. Rescuer 1 applies manual in-line immobilization from behind the patient or in front of the patient. Rescuer 1 maintains this position throughout the procedure. Rescuer 2 applies a rigid cervical collar.
2. Rescuer 2 slides the long spine board behind the patient from the side and presses it against the patient.
3. Rescuers 2 and 3 stand on either side of the patient and insert the hand that is closest to the patient under the patient's axilla and grasp the nearest handhold of the backboard without moving the patient's shoulders. The rescuers grab the higher handhold on the board with their other hands and lower the patient and backboard to the ground while maintaining manual in-line immobilization.
4. Once on the ground, the rescuers secure the patient to the long backboard as described.

IMMOBILIZING PEDIATRIC PATIENTS

As with adult patients, prehospital care of a pediatric patient with suspected spine trauma should be managed with manual in-line immobilization, a rigid cervical collar, and a long spinal immobilization device. Many different pediatric immobilization devices are available from

FIGURE 41-20 Long spine board immobilization (supine patient).

FIGURE 41-21 **A,** While Rescuer 1 maintains manual in-line stabilization, Rescuers 2 and 3 support the patient. **B,** In one organized move the rescuers lower the patient to the ground onto the long spine board for further immobilization.

FIGURE 41-22 Infant and pediatric immobilization board.

manufacturers (Figure 41-22). If pediatric immobilization devices are not available, children may be secured on an adult long spine board. (A great deal of padding, however, is needed to fill voids. The padding also helps to prevent movement.)

Helmet Issues

The purpose of helmets is to protect the head and brain. Helmets are not intended to protect the neck. (This leaves the cervical spine open to injury.) The various types of helmets include full-face or open-face designs (used in motorcycling, bicycling, in-line skating, and other activities), and helmets designed for sports such as football and motocross. Factors that the paramedic should consider when determining the need to remove a helmet from an injured patient who requires airway management and spinal immobilization include the following:

- Athletic trainers may have special equipment (and training) to remove face pieces from sports helmets, allowing easier access to the patient's airway.
- Sports garb (e.g., shoulder pads) could compromise the cervical spine further if only the helmet were removed.
- The firm fit of a helmet may provide firm support for the patient's head.

Helmet Removal

Patients who are wearing full-face helmets must have the helmet removed early in the assessment process. Removing the helmet allows the rescuers to assess and manage a patient's airway and ventilatory status completely. In addition, rescuers can look for bleeding. The bleeding may be hidden by the helmet. They also can move the patient's head (from the flexed position caused by large helmets) into neutral alignment. The paramedic should consult with medical direction if the patient complains of increased pain during removal of the helmet or if the helmet is hard to remove in the field. The following steps in full-face helmet removal are recommended by the American College of Surgeons Committee on Trauma[4]:

FIGURE 41-23 **A,** Rescuer 1 immobilizes the helmet and head in an in-line position. Rescuer 2 grasps the patient's mandible by placing the thumb at the angle of the mandible on one side and two fingers at the angle on the other side. Rescuer 2 places the other hand under the patient's neck at the base of the skull, producing in-line immobilization of the patient's head. **B,** Rescuer 1 carefully spreads the sides of the helmet away from the patient's head and ears. **C,** Rescuer 1 then rotates the helmet toward the rescuer to clear the nose and remove it from the patient's head in a straight line. **D,** After the removal of the helmet, Rescuer 1 applies in-line immobilization. Rescuer 2 applies a rigid cervical collar and places padding under the head.

1. Rescuer 1 immobilizes the helmet and head in an in-line position (Figure 41-23). Rescuer 1 presses his or her palms on each side of the helmet with the fingertips curled over the lower margin of the helmet.
2. Rescuer 2 removes the face shield and chinstrap. Rescuer 2 assesses the patient's airway and ventilatory status.
3. Rescuer 2 grasps the patient's mandible by placing the thumb at the angle of the mandible on one side and two fingers at the angle on the other side. Rescuer 2 places his or her other hand under the neck at the base of the skull, taking over in-line immobilization of the patient's head.
4. Rescuer 1 carefully spreads the sides of the helmet away from the patient's head and ears. Rescuer 1 then rotates the helmet toward the rescuer to clear the patient's nose. Rescuer 1 then removes the helmet from the patient's head in a straight line. Just before removing the helmet from under the patient's head, Rescuer 1 assumes in-line immobilization by squeezing the sides of the helmet against the patient's head.
5. Rescuer 2 repositions his or her hands to support the head and to prevent it from dropping as the helmet is removed completely. This is accomplished by the rescuer placing a hand farther up on the occipital area of the head and by grasping the maxilla with the thumb and first fingers of the other hand on each side of the nose. After securing this position, Rescuer 2 takes over in-line immobilization.

6. Rescuer 1 rotates the helmet about 30 degrees, following the curvature of the patient's head. Rescuer 1 completely removes the helmet by carefully pulling it in a straight line.
7. After removal of the helmet, Rescuer 1 applies in-line immobilization, and Rescuer 2 applies a rigid cervical collar.

> **NOTE**
> A key point to remember during helmet removal is that in-line immobilization must be maintained throughout the procedure. Thus the rescuers should never remove their hands from the patient at the same time. In addition, the helmet must be rotated in one direction to clear the nose. The helmet must be rotated in the opposite direction to clear the back of the patient's head.

Spinal Immobilization in Diving Incidents

Most diving incidents involve injury to the patient's head, neck, and spine. If the patient is still in the water when EMS arrives, the patient should be managed as follows:

1. Ensure scene and personal safety. Only rescuers trained in water rescue should enter the water (Figure 41-24).
2. Float a supine patient to a shallow area without unnecessary movement of the spine.
3. Approach a prone patient from the top of the head. Position one arm under the patient to support the head, neck, and torso. Place the other arm across the patient's head and back, splinting the head and neck between the rescuer's arms. Carefully turn the patient to a supine position and quickly assess airway and breathing. (The

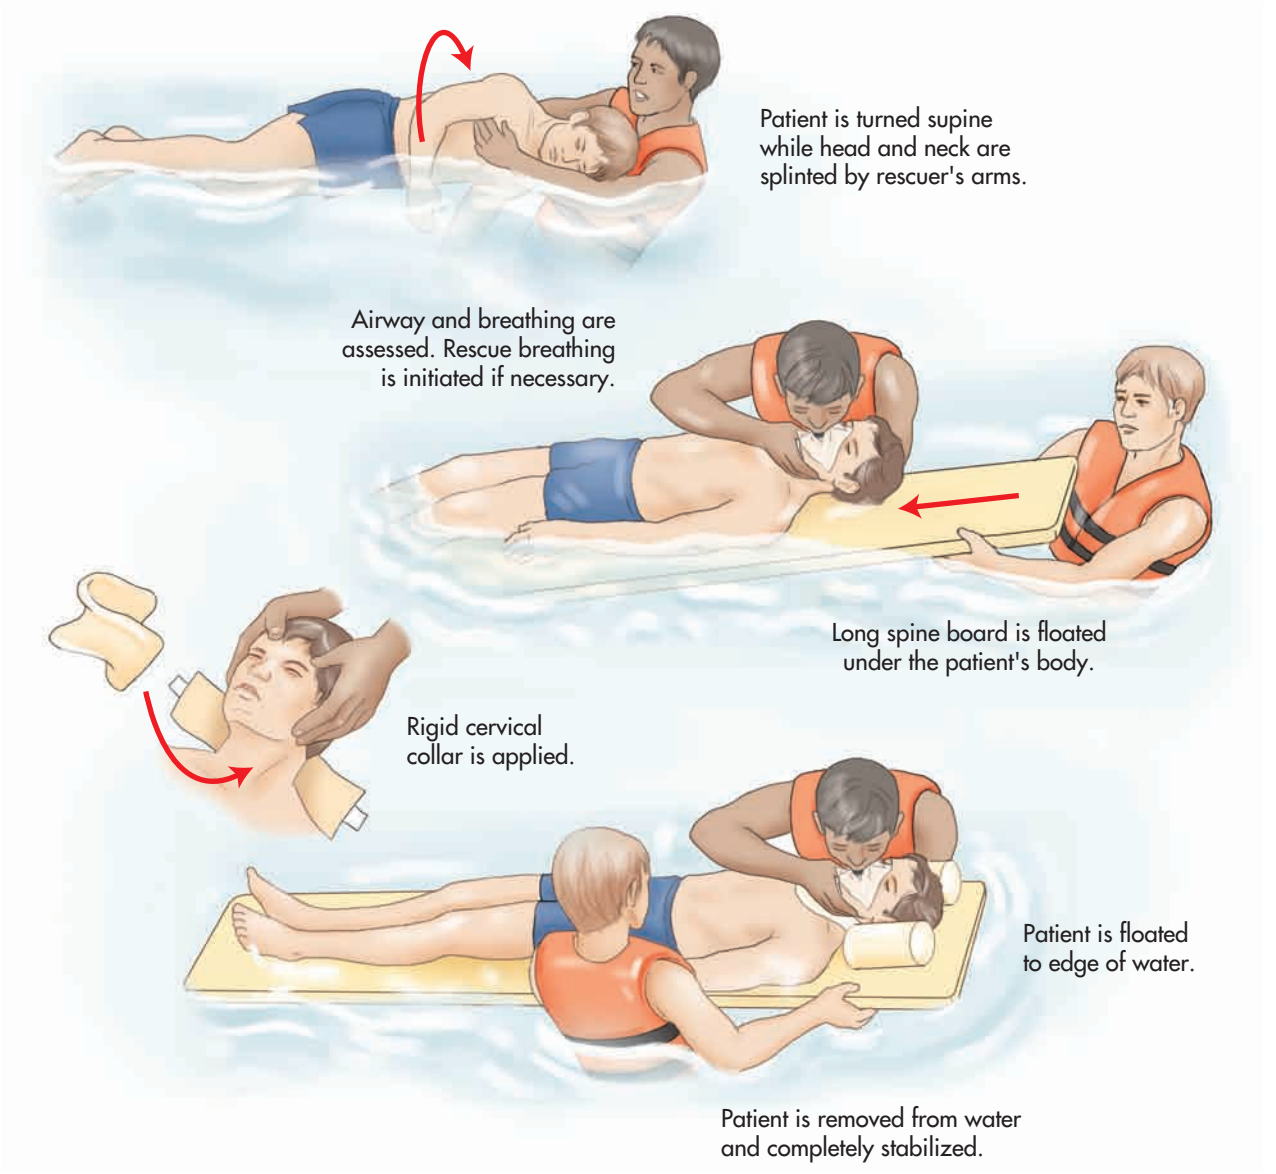

FIGURE 41-24 Extrication of a diving accident victim. Rescue breathing with barrier protection can begin in the water.

paramedic may initiate rescue breathing while in the water.[10])

4. A second rescuer slides a long spine board or other rigid device under the patient's body while the first rescuer continues to support the patient's head and neck without flexion or extension. Apply a rigid cervical collar. Maintain manual in-line immobilization throughout the rescue.
5. Float the spinal immobilization device to the edge of the water and lift it out.
6. The patient should be immobilized completely on the long spine board as previously described.

CORD INJURY PRESENTATIONS

Three cord injury presentations deserve special mention. These include spinal shock, neurogenic hypotension, and autonomic hyperreflexia syndrome.

Spinal Shock

Spinal shock refers to a temporary loss of all types of spinal cord function distal to the injury. Signs and symptoms of spinal shock include flaccid paralysis distal to the injury site and loss of autonomic function, which may be demonstrated by hypotension, vasodilation, loss of bowel and bladder control, priapism, and loss of thermoregulation. Spinal shock does not always involve permanent, primary injury. The autonomic dysfunction usually resolves within 24 hours. Rarely, though, spinal shock may last a few days to a few weeks. Careful handling of these patients to avoid secondary injury is crucial. Initial management includes full spinal immobilization, high-concentration oxygen administration, and administration of intravenous crystalloids (per protocol).

Neurogenic Shock

Neurogenic shock (*neurogenic hypotension*) following spinal shock results from the blockade of vasoregulatory fibers, motor fibers, and sensory fibers. This block produces a loss of sympathetic tone to the vessels or vasodilation. Patients with neurogenic hypotension often have relative hypotension (a systolic blood pressure of 80 to 100 mm Hg); warm, dry, and pink skin (from cutaneous vasodilation); and relative bradycardia.

Neurogenic hypotension is rare. Initially, it should not be considered as a cause of hypovolemia in the patient with a spine injury. The paramedic should consider other causes of hypotension, including internal hemorrhage, cardiac tamponade, and tension pneumothorax. If hypotension is severe, the paramedic should initiate shock management (per protocol), as described in Chapter 36: Shock.

Autonomic Hyperreflexia Syndrome

Autonomic hyperreflexia syndrome may occur after resolution of spinal shock and is associated with chronic SCI in patients who have injuries at T6 or above.[5] (The syndrome often is caused by a distended bladder or rectum.) The effects of this syndrome result from a massive, uncompensated cardiovascular response that stimulates the sympathetic nervous system. The stimulation of sensory receptors below the level of cord injury causes the intact autonomic nervous system to respond with spasms of the arterioles. These spasms in turn increase blood pressure. The baroreceptors sense the rise in blood pressure. They stimulate the parasympathetic nervous system. This decreases heart rate and sends the message to the peripheral and visceral vessels to dilate. Because of the cord injury, however, vasodilation is not possible. Thus blood pressure continues to rise and could pose a threat to life. The characteristics of this syndrome include the following:

- Paroxysmal hypertension (up to 300 mm Hg)
- Pounding headache
- Blurred vision
- Sweating (above the level of injury) with flushing of the skin
- Increased nasal congestion
- Nausea
- Bradycardia (30 to 40 beats/min)
- Distended bladder or rectum

Emptying of the bladder or bowel often relieves the syndrome. Blood pressure may need to be controlled with antihypertensive agents. These patients are best managed in the hospital setting under close physician supervision.

NONTRAUMATIC SPINAL CONDITIONS

The nontraumatic spinal conditions to be discussed in this chapter include low back pain, degenerative disk disease, spondylosis, herniated intervertebral disk, and spinal cord tumors.

Low Back Pain

Between 60% and 90% of the U.S. population is estimated to experience some form of low back pain.[11] Low back pain usually affects the area between the lower rib cage and the gluteal muscles. The pain often radiates into the thighs. About 1% of those with low back pain have sciatica. (This is pain in the lumbar nerve root accompanied by neurosensory and motor deficits in the thigh and leg.) Most low back pain is idiopathic. That makes a precise diagnosis difficult. Causes of this condition include the following (described in Chapter 33):

- Tension from tumors
- Disk prolapse
- Bursitis
- Synovitis
- Degenerative joint disease
- Abnormal bone pressure
- Inflammation caused by infection (e.g., osteomyelitis)
- Fractures
- Ligament strains

CRITICAL THINKING

What are some other medical conditions that may cause the patient to have a chief complaint of low back pain?

Risk factors associated with low back pain include occupations that require repetitive lifting or exposure to vibrations from vehicles or industrial machinery and also osteoporosis (elderly women report more symptoms than men).

Low back pain must come from innervated structures. However, deep pain and the way it is referred to other parts of the body vary by individual. Although the disk has no specific innervation, irritation of surrounding membranes that have pain receptors often develops. (This occurs especially in the presence of disk prolapse.) The source of most low back pain is at L3, L4, L5, and S1. Other areas of abundant pain receptors are found in anterior and posterior longitudinal ligaments that are vulnerable to strains and sprains.

Degenerative Disk Disease

Degenerative disk disease is a common finding in persons older than 50 years of age. The causes of this condition include deterioration of the tissue of the intervertebral disk that occurs with aging. The associated narrowing of the disk results in instability of the spine and can cause occasional low back pain.

Spondylosis

Spondylosis is a structural defect of the spine. It involves the lamina or vertebral arch. Spondylosis usually occurs in the lumbar spine between superior and inferior articulating surfaces. (Rotational stress fractures are common at the affected site.) Heredity appears to be a key factor for this condition.

Herniated Intervertebral Disk

Herniated intervertebral disk (*herniated nucleus pulposus*) refers to a tear in the posterior rim of the capsule that encloses the gelatinous center of the disk. Rupture of the disk usually is caused by trauma, degenerative disk disease, and improper lifting (most common). Men between the ages of 30 and 50 are more prone to develop this condition. Disks that most commonly are affected are L5-S1 and L4-L5. (Herniated intervertebral disk also at times occurs in the cervical area at C5-C6 and C6-C7.) These injuries may have an immediate onset. They also may develop over months to years.

Spinal Cord Tumors

Tumors in the spinal cord may develop from cord compression, from degenerative changes in bones and joints, or from an interruption in the blood supply to the cord. These tumors are classified by cell type, growth rate, and structure of origin. Clinical manifestations depend on tumor type and location. The manifestations may include bilateral or asymmetrical motor dysfunction, paresis, spasticity, pain, temperature dysfunction, sensory changes, and other abnormalities.

ASSESSMENT AND MANAGEMENT OF NONTRAUMATIC SPINAL CONDITIONS

As stated before, nontraumatic spinal conditions such as low back pain are difficult to diagnose. The assessment and management are based on the patient's chief complaint, the physical examination, and the evaluation of associated risk factors. Signs and symptoms that commonly are seen with nontraumatic spinal conditions include the following:

- Discomfort
- Difficulty in standing erect
- Pain with straining (e.g., coughing, sneezing)
- Limited range of motion
- Alterations in sensation, pain, and temperature
- Upper extremity pain or paresthesia that increases with motion
- Motor weakness

The management of patients with back pain in the prehospital setting mainly is supportive. Management focuses on decreasing the patient's pain and discomfort. Some patients are best managed with immobilization on a full spine board or vacuum-type stretcher. These devices prevent movement. Full spinal immobilization is not required unless the condition is a result of trauma. The in-hospital evaluation may include various testing such as computed tomography, electromyelography, and magnetic resonance imaging.

SUMMARY

- Most SCIs are the result of motor vehicle crashes. Other causes are falls, penetrating injuries from acts of human violence, and sport injuries.
- The spinal column is composed of 33 vertebrae. These are divided into five sections. The sections are 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused), and 4 coccygeal (fused).
- The paramedic can classify the MOI as positive, negative, or uncertain. This classification is combined with the clinical guidelines for evaluating SCI, which include

Continued

the following signs and symptoms: pain, tenderness, painful movement, deformity, cuts/bruises over spinal area, paralysis, paresthesias, and weakness. This system can help to identify cases in which spinal immobilization is appropriate.

- The specific mechanisms of injury that frequently cause spinal trauma are axial loading; extremes of flexion, hyperextension, or hyperrotation; excessive lateral bending; and distraction.
- Spinal injuries may be classified as sprains and strains, fractures and dislocations, sacral and coccygeal fractures, and cord injuries. The spinal cord may sustain a primary or a secondary injury. Lesions (transections) of the spinal cord are classified as complete or incomplete.
- With spinal injuries, the first priority is to evaluate and manage any threats to life. The second priority is to preserve spinal cord function. This includes avoiding secondary injury to the spinal cord. These goals are best met by maintaining a high degree of suspicion for the presence of spinal trauma, by providing early spinal immobilization, by rapidly correcting any volume deficit, and by administering oxygen.
- General principles of spinal immobilization include prevention of further injury; treating the spine as a long bone with a joint at either end (the head and pelvis); always using complete spinal immobilization; beginning spinal immobilization in the initial assessment and maintaining it until the spine is immobilized completely on the long spine board; and placing the patient's head in a neutral, in-line position, unless contraindicated.
- Spinal shock refers to a temporary loss of all types of spinal cord function distal to the injury.
- Neurogenic shock produces a loss of sympathetic tone to the vessels. This causes relative hypotension; warm, dry, and pink skin; and relative bradycardia.
- Autonomic hyperreflexia syndrome results from a massive, uncompensated cardiovascular response that stimulates the sympathetic nervous system. This response in turn causes an increase in blood pressure and other symptoms.

CHAPTER

42 Chest Trauma

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Discuss the mechanism of injury associated with chest trauma.
2. Describe the mechanism of injury, signs and symptoms, and management of skeletal injuries to the chest.
3. Describe the mechanism of injury, signs and symptoms, and prehospital management of pulmonary trauma.
4. Describe the mechanism of injury, signs and symptoms, and prehospital management of injuries to the heart and great vessels.
5. Outline the mechanism of injury, signs and symptoms, and prehospital care of the patient with esophageal and tracheobronchial injury and diaphragmatic rupture.

KEY TERMS

atelectasis An abnormal condition characterized by the collapse of lung tissue, which prevents the respiratory exchange of oxygen and carbon dioxide.

Beck's triad A combination of three symptoms that characterize cardiac tamponade: elevated central venous pressure, muffled heart sounds, and hypotension.

closed pneumothorax A collection of air or gas in the pleural space that causes the lung to collapse without exposing the pleural space to atmospheric pressure.

commotio cordis Sudden death that follows a blow to the chest.

costochondral separation Separation of the costochondral cartilages.

crepitus A grating sound associated with rubbing of bone fragments.

diaphragmatic rupture Traumatic rupture of the diaphragm that results from sudden compression of the abdomen.

electrical alternans Refers to a change in the amplitude of a patient's ECG waveforms that decrease with every other cardiac cycle; it is a rare finding in cardiac tamponade.

flail chest A chest wall injury in which three or more adjacent ribs are fractured in two or more places.

hemopneumothorax A collection of air and blood in the pleural space; also known as a *pneumohemothorax.*

hemothorax The accumulation of blood and other fluids in the pleural space caused by bleeding from the lung parenchyma or damaged vessels.

jugular notch The superior margin of the manubrium; it is palpated easily at the anterior base of the neck; also known as the *suprasternal notch.*

manubrium One of the three bones of the sternum; it has a broad, quadrangular shape that narrows caudally at its articulation with the superior end of the body of the sternum.

mediastinal shift A shift in a patient's mediastinum that moves tissue and organs within the chest cavity to one side.

myocardial rupture Traumatic rupture of the myocardium that occurs when blood-filled chambers of the ventricles are compressed with enough force to rupture the chamber wall, septum, or valve.

open pneumothorax A chest wall injury that exposes the pleural space to atmospheric pressure.

paradoxical motion Contrary movement of an injured segment of the chest wall with inspiration and expiration.

pericardial tamponade Compression of the heart produced by the accumulation of fluid or blood in the pericardial sac.

pulmonary contusion Bruising of the lung tissue that results in rupture of the alveoli and interstitial edema.

pulsus paradoxus An abnormal decrease in systolic blood pressure that drops more than 10 to 15 mm Hg during inspiration compared with expiration.

sternal angle The point at which the manubrium joins the body of the sternum; also known as the *angle of Louis.*

sternal fracture Fracture of the sternum.
sternoclavicular joint The double gliding joint between the sternum and the clavicle.
tension pneumothorax An accumulation of air or gas in the pleural cavity that can lead to collapse of the lung.
tracheal deviation Movement of the trachea from its midline position to the right or left.
traumatic aortic rupture Rupture of the aorta that is thought to be a result of shearing forces.
traumatic asphyxia A severe crushing injury to the chest and abdomen that causes an increase in the intrathoracic pressure. The increased pressure forces blood from the right side of the heart into the veins of the upper thorax, neck, and face.

Chest injuries are directly responsible for more than 20% of all traumatic deaths (regardless of mechanism) and account for about 16,000 deaths per year in the United States.[1] Chest injuries are caused by blunt trauma, penetrating trauma, or both.[2] They often are the result of motor vehicle crashes, falls from heights, blast injuries, blows to the chest, chest compression, gunshot wounds, and stab wounds. Thoracic trauma may be classified as skeletal injury, pulmonary injury, heart and great vessel injury, and diaphragmatic injury. (Anterior neck trauma is presented in Chapter 40.)

(Courtesy Ray Kemp, St. Charles, Mo.)

SKELETAL INJURIES

Skeletal injuries may be caused by blunt and/or penetrating trauma. The injuries discussed in this chapter include clavicular fractures, rib fractures, flail chest, and sternal fractures. Chest anatomy was presented in Chapter 10. To review, the thoracic cage protects vital organs within the chest. It also prevents the collapse of the thorax during respiration. The skeletal components of the thoracic cage include the 12 thoracic vertebrae, 12 ribs (with their associated costal cartilages), and the sternum. The superior 7 ribs (the *true ribs*) are attached by cartilage to the sternum. The inferior 5 ribs (the *false ribs*) articulate with the vertebrae, but do not attach directly to the sternum. Ribs 8, 9, and 10 are joined to a common cartilage, which is attached to the sternum. Ribs 11 and 12 are "floating ribs." These ribs have no attachment to the sternum.

The sternum has three parts: the **manubrium,** the *body,* and the **xiphoid process.** The **jugular notch** is located at the superior end of the manubrium. The manubrium joins the body of the sternum at the **sternal angle.** (The sternal angle is also known as the *angle of Louis*.) The **clavicles** are part of the appendicular skeleton. They attach the upper limbs to the axial skeleton. This attachment is made at the **sternoclavicular joint** between the clavicles and the sternum (Figure 42-1).

See Chapter 10: Review of Human Systems, pp. 158-162.

Clavicular Fractures

The clavicle accounts for 5% of all fractures and is the most frequently fractured bone in children.[1] An isolated clavicular fracture is seldom a significant injury (Figure 42-2). It is common in children who fall on their shoulders or outstretched arms. It also is common in athletes involved in contact sports. Treatment usually involves applying a clavicle strap or a sling and swathe that immobilizes the affected shoulder and arm (see Chapter 44). These injuries usually heal well within 4 to 6 weeks.

Signs and symptoms of clavicular fractures include pain, point tenderness, and evident deformity. A rare complication that may be associated with a clavicular fracture is injury to the subclavian vein or artery. Vascular injury can occur when bony fragments from the fracture puncture a vessel, resulting in a hematoma or venous thrombosis.

Rib Fractures

Rib fractures most often occur on the lateral aspect of the third through eighth ribs, where the ribs are least protected by musculature (Figure 42-3). Fractures are more likely to occur in adults than in children. This is because younger patients have more resilient cartilage that is not fully calcified. (When blunt forces are applied to the ribs of children, the energy is transmitted to the lung, where pulmonary contusion is a more frequent injury than rib fracture.) Morbidity or mortality from rib fractures depends on the patient's age and the number and location of the fractures.

FIGURE 42-3 Chest wall asymmetry caused by rib fractures. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

CRITICAL THINKING

Why would you expect greater underlying pulmonary injury in a child versus an adult with rib fractures?

NOTE

Separation of the costochondral cartilages also can occur from blunt anterior chest trauma. Signs and symptoms are similar to those for rib fracture. In addition, the patient may complain of a "snapping" sensation with deep respiration. These patients should be evaluated by a physician to rule out cardiac contusion. The pain associated with **costochondral separation** can persist for several weeks.

Simple rib fractures usually are very painful. However, they rarely are life threatening. Most patients can localize the fracture by pointing to the area. (This is confirmed by palpation.) Sometimes movement or grating of the bone ends (**crepitus**) can be felt. One complication of rib fracture is *respiratory or diaphragmatic splinting.* This occurs when the patient uses breath holding or minimizes chest wall movement to lessen pain. This splinting can lead to **atelectasis** (the collapse of lung tissue). Another complication is ventilation-perfusion mismatch (perfused alveoli that are not ventilated).

The goals of treatment for rib fractures are to relieve the pain and maintain pulmonary function to prevent atelectasis. (The paramedic should encourage the patient to cough and to breathe deeply.) Pain may be relieved by splinting the patient's arm against the chest wall with a sling and swathe. (Circumferential splinting should not be used because it may not allow complete expansion of the chest

wall during respiration.) Administration of analgesics (per protocol) also may be helpful. Based on the mechanism of injury, the paramedic should consider the possibility of more serious trauma, such as closed pneumothorax and internal bleeding. Fractures to the lower ribs (8 through 12) may be associated with injuries to the spleen, kidneys, or liver.

Great force is required to fracture the first and second ribs. This is because of their shape and the protection provided by the scapulae, clavicles, and upper chest musculature. Fractures of the first and second ribs may be associated with myocardial contusion, bronchial tears, and vascular injury.

NOTE
The true danger of a fractured rib is not the injured rib. Rather, it is the potential for penetrating injury to the pleura, lung, liver, or spleen. Elderly patients or patients with preexisting respiratory disease are often unable to compensate for even minor trauma to the chest wall. These patients require careful monitoring for respiratory distress or fatigue.

Flail Chest

A **flail chest** may occur when three or more adjacent ribs are fractured in two or more places[1] (Figure 42-4). This injury may be difficult to detect in the prehospital setting because of the muscle spasm that often accompanies the injury. Within 2 hours after the injury, however, the muscle spasm subsides. At that point, the injured segment of the chest wall may begin to move in a contrary fashion (**paradoxical motion**) with inspiration and expiration. This interrupts the normal mechanics of breathing and decreases effective ventilation.

Causes of flail chest include vehicle crashes, falls, industrial accidents, assault, and birth trauma. The mortality rate is 8% to 35% because of underlying, associated injuries.[1] The mortality rate increases with advanced age, seven or more rib fractures, three or more associated injuries, shock, and head injury.

As described in Chapter 15, the diaphragm descends during inspiration. This lowers the intrapleural pressure. The unstable chest wall is pushed ("sucked") inward by the negative intrathoracic pressure as the rest of the chest wall expands. During expiration, the diaphragm rises, and the intrapleural pressure exceeds atmospheric pressure. This causes the unstable chest wall to move outward. Patients with flail chest often develop hypoxia. This is because of the lung contusions usually related to this injury. Bleeding from the alveoli and the lung tissue causes the contusion. It is associated with decreased vital capacity and vascular shunting of deoxygenated blood. Signs and symptoms of flail chest include bruising, tenderness, and bony crepitus on palpation and paradoxical motion (a late sign).

Prehospital management of patients with flail chest includes assisting ventilation with high-concentration supplemental oxygen and providing fluid replacement as needed. Field stabilization of the flail segment is not recommended.[3] Many authorities recommend intubation and positive-pressure ventilation (internal splinting) in patients with severe respiratory distress and a flail chest. Intubation also may be indicated if the chest injury is associated with shock, other severe injuries, head injury, or pulmonary disease, or if it occurs in a patient older than 65 years of age.

As a rule, the most conservative methods for obtaining adequate oxygenation and ventilation should be used to manage patients with flail chest.[1] A large percentage

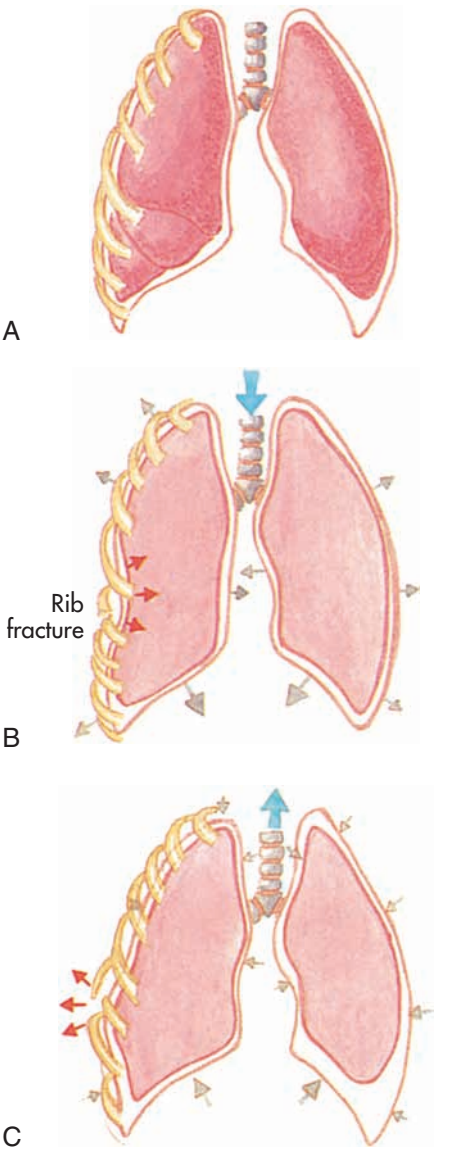

FIGURE 42-4 Flail chest. **A,** Normal lungs. **B,** Flail chest during inspiration. **C,** Flail chest during expiration.

LOOK AGAIN
See Chapter 15: Airway Management, Respiration, and Artificial Ventilation, pp. 391-393.

of patients with significant chest injury will progress to respiratory failure. This requires long-term ventilatory support and hospitalization.

CRITICAL THINKING
Why is positive-pressure ventilation the treatment of choice for this injury?

Sternal Fractures

A **sternal fracture** is an uncommon but serious injury. The fracture usually results from a direct blow to the chest (e.g., striking a steering column or dashboard) or from a massive crush injury (Figure 42-5). Sternal fractures usually are very painful. They may be associated with an unstable chest wall, myocardial injury, or cardiac tamponade. They occur in only 5% to 8% of patients with blunt chest trauma. However, the mortality rate is 25% to 45%.[4] Signs and symptoms include a history of significant anterior chest trauma, tenderness, and abnormal motion or crepitation over the sternum. Prehospital management includes maintaining a high degree of suspicion for associated injuries. These patients are best managed with airway maintenance, ventilatory support, pulse oximetry and electrocardiographic (ECG) monitoring, and rapid transport to an appropriate medical facility. Associated injuries that often contribute to serious disability or death include the following:

- Pulmonary and myocardial contusion
- Flail chest
- Vascular disruption of thoracic vessels (rare)
- Intraabdominal injuries
- Head injury

FIGURE 42-5 Well-marked band of spotty bruising caused by steering wheel impact. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

PULMONARY INJURIES

Pulmonary injuries may be classified as closed pneumothorax, tension pneumothorax, open pneumothorax, hemothorax, pulmonary contusion, and traumatic asphyxia. Any of these injuries can result in difficulty in breathing and respiratory insufficiency. Prehospital treatment must be directed at ensuring an open airway, providing ventilatory support, correcting immediately life-threatening ventilatory problems (e.g., tension pneumothorax), and arranging rapid transport for definitive care.

Closed Pneumothorax

A **closed pneumothorax** (*simple pneumothorax*) is caused by the presence of air in the pleural space. This air causes the lung to partially or totally collapse (Figure 42-6). A common cause of pneumothorax is a fractured rib that penetrates the underlying lung. Pneumothoraces also may occur without rib fractures. They may be caused by excessive pressure on the chest wall against a closed glottis (paper bag effect; see Chapter 37: Trauma Overview and Mechanism of Injury). They also may be caused by rupture or tearing of the lung tissue and visceral pleura from no apparent cause (e.g., spontaneous pneumothorax). Closed pneumothorax occurs in 15% to 50% of patients with severe blunt chest trauma, and in almost 100% of patients with penetrating chest trauma.[1]

CRITICAL THINKING
How does high-flow oxygen promote faster resolution of a closed pneumothorax?

FIGURE 42-6 Closed (simple) pneumothorax.

The signs and symptoms of a closed pneumothorax are dependent on the severity of hypoxia, the degree of impairment of ventilation, and the percentage of the lung that has collapsed. These signs and symptoms may include chest pain, dyspnea, and tachypnea. Breath sounds may be diminished or absent on the affected side. Treatment includes ventilatory support with high-concentration oxygen. The patient should be carefully monitored for signs of a tension pneumothorax (described later). Patients should be transported in a semisitting position of comfort unless this position is contraindicated by the mechanism of injury. If the patient's respiratory rate is below 12 or above 28 breaths per minute, ventilatory assistance with a bag-valve-mask (BVM) may be indicated.[3]

Most healthy patients have large circulatory and ventilatory reserve capacities. Therefore closed pneumothoraces usually do not pose a threat to life. However, life-threatening consequences may develop if the pneumothorax is a tension pneumothorax, if it occupies more than 40% of the hemithorax, or if it occurs in a patient with shock or preexisting pulmonary or cardiovascular diseases.

Open Pneumothorax

An **open pneumothorax** (*communicating pneumothorax*) develops when a chest injury exposes the pleural space to atmospheric pressure (Figure 42-7). The severity of the injury is directly proportional to the size of the wound. When a chest wound is larger than the normal pathway for air through the nose and mouth, atmospheric pressure forces the air through the open wound and into the thoracic cavity during inspiration. As the air accumulates in the pleural space, the lung on the injured side collapses. The lung begins to shift toward the uninjured side. Very little air enters the tracheobronchial tree to be exchanged with intrapulmonary air on the affected side. This results in decreased alveolar ventilation and decreased perfusion. The normal side also is adversely affected. That is because expired air may enter the lung on the collapsed side. It then is rebreathed into the functioning lung with the next ventilation. This may result in severe ventilatory dysfunction, hypoxemia, and death unless the condition is quickly recognized and corrected.

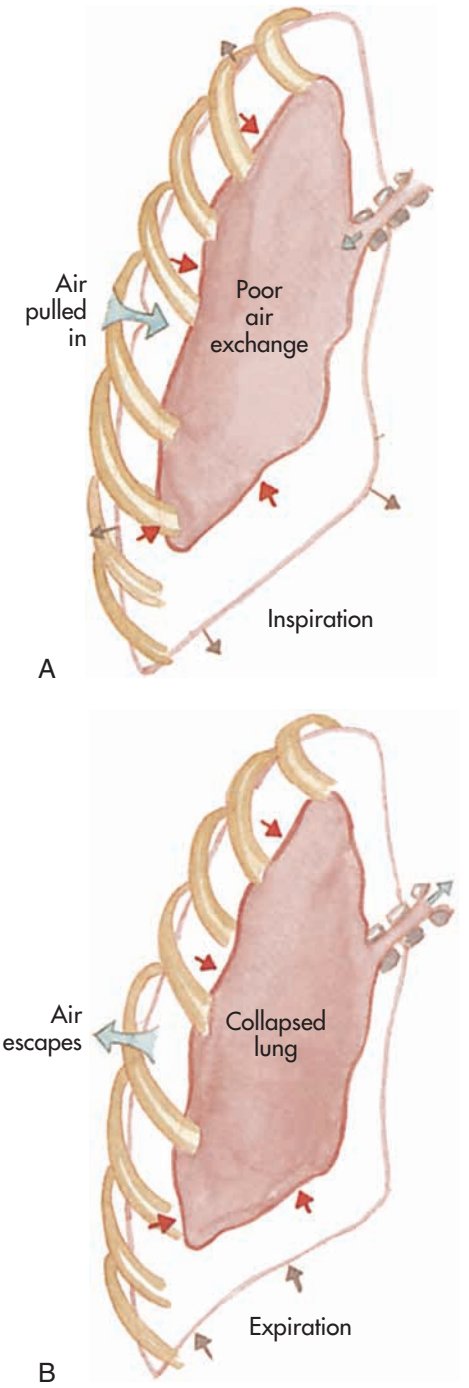

FIGURE 42-7 Open pneumothorax. **A,** Air enters the pleural cavity during inspiration. **B,** Air exits the pleural cavity during expiration.

NOTE
A small open chest wound may function like a ball-valve mechanism. That is, it may allow air in but not out. The accumulation of air may result in a shift in the patient's mediastinum, moving the tissue and organs within the chest cavity to one side. A **mediastinal shift** can lead to reduced preload and a reduction in cardiac output (Figure 42-8).

Signs and symptoms of open pneumothorax include shortness of breath, pain, and a sucking or gurgling sound as air moves in and out of the pleural space through the open chest wound (thus the term *sucking chest wound*).

Prehospital treatment of an open pneumothorax proceeds as follows (Figure 42-9):

1. Close the chest wound by first applying direct pressure with a gloved hand. The chest wound can then be sealed by applying an occlusive dressing of petroleum gauze[1] or a dressing of foil or plastic, and securing it with tape.[3] Medical direction may advise that only three sides of the dressing be taped. This provides a venting mechanism (or one-way valve). It also may allow spontaneous

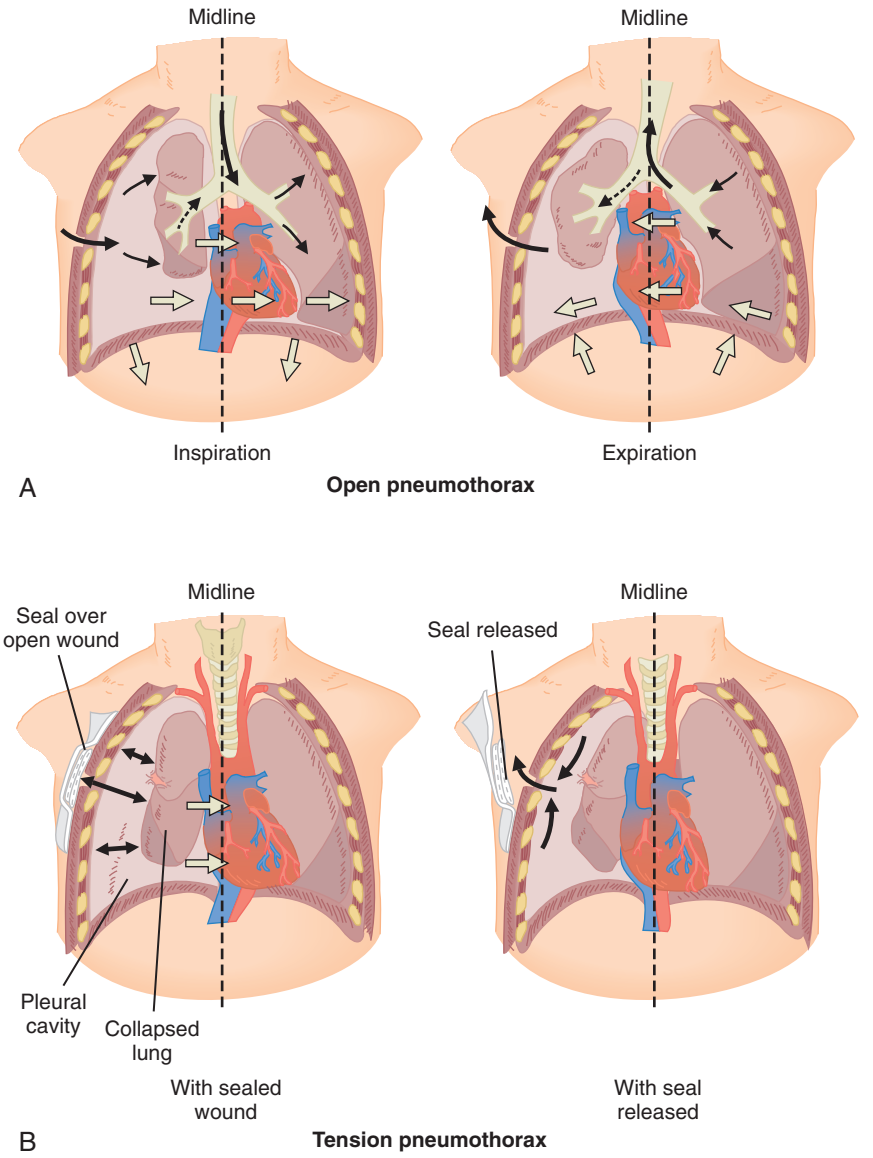

FIGURE 42-8 **A,** Open pneumothorax. Solid and dashed arrows represent air movement; open arrows represent structural movement. On inspiration, air is sucked into the pleural space through the open chest wound and the lung on the affected side collapses. The mediastinal contents shift toward the unaffected side. On expiration, air exits through the open wound and the mediastinal contents swing back toward the affected side (mediastinal flutter). **B,** An airtight dressing can cause a tension pneumothorax when air accumulates in the pleural space through a tear in the lung tissue. The air cannot exit if there is no open chest wound, and pressure builds, shifting the contents of the mediastinum toward the unaffected side and impairing circulatory and respiratory function (mediastinal shift). (From Linton AD: *Introduction to medical surgical nursing,* ed 4, St Louis, 2007, Saunders.)

decompression of a developing tension pneumothorax. The paramedic should closely monitor for the development of a tension pneumothorax if the patient's dressing does not provide a venting mechanism.

2. Provide ventilatory support with high-concentration oxygen and monitor oxygen saturation. Airway management includes assisting ventilations with a bag-mask device and intubation.
3. Treat the patient for shock by administering crystalloid (per protocol).
4. Rapidly transport the patient to an appropriate medical facility.

Tension Pneumothorax

When air in the thoracic cavity cannot exit the pleural space, a **tension pneumothorax** may develop (Figure 42-10). This is a true emergency. It results in profound hypoventilation and impaired perfusion. Tension pneumothorax may result in death if it is not immediately recognized and managed.

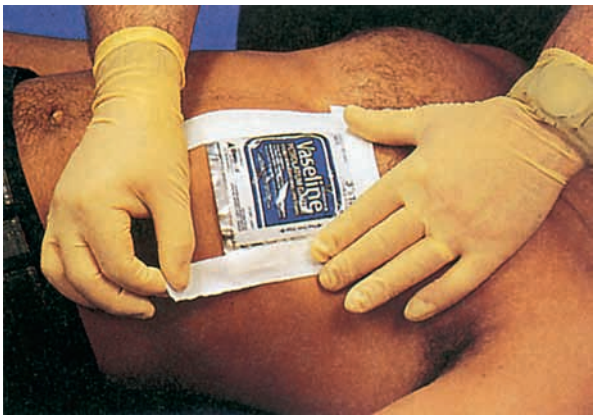

FIGURE 42-9 Sealing a chest wound.

When air is allowed to leak into the pleural space during inspiration and becomes trapped during expiration, the pleural pressure increases. This increase in pressure produces a shift in the mediastinum. It further compresses the lung on the uninjured side. In addition, compression of the vena cava reduces venous return to the heart. This results in a decrease in cardiac output. The signs and symptoms of a tension pneumothorax include the following:

- Anxiety
- Cyanosis
- Increasing dyspnea
- Tracheal deviation (a late sign)
- Tachycardia
- Hypotension or unexplained signs of shock
- Diminished or absent breath sounds on the injured side
- Distended neck veins (unless the patient is hypovolemic)
- Unequal expansion of the chest (tension does not fall with respiration)
- Subcutaneous emphysema

NOTE

Tracheal deviation may result from the displacement of mediastinal structures. However, tracheal deviation is an inconsistent finding with pneumothorax. If it occurs, it is often a late finding.[5] Tracheal deviation that results from chest injury is seldom seen in the prehospital setting.

CRITICAL THINKING

Why might the neck veins be distended in a patient with a tension pneumothorax?

A suspected tension pneumothorax should be managed aggressively. It is evidenced by increasing dyspnea, compromised ventilation, tachycardia, tachypnea, unilateral decreased or absent breath sounds, and hyperresonance on percussion. Emergency care is directed at reducing the pressure in the pleural space, that is, returning the intrapleural pressure to atmospheric or subatmospheric levels.

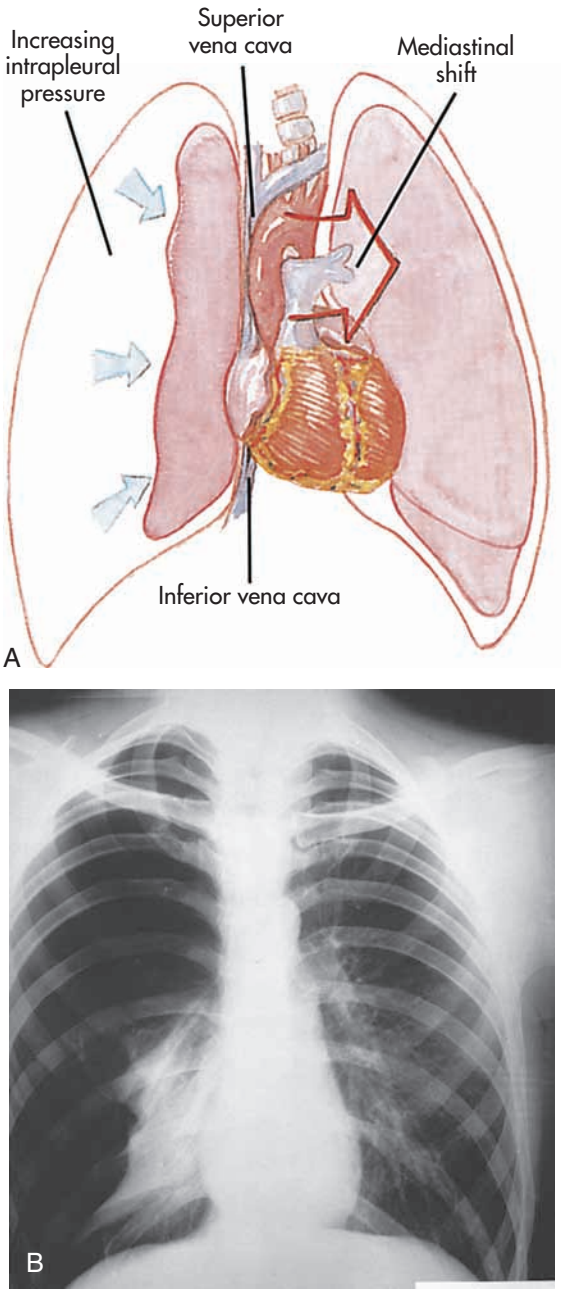

FIGURE 42-10 **A,** Tension pneumothorax. **B,** Tension pneumothorax of the right lung after a stab wound in this 25-year-old man. The collapsed lung has almost no air in it and is seen as a soft tissue density adjacent to the heart. (B from Kowalczyk N, Mace JD: *Radiographic pathology for technologists,* ed 5, St Louis, 2009, Mosby.)

NOTE

The value of chest percussion in the prehospital setting is questionable. In the field, it should not be the only method used to identify a tension pneumothorax or hemothorax.[3] As a rule, hyperresonance on percussion points to the presence of air (*pneumothorax*) or dullness on percussion pointing to the presence of blood and other fluids (*hemothorax*) should be used as identifiers.

SHOW ME THE EVIDENCE

Seattle authors reviewed 39 cases of needle thoracostomy (NT) in the field. In this EMS system NT is permitted after direct consultation with an online physician. Their insertion criteria include decreased breath sounds and blood pressure less than 90 mm Hg. In their study group, 56.4% (22) of patients were in cardiac arrest (12 trauma, 10 nontrauma). Of the remaining patients, 16 had trauma and 1 patient had a spontaneous tension pneumothorax. Of the 31 patients available for follow-up all had appropriately placed NT and none had complications related to the NT. Eight patients did not meet all insertion criteria. Of those eight, three had no evidence of pneumothorax. Four patients had return of circulation after NT. Data regarding survival to discharge were not available. The authors acknowledge the risk of NT, but conclude that under close medical supervision in an urban EMS system prehospital NT is a safe procedure.

From Warner KJ, Copass M, Bulger EM: Paramedic use of needle thoracostomy in the prehospital environment, *PEC* 12(2):162-168, 2008.

needle should be inserted just above the rib. (This point is used to avoid the nerve, artery, and vein that lie just beneath each rib.) After insertion of the needle, an audible rush of air should be noted. This is pressure escaping from the pleural space (confirming the tension pneumothorax). At this point, the patient should show signs of improvement (i.e., the patient's lungs will be easier to ventilate or the patient's breathing will be less labored). The needle should be withdrawn and the catheter secured in place with tape. Needle decompression may need to be repeated if the catheter becomes occluded with a blood clot and tension pneumothorax recurs.[3]

CRITICAL THINKING

Put your finger on the point on your chest where a needle would be inserted for decompression of a tension pneumothorax. Is it easy to identify?

TENSION PNEUMOTHORAX ASSOCIATED WITH PENETRATING TRAUMA

As mentioned previously, sealing an open pneumothorax with an occlusive dressing may produce a tension pneumothorax. In such cases the increased pleural pressure can be relieved by momentarily removing the dressing. When the dressing is lifted from the wound, an audible release of air from the thoracic cavity should be noted. If this does not occur and the patient's condition remains unchanged, the wound should be gently spread open with gloved fingers. This may allow the trapped air to escape. After the pressure has been released, the wound should again be sealed. The dressing may need to be removed more than once to relieve pleural pressure during transport. If the tension is not relieved with this procedure, needle decompression of the thorax (*needle thoracentesis; needle thoracostomy*) should be performed. Needle decompression should be performed when three findings are present[3]:

1. Worsening respiratory distress or increasing difficulty ventilating with a BVM device
2. Unilateral decreased or absent breath sounds
3. Decompensated shock (systolic blood pressure <90 mm Hg)

TENSION PNEUMOTHORAX ASSOCIATED WITH CLOSED TRAUMA

A tension pneumothorax that develops in a patient with closed chest trauma must be relieved through thoracic decompression. This can be done with a large-bore needle or a commercially available thoracic decompression kit.

For needle decompression, a large-bore, 10- or 14-gauge hollow catheter-over-needle (8 cm or longer)[3] is inserted into the affected pleural space. The needle can be inserted anteriorly in the second intercostal space in the midclavicular line. It may also be placed in the fourth or fifth intercostal space laterally on the involved side[1] (Figure 42-11). The

HEMOTHORAX

A **hemothorax** is the accumulation of blood in the pleural space. It is caused by bleeding from the lung parenchyma or damaged vessels (Figure 42-12). If this condition is associated with a pneumothorax, it is called a **hemopneumothorax.** Blood loss may be massive in these patients; each side of the thorax can hold 30% to 40% (2000 to 3000 mL) of the patient's blood volume.[6] (A severed intercostal artery can easily bleed 50 mL per minute.) Thus patients with a hemothorax often have hypovolemia and hypoxemia. Hemothorax is commonly associated with pneumothorax (25%) and extrathoracic injuries (73%).[1]

As blood continues to fill the pleural space, the lung on the affected side may collapse. In rare cases the mediastinum may even shift away from the hemothorax. This would compress the unaffected lung. The resultant effects of respiratory and circulatory compromise are responsible for the following signs and symptoms:

- Tachypnea
- Dyspnea
- Cyanosis (often not evident in hemorrhagic shock)
- Diminished or decreased breath sounds (dullness on percussion)
- Hypovolemic shock
- Narrow pulse pressure
- Tracheal deviation to the unaffected side (rare)

Prehospital care for patients with a hemothorax is directed at correcting ventilatory and circulatory problems. This involves administration of high-concentration oxygen; implementation of ventilatory support with a bag-mask device or intubation, or both; administration of volume-expanding fluids to correct the hypovolemia; and rapid transport to an appropriate medical facility. Hemothorax associated with great vessel or cardiac injury has a high mortality rate: 50% of these patients die within 1 hour of their injury.[7]

FIGURE 42-11 Needle decompression. **A,** A 2-inch, 10- or 14-gauge hollow needle or catheter is inserted into the affected pleural space, usually in the second intercostal space in the midclavicular line. **B,** After insertion of the needle, an audible rush of air should be noted as pressure escapes from the pleural space. **C,** The catheter is secured in place with tape. Care is taken to prevent reentry of air into the pleural space. The patient's respiratory status is monitored carefully.

CRITICAL THINKING

Hemothorax is associated with a higher mortality rate than a simple (closed) pneumothorax. Why is that the case?

Pulmonary Contusion

Pulmonary contusion most often is caused by rapid deceleration forces. (Such forces may be created by motor vehicle crashes and by injuries that result in a flail chest.) These forces push the lung against the chest wall. This results in rupture of the alveoli, with hemorrhage and swelling of the lung tissue. More than 50% of patients with blunt chest trauma have pulmonary contusion.[1]

During sudden inertial deceleration and direct impact, fixed and mobile parts of the lung move at varying speeds. The result is stretching and shearing of alveoli and intravascular structures. (This is the *inertial effect*.) This kinetic wave of energy is partly reflected at the alveolar membrane surface. The remainder causes a localized release of energy. (This is the *Spalding effect*.) Overexpansion of air in the lungs occurs after the primary energy wave has passed (*implosion effect*). Then low-pressure rebound shock waves cause overstretching and damage to lung tissue. The combination of these events results in alveolar and capillary damage with bleeding into the lung tissue and alveoli. The contused area of the lung is unable to function properly after injury. Therefore profound hypoxemia may develop. The degree of respiratory complication is directly related to the size of the contused area.

The signs and symptoms of pulmonary contusion are subtle at first. They should be suspected based on the kinematics of the event and the presence of associated injuries. Common signs and symptoms include the following:

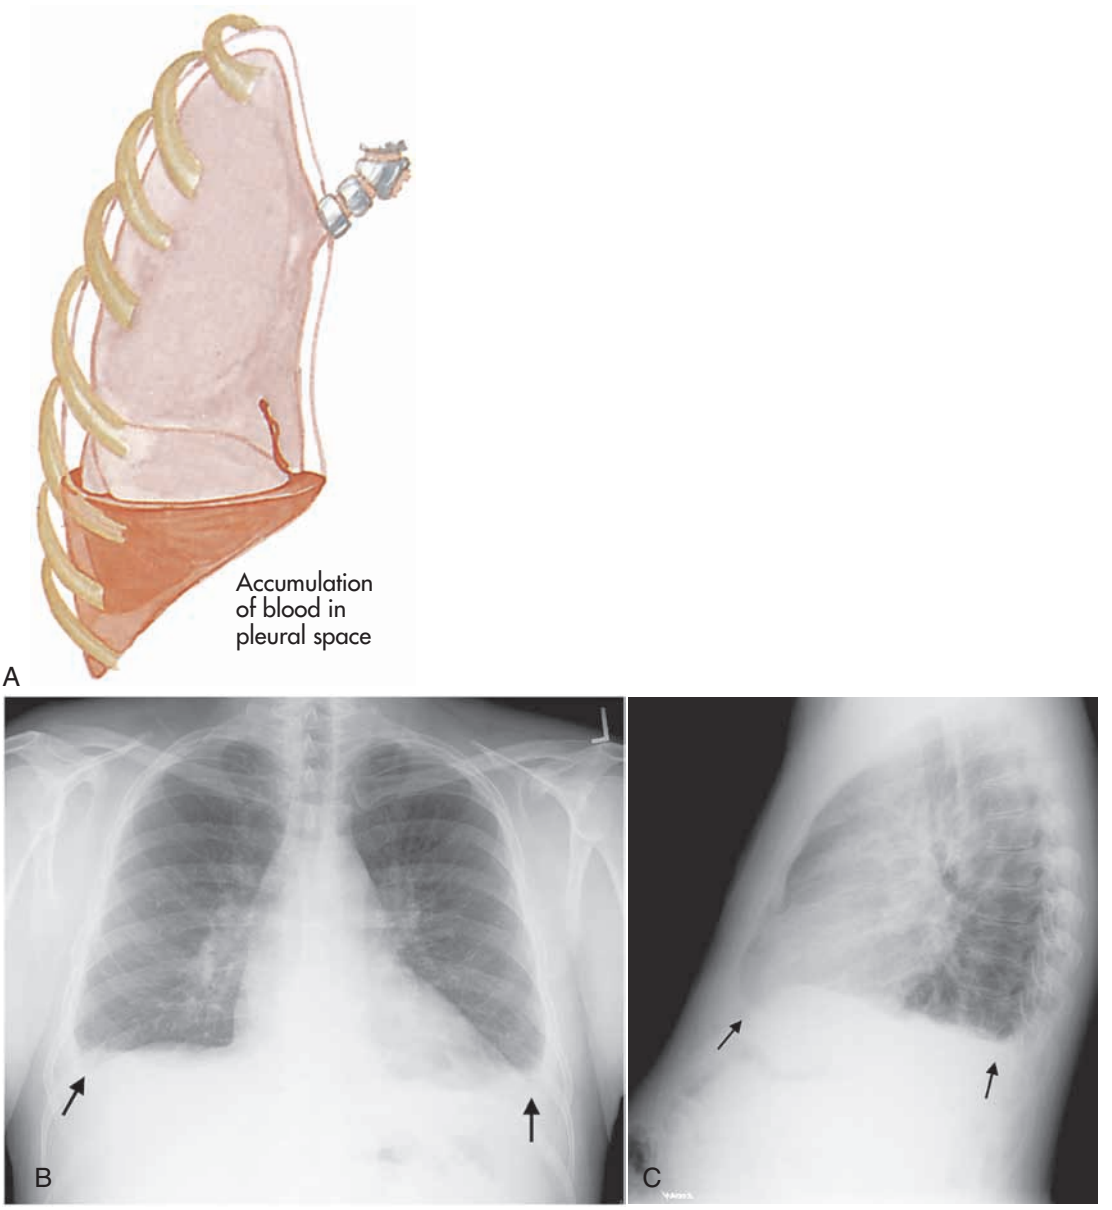

FIGURE 42-12 **A,** Hemothorax. **B,** Posteroanterior view. **C,** Left lateral chest radiograph demonstrating bilateral pleural effusions. (**B, C** from Kowalczyk N, Mace JD: *Radiographic pathology for technologists,* ed 5, St Louis, 2009, Mosby.)

- Tachypnea
- Tachycardia
- Cough
- Hemoptysis
- Apprehension
- Respiratory distress
- Dyspnea
- Evidence of blunt chest trauma
- Cyanosis

CRITICAL THINKING

Will you always be able to distinguish between simple pneumothorax and pulmonary contusion in the prehospital setting? Why or why not?

Emergency care for pulmonary contusion includes ventilatory support and administration of high-concentration oxygen. Patients with associated injuries or preexisting pulmonary or cardiovascular disease should be closely monitored in case ventilations need to be assisted with a bag-valve device, intubation, or both. Pulmonary contusions may be associated with a major chest injury. However, they generally heal spontaneously over several weeks.

Traumatic Asphyxia

The term **traumatic asphyxia** is used to describe a severe crushing injury to the chest and abdomen (Figure 42-13). It results from an increase in intrathoracic pressure. This pressure increase forces blood from the right side of the heart into the veins of the upper thorax, neck, and face. The

FIGURE 42-13 A victim of traumatic asphyxia displays ecchymosis and swelling above the level of the heart. A truck with a rear tire removed had slipped off the jack, trapping the patient underneath. At rescue the patient was in cardiac arrest. Prompt cardiopulmonary resuscitation by bystanders and early EMS response restored his circulation. He survived the injury. (From Henry MC, Stapleton ER: *EMT prehospital care,* ed 4, St Louis, 2009, Mosby.)

forces involved in this phenomenon may cause lethal injury, but traumatic asphyxia alone is not life threatening[1] (although brain hemorrhages, seizures, coma, and death have been documented to occasionally occur).

Signs and symptoms of traumatic asphyxia include reddish purple discoloration of the face and neck (the skin below the area remains pink), jugular vein distention, and swelling or hemorrhage of the conjunctiva (subconjunctival petechiae may appear). Emergency care is directed at ensuring an open airway, providing adequate ventilation, and caring for associated injuries. The paramedic should be ready to manage hypovolemia and shock when the compressive force is released.

HEART AND GREAT VESSEL INJURIES

Trauma to the heart and great vessels (i.e., the aorta, pulmonary arteries and veins, and superior and inferior venae cavae) may result from blunt or penetrating trauma and associated forces. The injuries discussed in this section include myocardial contusion, pericardial tamponade, myocardial rupture, and traumatic aortic rupture. Potentially fatal complications of these injuries include:

- Life-threatening dysrhythmias
- Conduction abnormalities
- Congestive heart failure
- Cardiogenic shock
- Cardiac tamponade
- Cardiac rupture
- Coronary artery occlusion

Myocardial Contusion

Myocardial contusions usually are caused by a vehicle collision. In these cases the chest wall strikes the dashboard or steering column. (Sternal and multiple rib fractures are common.) Therefore a deformed dashboard or steering column should alert the paramedic to the possibility of a cardiac injury. Blunt myocardial injury occurs in as many as 55% of patients who suffer blunt trauma to the chest.[1]

NOTE
The clinical findings in blunt cardiac trauma are often subtle and frequently overlooked for several reasons: (1) multiple injuries direct attention elsewhere; (2) often little evidence of thoracic injury is present; and (3) signs of cardiac injury may not be present on initial examination. The goals of prehospital care are to recognize the potential for cardiac trauma (based on mechanism of injury) and to monitor the patient for potentially fatal complications that may arise.

CRITICAL THINKING
How would you manage a cardiac rhythm disturbance resulting from a myocardial contusion?

The extent of injury may vary. The injury may be only a localized bruise. It also may be a full-thickness injury to the wall of the heart with hemorrhage and edema. Blood may accumulate in the pericardium (*hemopericardium*) as a result of a tear in the epicardium or endocardium. This, in turn, may result in cardiac rupture or a traumatic myocardial infarction. The fibrinous reaction at the contusion site may lead to delayed rupture or ventricular aneurysm.

Patients with a myocardial contusion may have no symptoms, or they may complain of chest pain similar to that seen with a myocardial infarction. Other signs and symptoms include ECG abnormalities, a new cardiac murmur, pericardial friction rub (late), persistent tachycardia (sinus tachycardia occurs in 70% of patients[1]), and palpitations. Emergency care for these patients is similar to that for myocardial infarction: oxygen administration, ECG monitoring, and pharmacological therapy for dysrhythmias and hypotension (see Chapter 22). Any intervention that increases myocardial oxygen demand should be avoided (Box 42-1).

Pericardial Tamponade

Penetrating trauma (and, in rare cases, blunt trauma) may cause tears in the heart chamber walls. This allows blood to leak from the heart. If the pericardium has been torn sufficiently, blood can leak into the thoracic cavity and the patient rapidly dies from hemorrhage. Often, however, the pericardium remains intact. In such cases the blood enters the pericardial space. This causes an increase in pericardial pressure and volume (**pericardial tamponade**). The increased pressure prevents the heart from expanding and refilling with blood (60 to 100 mL of blood and clots in the pericardial sac can cause tamponade). This results in a decrease in stroke volume and cardiac output. Myocardial

BOX 42-1 Commotio Cordis

Commotio cordis is a Latin term that means *commotion or disturbance of the heart*. The condition describes sudden death that follows a blow to the chest.[8] Cardiac arrest is thought to be secondary to ventricular fibrillation (VF) when the chest trauma coincides with the cardiac T wave. It may also be associated with coronary vasospasm or changes in mycoardial contractility as a result of the chest trauma. Although commotio cordis can happen to anyone, victims are overwhelmingly young male athletes. Despite the fact that it is very rare, commotio cordis is the leading cause of death in youth baseball (accounting for 2 to 20 deaths per year).[3,9]

Commotio cordis has also been documented in hockey, lacrosse, karate, and soccer.

Commotio cordis is managed in a manner similar to that used for cardiac arrests resulting from myocardial infarction rather than those resulting from trauma. The cardiac rhythm should be determined quickly and rapid defibrillation should be administered if VF is identified.[3]

perfusion decreases because of pressure effects on the walls of the heart and decreased diastolic pressures. Associated ischemic dysfunction may result in myocardial infarction. Pericardial tamponade occurs in fewer than 2% of patients who suffer blunt chest trauma; 60% to 80% of patients with stab wounds involving the heart develop tamponade.[1]

NOTE

Penetrating injuries to the heart, such as those caused by some knife and gunshot wounds, may result in death from hemorrhage rather than tamponade. This happens when the wound in the heart is so large that the blood in the pericardial space cannot be contained.

At first, most patients with pericardial tamponade have peripheral vasoconstriction. (The diastolic blood pressure rises more than the systolic blood pressure. This causes a decrease in pulse pressure.) These patients are also tachycardic. The increase in heart rate compensates for the decrease in cardiac output. Up to this point, pericardial tamponade and hemorrhagic shock have similar signs. Yet a key clinical finding often allows differentiation of the two forms of shock. This clinical finding was first described by Beck in 1935. It and two other clinical clues compose **Beck's triad.** Beck's triad consists of elevated central venous pressure (evidenced by jugular vein distention), muffled heart sounds, and hypotension. The first element of Beck's triad, elevated central venous pressure, is the single best way to distinguish pericardial tamponade from hemorrhagic shock.[1] Other signs and symptoms of pericardial tamponade include the following:

- Tachycardia
- Respiratory distress

FIGURE 42-14 Lead II rhythm strip taken from a patient with acute pericarditis complicated by a large pericardial effusion and tamponade physiology. Note the resting sinus tachycardia with relatively low voltage and electrical alternans. (Courtesy Ary L. Goldberger, MD.)

- Narrow pulse pressure
- Cyanosis of the head, neck, and upper extremities

NOTE

It is important to stress that injuries other than pericardial tamponade can cause hypotension and elevated central venous pressure. These are most notably tension pneumothorax in trauma victims and cardiogenic shock. Patients with tamponade and hemorrhage may not initially have an elevated central venous pressure. In the field, a good indication of cardiac tamponade is the presence of jugular vein distention along with hypotension and tachycardia.

Two other findings in pericardial tamponade may include *pulsus paradoxus* and *electrical alternans*. **Pulsus paradoxus** is a systolic blood pressure that drops more than 10 to 15 mm Hg during inspiration compared with expiration. (Normally this drop is minimal.) The excessive decline in systolic pressure occurs in cardiac tamponade when pleural pressure is reduced during inspiration. The reduction of pleural pressure provides some relief from the tamponade and causes the inspiratory fall in arterial flow and systolic pressure. (Pulsus paradoxus is difficult to measure in the prehospital setting, especially if the patient is hypotensive.) **Electrical alternans** refers to a change in the amplitude of a patient's ECG waveforms that decrease with every other cardiac cycle (Figure 42-14). It is a rare finding in cardiac tamponade.

Pericardial tamponade is a true emergency. Pericardial blood must be removed in these patients. Also, the bleeding must be stopped if the patient is to survive the injury. Prehospital management includes careful monitoring, oxygen administration, aggressive fluid replacement to maintain adequate preload (if transport time is short), and rapid transport to an appropriate medical facility. Treatment at the medical facility involves *needle pericardiocentesis* to remove blood from the pericardial sac. Removal of as little as 20 mL may drastically improve cardiac output.[1]

Myocardial Rupture

Myocardial rupture occurs when blood-filled chambers of the ventricles are compressed with enough force to rupture the chamber wall, septum, or valve. The injury is nearly always immediately fatal. However, about 20% of patients will survive 30 minutes or longer, allowing time for surgical repair.[1] This may allow time for rapid transport and

surgical repair. Motor vehicle crashes are responsible for most cases of myocardial rupture, accounting for 15% of fatal thoracic injuries. Other proposed mechanisms include the following:

- Deceleration or shearing forces that disrupt the inferior and superior venae cavae
- Upward displacement of blood (causing an increase in intracardiac pressure) after abdominal trauma
- Direct compression of the heart between the sternum and vertebrae
- Laceration from a rib or sternal fracture
- Complications of myocardial contusion

These patients often present with a significant mechanism of injury. Signs and symptoms of congestive heart failure and cardiac tamponade may be present. (The patient should be closely monitored for signs of pericardial tamponade.) Prehospital care for these patients is mainly supportive. It includes airway and ventilatory support and rapid transport for definitive care. It is crucial that paramedics also consider the possibility of a tension pneumothorax in these patients. The signs and symptoms of tension pneumothorax mimic those of myocardial rupture with tamponade.

Traumatic Aortic Rupture

Traumatic aortic rupture is thought to be a result of shearing forces. These forces develop between tissues that decelerate at different rates. Common mechanisms of injury include rapid deceleration in high-speed motor vehicle crashes, falls from great heights, and crushing injuries. It has been estimated that one in six people who die in motor vehicle crashes has a rupture of the aorta.[1] Of these patients, 80% to 90% die at the scene as a result of massive hemorrhage. About 10% to 20% survive the first hour. This is because the bleeding is tamponaded by the surrounding adventitia of the aorta and intact visceral pleura. Of these individuals, 30% have ruptures within 6 hours. For these reasons, rapid and pertinent evaluation and transport to an appropriate medical facility are critical. Aortic rupture is responsible for 15% of all deaths from blunt trauma.

The usual site of damage to the aorta is in the distal arch. This is just beyond the branching of the left subclavian artery and proximal to the ligamentum arteriosum (Figure 42-15). The ligamentum arteriosum and descending thoracic arch are somewhat fixed. On the other hand, the transverse portion of the arch is somewhat mobile. If shearing forces exceed the tensile strength of the arch, the junction of the mobile and fixed points of attachment may be partly torn. If the outer layer of tissue around the aorta remains intact, the patient may survive long enough for surgical repair.

Aortic rupture is a severe injury. About 85% of patients die before reaching a hospital.[10] Any trauma patient who has unexplained shock and an appropriate mechanism of injury (rapid deceleration) should be suspected of having a ruptured aorta. Blood pressure may be normal or elevated, with a significant difference between the two arms. In addition, upper extremity hypertension with absent or weak femoral pulses can occur in these patients. (This is thought to result from compression of the aorta by the expanding hematoma.) Other patients have hypertension because of increased activity of the sympathetic nervous system. About 25% of these patients have a harsh systolic murmur that can be heard over the pericardium or between the scapulae. In rare cases these patients may have paraplegia without a cervical or thoracic spine injury. This occurs as a consequence of decreased blood flow through the anterior spinal artery. The anterior spinal artery is in the thoracic region. It is composed of branches from the posterior intercostal arteries. These in turn are branches of the thoracic aorta.

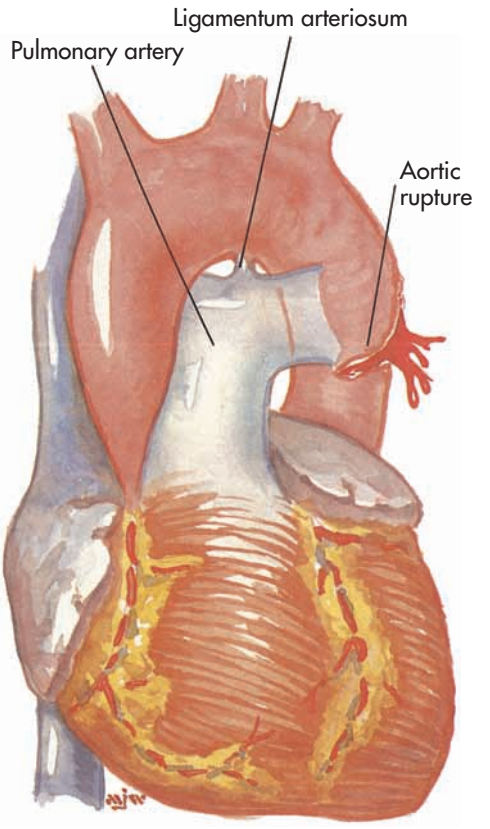

FIGURE 42-15 Aortic rupture.

NOTE
A difference in pulse quality between the arms and lower torso or between the left and right arms is sometimes detected with aortic rupture. Therefore checking both radial and femoral pulses is important.[3]

Prehospital management of these patients includes advising medical direction of the suspected rupture, administering high-concentration oxygen, providing ventilatory support with spinal precautions, replacing fluids judiciously (avoiding overhydration), and ensuring rapid transport for surgical repair.

NOTE
Fluid replacement should be limited in patients who have a stable blood pressure. This helps to prevent an increase in pressure in the remaining aortic wall tissue.

Penetrating Wounds of the Great Vessels

Penetrating wounds of the great vessels usually involve injury to the chest, abdomen, or neck. These wounds often are accompanied by massive hemothorax, hypovolemic shock, cardiac tamponade, and enlarging hematomas that may cause compression of the vena cava, trachea, esophagus, great vessels, and heart. Prehospital care for patients with penetrating injury to the great vessels is directed at providing airway and ventilatory support, managing hypovolemia with judicious fluid therapy (guided by medical direction), and ensuring rapid transport for definitive care.

OTHER THORACIC INJURIES

Other injuries that may be associated with blunt or penetrating trauma to the thorax include esophageal and tracheobronchial injuries and diaphragmatic rupture.

Esophageal and Tracheobronchial Injuries

As discussed in Chapter 40, esophageal injuries most often are caused by penetrating trauma. (For example, these may be caused by projectile or knife wounds.) They also can result from spontaneous perforation caused by cancer and from anatomical distortions caused by diverticula or gastric reflux, both of which can lead to violent vomiting. Assessment findings may include pain, fever, hoarseness, dysphagia, respiratory distress, and shock. If esophageal perforation occurs in the cervical region, local tenderness, subcutaneous emphysema, and resistance to neck movement may be noted. Esophageal perforation that occurs lower in the thoracic region may result in mediastinal and subcutaneous emphysema, inflammation of the mediastinum, and splinting of the chest wall.

LOOK AGAIN
See Chapter 40: Head, Face, and Neck Trauma, pp. 1158-1161.

Tracheobronchial injuries (*tracheobronchial disruptions*) are rare. They occur in fewer than 3% of victims of blunt or penetrating chest trauma. The mortality rate for these injuries is about 10%, depending on associated injuries, early diagnosis, and surgical repair.[1] Most injuries occur within 3 cm (about 1½ inches) of the carina. However, they can occur anywhere along the tracheobronchial tree. Signs and symptoms of tracheobronchial injury include the following:

- Severe hypoxia
- Tachypnea
- Tachycardia
- Massive subcutaneous emphysema
- Dyspnea
- Respiratory distress
- Hemoptysis

Emergency care for patients with an esophageal or a tracheobronchial injury is directed at providing airway, ventilatory, and circulatory support and ensuring rapid transport for definitive care at an appropriate medical facility.

NOTE
A tension pneumothorax that does not improve after needle decompression or the absence of a continuous flow of air from the needle after decompression should alert the paramedic to the possibility of a tracheobronchial injury.

Diaphragmatic Rupture

As described in Chapter 10, the diaphragm is a sheet of dome-shaped muscle. This sheet of muscle separates the abdominal cavity from the thoracic cavity. Sudden compression of the abdomen (such as with blunt trauma to the trunk) results in a sharp increase in intraabdominal pressure. When this occurs, the pressure differences may cause abdominal contents to rupture through the thin diaphragmatic wall and enter the chest cavity (Figure 42-16). **Diaphragmatic rupture** is detected more often on the left side

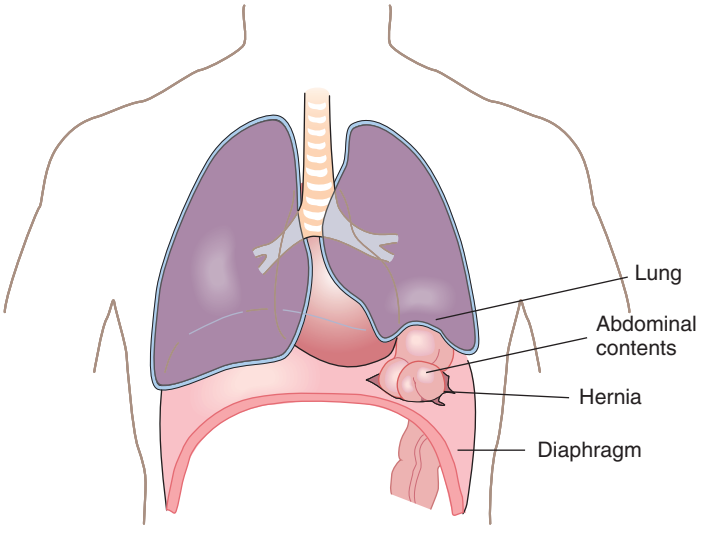

FIGURE 42-16 Diaphragmatic rupture. Sudden compression of the abdomen may increase intraabdominal pressure, causing the abdominal contents to rupture through the thin diaphragmatic wall and enter the chest cavity. (From National Association of Emergency Medical Technicians: *PHTLS: prehospital trauma life support,* ed 6, St Louis, 2007, Mosby.)

than on the right side. However, rupture on either side may allow intraabdominal organs to enter the thoracic cavity, where they may compress the lung, resulting in reduced ventilation, decreased venous return, decreased cardiac output, and shock. Because of the mechanical forces involved, patients with diaphragmatic rupture often have multiple injuries.

Signs and symptoms of a ruptured diaphragm include abdominal pain, shortness of breath, and decreased breath sounds. If most of the abdominal contents are forced into the chest, the abdomen may have a hollow or empty appearance. Also, bowel sounds may be heard in the chest. Prehospital management includes oxygen administration, ventilatory support as needed (positive-pressure ventilation may worsen the injury), use of volume-expanding fluids, and rapid transport with the patient in a supine position to an appropriate medical facility for surgical repair. Some medical direction agencies also may recommend that a nasogastric tube be placed to empty the stomach and reduce abdominal pressure.

SUMMARY

- Chest injuries are caused by blunt or penetrating trauma. Such trauma often results from motor vehicle crashes, falls from heights, blast injuries, blows to the chest, chest compression, gunshot wounds, and stab wounds.
- Fractures of the clavicle, ribs, or sternum as well as flail chest may be caused by blunt or penetrating trauma. Complications of skeletal trauma of the chest may include cardiac, vascular, or pulmonary injuries.
- Closed pneumothorax may be life threatening if (1) it is a tension pneumothorax, (2) it occupies more than 40% of the hemithorax, or (3) it occurs in a patient in shock or with a preexisting pulmonary or cardiovascular disease.
- Open pneumothorax may result in severe ventilatory dysfunction, hypoxemia, and death unless it is quickly recognized and corrected.
- Tension pneumothorax is a true emergency. It results in profound hypoventilation. It may result in death if it is not quickly recognized and managed.
- Hemothorax may result in massive blood loss. These patients often have hypovolemia and hypoxemia.
- Pulmonary contusion results when trauma to the lung causes alveolar and capillary damage. Severe hypoxemia may develop. The degree of hypoxemia is directly related to the size of the contused area.
- Traumatic asphyxia results from forces that cause an increase in intrathoracic pressure. When it occurs alone, it is often not lethal. However, brain hemorrhages, seizures, coma, and death have been reported after these injuries.
- The extent of injury from myocardial contusion may vary. The injury may be only a localized bruise. However, it also may be a full-thickness injury to the wall of the heart. The full-thickness injury may result in cardiac rupture, ventricular aneurysm, or a traumatic myocardial infarction.
- Pericardial tamponade occurs if 150 to 200 mL of blood enters the pericardial space suddenly. This results in a decrease in stroke volume and cardiac output. *Myocardial rupture* refers to an acute traumatic perforation of the ventricles or atria. It is nearly always immediately fatal. However, death may be delayed for several weeks after blunt trauma.
- Aortic rupture is a severe injury. There is an 80% to 90% mortality rate in the first hour. The paramedic should consider the possibility of aortic rupture in any trauma patient who has unexplained shock after a rapid deceleration injury.
- Esophageal injuries most frequently are caused by penetrating trauma (e.g., missile projectile and knife wounds). Tracheobronchial injuries are rare. (They occur in fewer than 3% of victims of blunt or penetrating chest trauma, but the mortality rate is more than 30%.) A tension pneumothorax that does not improve following needle decompression or the absence of a continuous flow of air from the needle following decompression should alert the paramedic to the possibility of a tracheobronchial injury.
- Diaphragmatic ruptures may allow abdominal organs to enter the thoracic cavity. There they may cause compression of the lung, resulting in a reduction in ventilation, a decrease in venous return, a decrease in cardiac output, and shock.

CHAPTER

43 Abdominal Trauma

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Identify mechanisms of injury associated with abdominal trauma.
2. Describe mechanisms of injury, signs and symptoms, and complications associated with abdominal solid organ, hollow organ, retroperitoneal organ, and pelvic organ injuries.
3. Outline the significance of injury to intraabdominal vascular structures.
4. Describe the prehospital assessment priorities for the patient suspected of having an abdominal injury.
5. Outline the prehospital care of the patient with abdominal trauma.

KEY TERMS

Cullen's sign The appearance of irregularly formed hemorrhagic patches on the skin around the umbilicus.

Grey Turner's sign Bruising of the skin of the flanks or loin in acute hemorrhagic pancreatitis; also known as *Turner's sign*.

hematuria The abnormal presence of blood in the urine.

hemodilution The dilution of the blood of elements.

hemoperitoneum The presence of extravasated blood in the peritoneal cavity.

Kehr's sign Pain in the left shoulder thought to be caused by referred pain secondary to irritation of the adjacent diaphragm.

peritonitis Inflammation of the serous membrane that covers the abdominal wall.

ultrasound A diagnostic test that uses sound waves to make images of internal organs and structures; often used in the emergency department to view the peritoneal cavity for the presence of fluid or blood. Also known as a *sonogram*.

Abdominal trauma may be difficult to evaluate in the prehospital setting because of the wide spectrum of potential injuries to multiple organs. In addition, physical findings may be absent, minimal, or exaggerated. Patients may also have altered levels of pain perception as a result of preexisting conditions, shock, alcohol or other drug use, head injury, or other factors. Therefore the paramedic must have a high degree of suspicion based on the mechanism of injury and kinematics. Death from abdominal trauma usually is a result of ongoing hemorrhage and the delay of surgical repair.

(Courtesy Ray Kemp., St. Charles, Mo.)

NOTE

Like most other types of trauma, many abdominal injuries can be prevented. An important prevention strategy is taking part in community programs that promote safety. (For example, one could work to promote gun safety legislation.) Another crucial approach is stressing the importance of using personal restraints (see Chapter 3).

REVIEW OF ABDOMINAL ANATOMY

The structures of the abdomen were presented in Chapter 10. To review, organs in the abdomen include the intestines, kidneys, liver, gallbladder, pancreas, spleen, and stomach (Figures 43-1 and 43-2). In addition to these organs, the abdomen has many vascular structures. Some of these structures include[1]:

- Abdominal aorta
- Superior and inferior mesenteric arteries
- Renal artery
- Splenic artery
- Hepatic artery
- Iliac arteries
- Hepatic portal system
- Inferior vena cava

All abdominal organs and vascular structures are susceptible to injury. Quick recognition of injury, emergency care, and rapid transport for definitive care can tremendously alter morbidity and mortality.

LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 196-199.

MECHANISMS OF ABDOMINAL INJURY

Abdominal injury may result from blunt or penetrating trauma. Regardless of the organ injured, management usually is limited to securing the airway with spinal

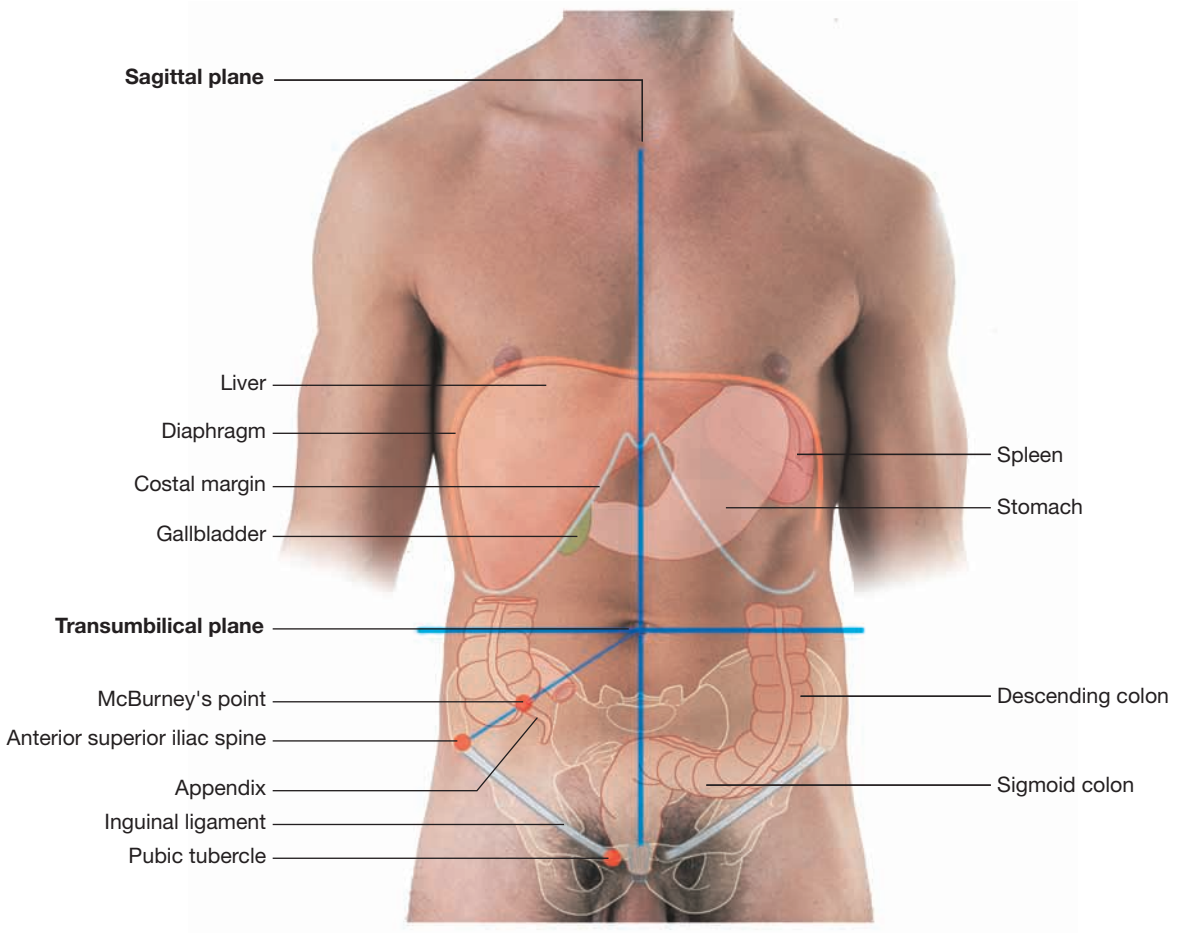

FIGURE 43-1 Abdominal quadrants and the positions of major viscera. Anterior view of a man. (From Drake R, et al: *Gray's anatomy for students,* ed 2, Philadelphia, 2010, Churchill Livingstone.)

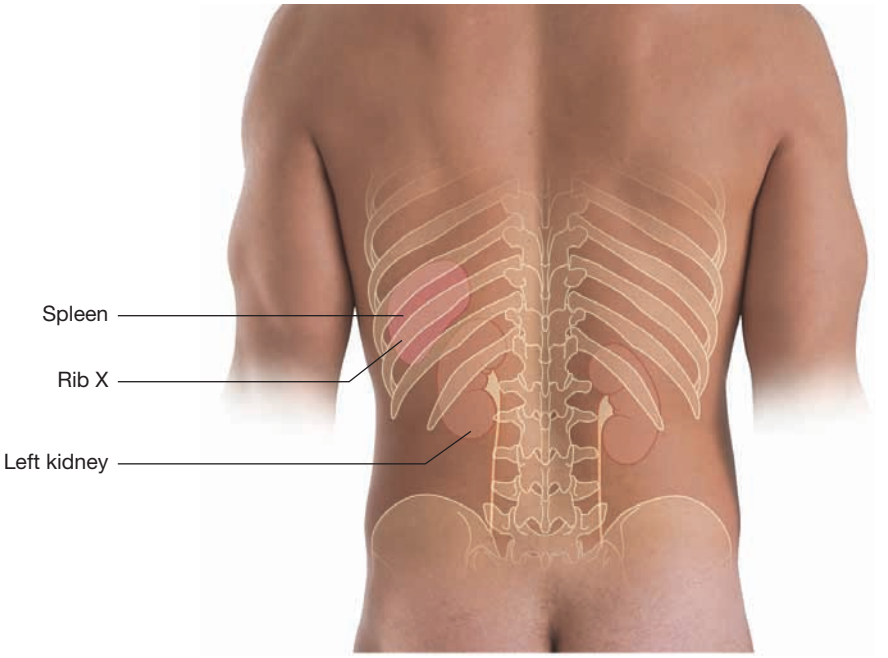

FIGURE 43-2 Surface projection of the spleen. Posterior view of a man. (From Drake R, et al: *Gray's anatomy for students,* ed 2, Philadelphia, 2010, Churchill Livingstone.)

precautions, providing ventilatory support, providing wound management, managing shock with fluid replacement and application of a pneumatic antishock garment (PASG) (per protocol), and rapidly transporting the patient for definitive care (Box 43-1).

The paramedic should be keenly aware of the kinematics and the mechanism of injury (described in Chapter 37) when evaluating a patient with abdominal trauma. For example, in the cases of a motor vehicle collision, the paramedic should note the extent of damage to the car; the patient's location within the car; whether the patient struck the steering wheel or dash; and if personal restraints were used properly. In the case of penetrating injury, the type, size, and direction of the penetrating object; the posture or position of the victim during the injury; and the amount of blood loss at the scene can provide valuable information to the receiving hospital.

Blunt Trauma

Blunt trauma to abdominal organs usually is caused by compression or shearing forces. Compression forces may cause the abdominal organs to be crushed between solid objects (e.g., between the steering column and the spinal vertebrae). Shearing forces may cause a tear or rupture of the solid organs or blood vessels. This occurs when the tissues are stretched at their points of attachment (stabilizing ligaments or blood vessels). The severity of injury usually is related to the degree and duration of force applied. It also is related to the type of abdominal structure injured (fluid filled, gas filled, solid, or hollow).

BOX 43-1 Prehospital Care for Abdominal Injury

1. Secure the airway with spinal precautions.
2. Provide ventilatory support.
3. Provide wound management.
4. Manage shock with fluid replacement and pneumatic antishock garment (per protocol).
5. Rapidly transport the patient for definitive care.

Blunt abdominal trauma may be caused by motor vehicle and motorcycle collisions (including injuries that result from the use of personal restraints), pedestrian injuries, falls, assaults, and blast injuries. The automobile is the major cause of blunt abdominal trauma (Figure 43-3). Automobile-automobile and automobile-pedestrian crashes have been cited as causes in 50% to 75% of cases, blows to the abdomen in about 15% of cases, and falls in 6% to 9% of cases.[2] Box 43-2 lists some signs of abdominal trauma.

CRITICAL THINKING

Young children are more susceptible to abdominal injuries than adults. Why?

FIGURE 43-3 Marks of impact on the front-seat passenger in a car crash. (From National Association of Emergency Medical Technicians: *PHTLS: Prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

BOX 43-2 Signs of Abdominal Trauma

Findings that raise the suspicion for abdominal trauma include[3]:

- Mechanism of injury consistent with rapid deceleration or significant compression forces
- Bent steering wheel
- Soft tissue injuries to the abdomen, flank, or back
- Shock without an obvious cause
- Level of shock greater than explained by other injuries
- "Seat belt signs"
- Peritoneal signs

Penetrating Trauma

Penetrating injury may result from stab wounds, gunshot wounds, or impalement. A major complication of this type of trauma is hemorrhage from a major vessel or solid organ. The amount of internal bleeding is related to the type and number of blood vessels injured and the vascularity of the solid organ. Penetrating injury also may cause perforation of a segment of bowel. As a rule, injuries caused by penetrating trauma do not have as high a mortality rate as those caused by blunt trauma. This is because injuries from blunt trauma are more difficult to diagnose. They are also often accompanied by injury to multiple organ systems.

SPECIFIC ABDOMINAL INJURIES

An abdominal injury may be classified as a solid organ, hollow organ, retroperitoneal organ, pelvic organ, or vascular injury (Figure 43-4).

Solid Organ Injury

Injury to solid organs usually results in rapid and significant blood loss. The two solid organs most often injured are the liver and spleen. Both of these organs are primary sources of life-threatening hemorrhage.

CRITICAL THINKING
When does shock associated with injury to the liver or spleen develop?

LIVER

The liver is the largest organ in the abdominal cavity. Because of its location, it often is injured by trauma to the eighth through twelfth ribs on the right side of the body. It also is often injured by trauma to the upper central part of the abdomen. Injury to the liver should be suspected in any patient with a steering wheel injury, lap belt injury, or history of epigastric trauma. After an injury to the liver, blood and bile escape into the peritoneal cavity. This results in the signs and symptoms of shock and peritoneal irritation (abdominal pain, tenderness, rigidity). The liver is the second most commonly injured intraabdominal organ (the spleen is first). The liver is damaged in about 15% to 20% of blunt abdominal trauma cases, and in about 37% of cases of penetrating trauma.[4] The mortality rate for liver injury is 10%.[5]

SPLEEN

The spleen lies in the upper left quadrant of the abdomen. It is slightly protected by the organs that surround it medially and anteriorly. It also is protected by the lower portion of the rib cage. Injury to the spleen often is associated with other intraabdominal injuries. Splenic injury should be suspected in motor vehicle crashes and in falls or sports injuries involving an impact to the lower left chest or flank or to the upper left abdomen. About 40% of patients with splenic injuries have no symptoms. However, the patient may complain of pain in the left shoulder **(Kehr's sign)**. Pain in the left shoulder or left upper abdomen or generalized abdominal pain is thought to be caused by referred pain that occurs as a result of irritation of the adjacent diaphragm by a splenic hematoma or **hemoperitoneum.** The spleen is damaged in about 25% of cases of blunt abdominal trauma and in about 7% of cases of penetrating trauma.[6]

Hollow Organ Injury

Injuries to the hollow organs of the abdomen may result in sepsis, wound infection, and abscess formation, particularly if trauma to the intestine remains undiagnosed for an extended period. With injuries to solid organs, hemorrhage is the major cause of symptoms. In contrast, injury to the hollow organs results in symptoms from spillage of their contents (this spillage results in **peritonitis**) (Box 43-3).

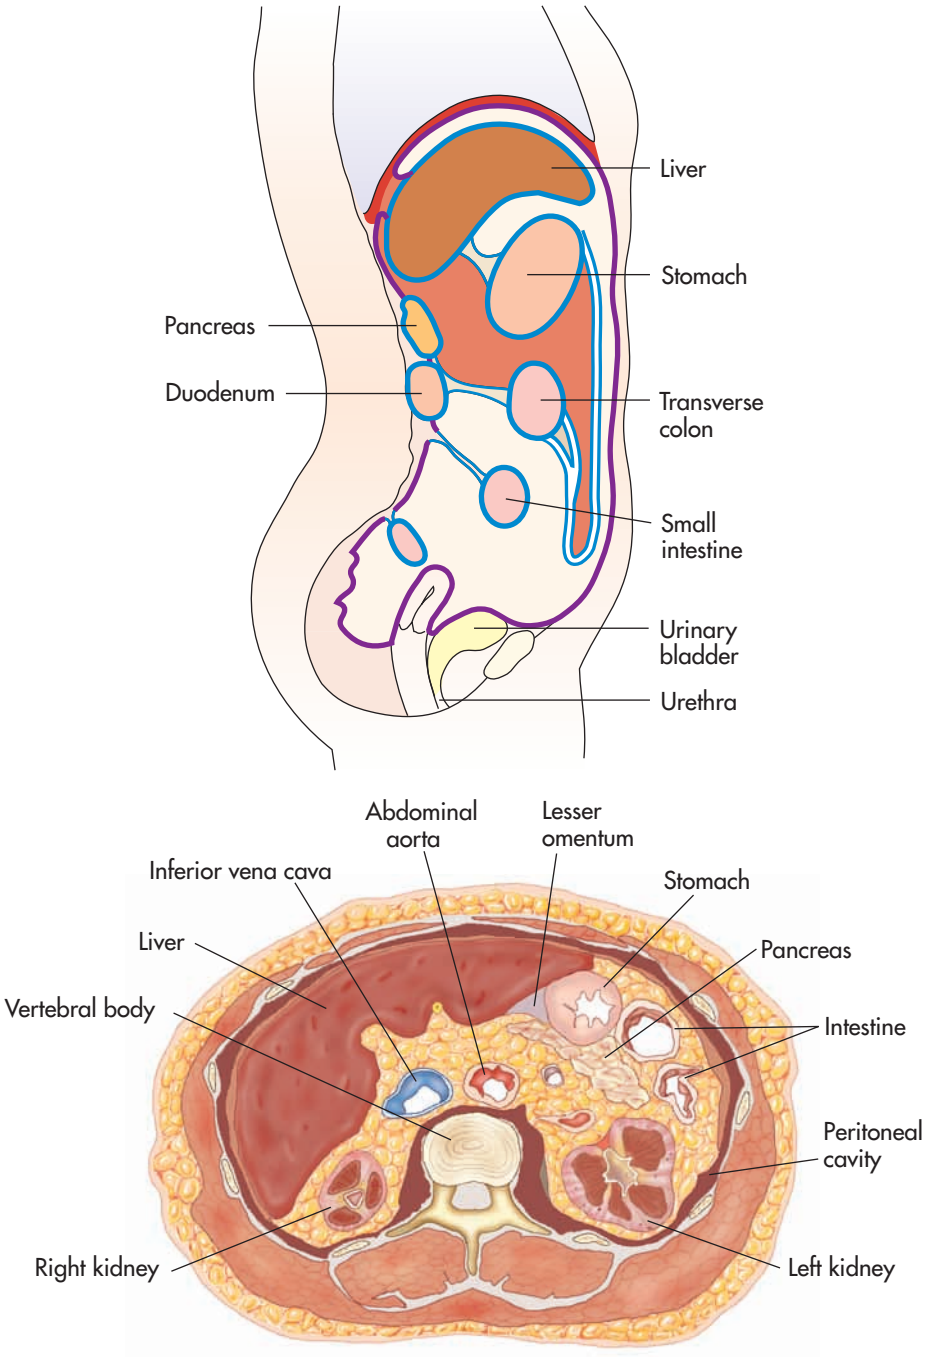

FIGURE 43-4 Hollow, solid, retroperitoneal, and pelvic organs.

STOMACH

Because of its protected location in the abdomen, the stomach is not often injured by blunt trauma. However, penetrating trauma may cause gastric transection or laceration. Patients with either of these injuries may show signs of peritonitis rather quickly as a result of leakage of acidic gastric contents. The diagnosis of injury to the stomach usually is confirmed during surgery or when nasogastric drainage returns blood. The stomach is damaged in about 1% of cases of blunt abdominal trauma and in 10% to 15% of cases of penetrating trauma.[5]

COLON AND SMALL INTESTINE

The colon and small intestine, like the stomach and duodenum, are more likely to be injured as a result of penetrating trauma than blunt trauma. (For example, the injury may be caused by a gunshot wound to the abdomen or buttocks.) However, the large bowel and small bowel also may be injured by compression forces in high-speed motor vehicle crashes. They also may sustain deceleration injuries associated with the wearing of personal restraints. Considerable force is required to cause an injury to the colon or small intestine. Therefore other injuries usually are present.

BOX 43-3 Peritoneal Irritation

Peritonitis usually is acute and quite painful. It may be delayed for hours or days after injury to a hollow viscus organ. It results from the spillage of enzymes, acids, and bacteria into the abdominal cavity. The spillage causes chemical irritation of the peritoneum. The peritoneum is the membrane that lines the wall of the abdomen and covers the abdominal organs. (Blood is not a chemical irritant to the abdomen.) The pain of peritonitis usually is localized (via somatic nerve fibers). However, it also may be diffuse. Signs and symptoms of peritonitis include the following:

- Pain
- Tenderness on percussion or palpation
- Guarding, rigidity
- Fever (if untreated)
- Distention (a late finding)

NOTE: The adult abdomen can accommodate 1.5 L of fluid without the belly looking bloated (abdominal distention).

Peritoneal contamination with bacteria is a common problem. With blunt abdominal trauma, the colon is damaged in about 2% to 5% of cases and the small intestine in about 5% to 15% of cases. The colon is damaged in about 25% of gunshot wounds and in about 5% of stab wounds. The small intestine is damaged in about 26% of these cases.[5]

Retroperitoneal Organ Injury

Injury to the retroperitoneal organs (kidneys, ureters, pancreas, duodenum) may occur as a result of blunt or penetrating trauma to the anterior abdomen, posterior abdomen (particularly the flank area), or thoracic spine. Hemorrhage within the retroperitoneal area may be massive (Figure 43-5). Most retroperitoneal hemorrhages result from pelvic or lumbar fractures. Retroperitoneal structures are damaged in about 9% of cases of blunt abdominal injuries and in about 11% of cases of penetrating trauma.[5]

NOTE

Bruising of the flanks (**Grey Turner's sign**) or around the umbilicus (**Cullen's sign**) indicates retroperitoneal hemorrhage (Figure 43-5). However, these signs usually are delayed 12 hours to several days.

KIDNEYS

The kidneys are solid organs that lie in the retroperitoneal space. They may be injured by abdominal trauma. The trauma may cause minor lacerations and contusions (Figure 43-6) as well as major lacerations and fractures to the organ (Figure 43-7). These injuries can result in hemorrhage, extravasation of urine, or both. Contusions usually are self-limiting and usually heal with bed rest and forced fluids. Organ fractures and lacerations are more severe. They may require surgical repair, depending on which part of the kidney is damaged.

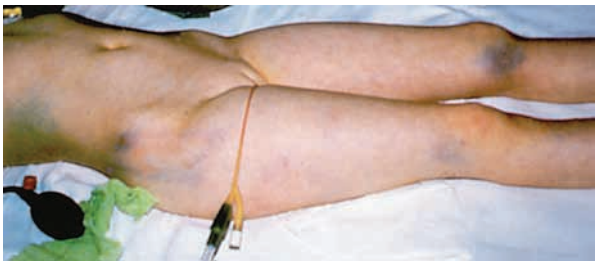

FIGURE 43-5 Bruising caused by rupture of the liver and right kidney. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

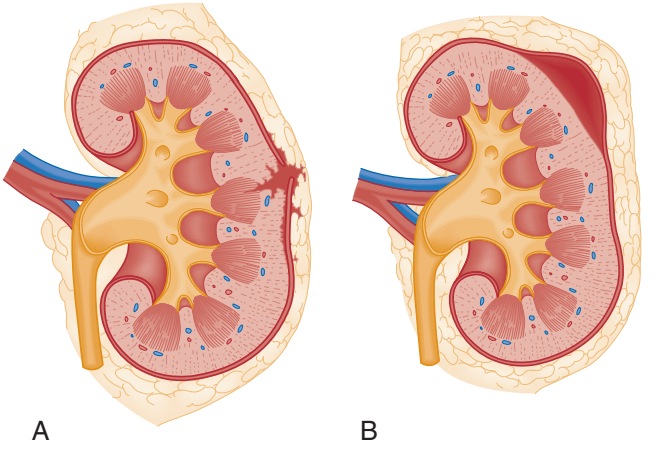

FIGURE 43-6 Minor renal injuries. **A,** Minor renal laceration. **B,** Renal contusion. (From Nicolaisen GS, McAninch JW, Marshall GA, et al: Renal trauma: re-evaluation of the indication for radiographic assessment, *J Urol* 133[2]:183, 1985.)

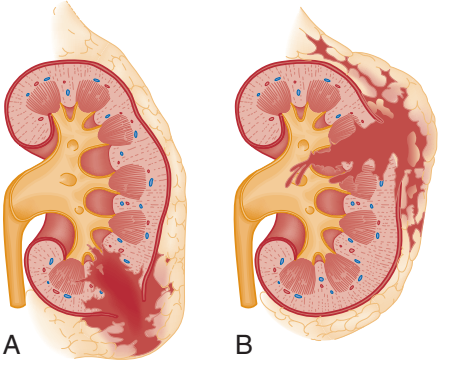

FIGURE 43-7 Major renal lacerations. **A,** Deep medullary laceration. **B,** Laceration into collecting system. (From Nicolaisen GS, McAninch JW, Marshall GA, et al: Renal trauma: re-evaluation of the indication for radiographic assessment, *J Urol* 133[2]:183, 1985.)

URETERS

The ureters are hollow organs that are rarely injured by blunt trauma. This is because of their flexible structure. When injury occurs, it usually is the result of penetrating abdominal or flank wounds (e.g., stab wounds, firearm injuries).

PANCREAS

The pancreas is a solid organ that lies within the retroperitoneal space. Injury to the pancreas is rare. When it occurs, it usually is caused by compressive or penetrating forces on the upper left quadrant, as in steering wheel and bicycle handlebar impalement. The pancreas more often is injured by penetrating trauma (particularly firearms) than by blunt trauma.

CRITICAL THINKING

What functions of the pancreas may be disrupted after injury? What might be the effects of spillage of pancreatic juices into the abdominal cavity?

DUODENUM

The duodenum, which lies across the lumbar spine, is seldom injured. This is due to its location in the retroperitoneal area, near the pancreas. When great force from blunt trauma or a penetrating injury occurs, the duodenum may be crushed or lacerated. Injury to this organ usually is associated with concurrent pancreatic trauma; it is confirmed through surgery.

Pelvic Organ Injury

Injury to pelvic organs (bladder, urethra) usually results from motor vehicle crashes that cause pelvic fractures. Other, less frequent causes of pelvic organ injury are penetrating trauma, straddle-type injuries from falls, pedestrian injuries, and some sexual acts. The pelvis supports and protects multiple organ systems. Therefore the risk of associated injury is high. The most common associated injuries are those to the urinary bladder and urethra. Fractures of the pelvis (Figure 43-8) often are associated with severe retroperitoneal hemorrhage. The mortality rate for pelvic fractures ranges from 6.4% to 19%[5] (pelvic fractures are further described in Chapter 44).

URINARY BLADDER

The urinary bladder is a hollow organ that may be ruptured by blunt trauma, penetrating trauma, or pelvic fracture. Rupture is more likely if the bladder is distended at the time of injury. With rupture, the integrity of the peritoneum may be disrupted. Urine may enter the peritoneal cavity. Bladder injury should be suspected in inebriated patients who suffer trauma to the lower abdomen. Gross hematuria (blood in the urine) may be present. The patient also may complain of being unable to void. The urinary bladder and surrounding structures are damaged in about 6% of cases of abdominal trauma.[5]

URETHRA

A tear in the urethra occurs more often in men than in women. It usually occurs as a result of blunt trauma associated with pelvic fracture. The patient may complain of abdominal pain and of being unable to urinate. Blood at the meatus indicates urethral injury. Passage of an indwelling urinary catheter is contraindicated in these patients.

FIGURE 43-8 Massive swelling and bruising from a pelvic fracture. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

VASCULAR STRUCTURE INJURIES

Injuries to arterial and venous vessels in the abdomen can be life threatening because of their potential for massive hemorrhage. These injuries usually are caused by penetrating trauma. However, they may also be the result of compression or deceleration forces on the abdomen. As in solid organ injury, vascular injury usually is marked by hypovolemia. In some cases vascular injuries are associated with a palpable abdominal mass. The major vessels most often injured are the aorta, the inferior vena cava, and the renal, mesenteric, and iliac arteries and veins. Injury to major vessels in the abdomen has a high mortality rate. Immediate surgical repair is often required.

CRITICAL THINKING

How can you attempt to manage shock when major vessels have been injured as a result of a severe pelvic fracture?

ASSESSMENT OF ABDOMINAL TRAUMA

The most significant sign of severe abdominal trauma is unexplained shock. The mechanism of injury and the classic presentation of hypovolemia are important indicators. Other signs and symptoms that should alert the paramedic to the possibility of severe abdominal trauma are abdominal wall injuries (e.g., bruising and discoloration of the abdomen, abrasions) and the following:

- Obvious bleeding
- Pain and abdominal tenderness or guarding
- Abdominal rigidity and distention
- **Evisceration** (Box 43-4)

BOX 43-4 Evisceration

Evisceration is the protrusion of an internal organ or the peritoneal contents through a wound or surgical incision, especially in the abdominal wall (Figure 43-9). The presence of an evisceration from abdominal trauma generally is associated with major abdominal injury. In the prehospital setting the wound is managed by covering the eviscerated contents with moist, sterile gauze or a dressing with an outer cover that is occlusive to prevent further contamination and drying. No attempt should be made to replace eviscerated organs into the peritoneal cavity; this would increase the risk of infection. It also would complicate surgical evaluation of the injury.

- Rib fractures
- Pelvic fractures

However, the absence of these signs and symptoms does not rule out an abdominal injury. The paramedic must maintain a high degree of suspicion based on the mechanism of injury.

NOTE

Assessment and management of abdominal trauma in children and older adults basically follow the same principles outlined in this chapter. Specific care considerations for pediatric and geriatric patients will be presented in Chapter 48 and Chapter 49. Trauma care considerations for pregnant patients will be presented in Chapter 46. Trauma that results from sexual assault will be presented in Chapter 50.

Focused History

When possible, a focused history should be obtained from the patient or a reliable source. Historical facts that may be important include events before the injury (e.g., use of seat belts; location in the vehicle), alcohol or other drug use, and underlying medical problems such as diabetes, cardiovascular disease, respiratory disease, or seizure disorder. Medication use (e.g., anticoagulants) and drug allergies can also be important in the course of the patient's care.

MANAGEMENT OF ABDOMINAL TRAUMA

Emergency care of patients with abdominal trauma usually is limited to two courses of action: (1) stabilizing the patient's condition and (2) rapidly transporting the patient to a hospital for physician evaluation and surgical repair of the injury.

The following are the most important components of on-scene care:

- A thorough scene survey to identify forces involved in abdominal trauma
- Rapid evaluation of the patient and the mechanism of injury

FIGURE 43-9 A loop of gut that emerged through a stab wound to the abdomen. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

DID YOU KNOW?

An **ultrasound** uses sound waves to make images of internal organs and structures. Also known as a *sonogram,* the technology is often used in the emergency department to view the peritoneal cavity for the presence of fluid or blood. Advantages of a sonogram are that it can be rapidly performed at the patient's bedside, it does not interfere with resuscitation, and it is noninvasive and less costly than a CT scan. It also does not use ionizing radiation.

Although the test cannot differentiate the types of fluids that are present in the peritoneal cavity, any fluid in the trauma patient is presumed to be blood. The presence of fluid in one or more areas is considered a positive scan. These areas appear black on the monitor screen (Figure 43-10).

Note: Studies are underway to evaluate the efficacy of sonogram technology in the prehospital setting.

SHOW ME THE EVIDENCE

This multicenter study conducted in Frankfurt, Germany, sought to evaluate whether prehospital focused abdominal sonography for trauma (PFAST) was feasible and accurate. In 2002 to 2003 physicians and paramedics on ground and air ambulance performed PFAST on all patients with suspected abdominal trauma. The goal was to detect blood in the peritoneum. A total of 230 patients with a wide variety of mechanisms of injury were included in the study. In 219 (95%) cases, rescuers stated the exam could be performed without exceeding target on-scene times. In the other cases, the crews indicated the procedure extended scene times by 4 minutes. PFAST exams in 214 (93%) of the cases provided good or acceptable diagnostic images. Free blood was detected in the abdomen in 28 (14%) cases. There were 26 (11%) true positives, 1 false positive, and 2 false negatives. PFAST findings changed prehospital care in 42 (21%) cases. In 44 (22%) of the patients with positive findings the transport destination decision changed. Following this study, one air ambulance service in Germany implemented PFAST.

From Walcher F, Weinlich M, Conrad G et al: Prehospital ultrasound imaging improves management of abdominal trauma, *Br J Surg* 93:238-242, 2006.

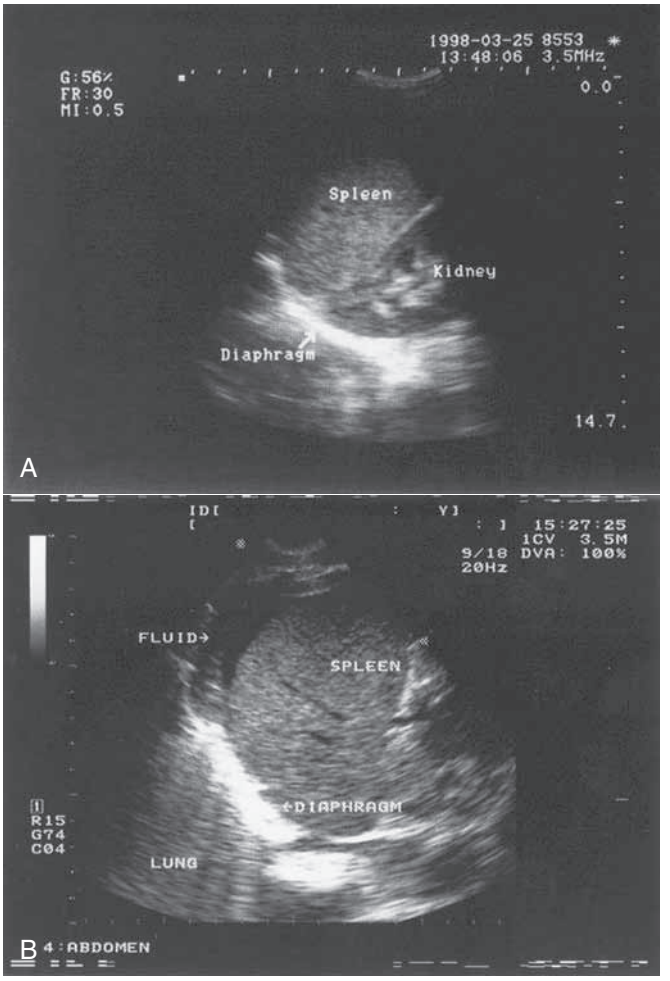

FIGURE 43-10 Abdominal ultrasound indicating trauma. **A,** Normal splenorenal view. **B,** The presence of fluid blood (black stripe next to spleen). (From National Association of Emergency Medical Technicians: *PHTLS: Prehospital trauma life support,* ed 7, St Louis, 2011, Mosby.)

- Airway maintenance with spinal precautions
- Administration of high-concentration oxygen ≥85%
- Ventilatory support as needed
- Reduction of hemorrhage by application of pressure
- Fluid replacement with volume expanders
- Use of a PASG (per protocol)
- Cardiac monitoring

Oxygen saturation should be maintained at or above 90%. The goal of fluid resuscitation for a patient with abdominal injury and hypotension is to maintain a systolic blood pressure between 80 and 90 mm Hg (mean arterial pressure of 60 to 65 mm Hg).[3] Aggressive fluid replacement in these patients can reinitiate bleeding in the abdomen from sites that had stopped bleeding from blood clots and hypotension. Therefore paramedics should strive to balance perfusion to vital organs without restoring blood pressure to normal limits.

NOTE

Hemodilution is an increase in the fluid content of blood that results in a lowered concentration of formed elements and lowered blood viscosity. Hemodilution can occur from aggressive IV fluid therapy and can affect or disrupt clot formation. After hospital arrival, fluid resuscitation will be guided by serial hematocrit measurements.

En route to the hospital, a full physical examination and ongoing assessment can be performed. These procedures should include vital sign assessment (and reassessment), and inspection, percussion, and palpation of the abdomen (see Chapter 20). Auscultation of the abdomen for the presence of bowel sounds can establish a baseline measurement for hospital personnel. This assessment is difficult and time-consuming in the prehospital setting and should never delay patient transport.

LOOK AGAIN
See Chapter 20: Secondary Assessment, pp. 542-546.

SUMMARY

- Blunt trauma to abdominal organs usually results from compression or shearing forces.
- Penetrating injury may result from stab wounds, gunshot wounds, or impaled objects.
- The two solid organs most commonly injured are the liver and the spleen. Both of these organs are primary sources of death from hemorrhage. Injuries to the hollow abdominal organs may result in sepsis, wound infection, and abscess formation.
- Injury to the retroperitoneal organs (kidneys, ureters, pancreas, duodenum) may cause massive hemorrhage.
- Injury to the pelvic organs (bladder, urethra) usually results from motor vehicle crashes that produce pelvic fractures.
- Injuries to abdominal vascular structures may be life threatening. This is due to their potential for massive hemorrhage.
- The most significant sign of severe abdominal trauma is the presence of unexplained shock.
- Emergency care of patients with abdominal trauma usually is limited to two courses of action. One is to stabilize the patient. The other is to rapidly transport the patient to a hospital for surgery to repair the injury.

CHAPTER

44 Orthopedic Trauma

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the features of each class of musculoskeletal injury.
2. Describe the features of bursitis, tendonitis, and arthritis.
3. Given a specific patient scenario, outline the prehospital assessment of the musculoskeletal system.
4. Outline general principles of splinting.
5. Describe the significance and prehospital management principles for selected upper extremity injuries.
6. Describe the significance and prehospital management principles for selected lower extremity injuries.
7. Identify prehospital management priorities for open fractures.
8. Describe the principles of realignment of angular fractures and dislocations.

KEY TERMS

Achilles tendon The largest tendon in the body; connects the calf muscle to the heel bone; also known as the *tendon calcaneus*.

Achilles tendon rupture A complete tear through the Achilles tendon.

appendicular skeleton The bones of the upper and lower extremities.

axial skeleton The bones of the head, neck, and torso.

boxer's fracture Fracture of the fifth metacarpal bone from direct trauma to a closed fist.

Colles' fracture A fracture of the radius at the epiphysis within 1 inch of the joint of the wrist; it is easily recognized by the resultant dorsal and lateral position of the hand.

epiphyseal fracture A fracture involving the epiphyseal plate of a long bone.

epiphyseal plate The site of bone elongation; also known as the *growth plate*.

false movement An unnatural movement of an extremity, usually associated with fracture.

first-degree sprain An injury in which there is partial tearing of a ligament without joint disability.

fracture A break in the continuity of bone or cartilage.

joint dislocation An injury that occurs when the normal articulating ends of two or more bones are displaced.

luxation A complete dislocation.

nursemaid's elbow Subluxation of the radial head.

open fracture A break in a bone that has penetrated the soft tissue or skin; also known as *compound fracture*.

rigid splint A splint in which the shape cannot be changed.

second-degree sprain An injury that results from some stretching and tearing of ligaments.

soft splint A splint that can be molded into a variety of shapes and configurations to accommodate the injured body part.

sprain A partial tearing of a ligament caused by a sudden twisting or stretching of a joint beyond its normal range of motion.

strain An injury to the muscle or its tendon from overexertion or overextension.

subluxation A partial dislocation.

third-degree sprain An injury that results from severe stretching and tearing of ligaments.

torus The buckling of the cortex of bone.

traction splint A splint specifically designed for midshaft femoral fractures.

Volkmann's contracture A serious, persistent flexion contraction of the forearm and hand caused by ischemia.

Orthopedic trauma and related complications are very common complaints. These injuries account for a large number of the more than 100 million patients in the United States who seek emergency department care each year.[1] Trauma to an extremity is seldom life threatening. However, early recognition and management may prevent long-term disability.

NOTE
Extremity trauma usually results from motor vehicle crashes, falls, acts of violence, and contact sports. Prevention strategies include proper sports training (working with athletic trainers on the use of protective equipment), use of personal restraints, gun safety education, and fall prevention (e.g., high-rise window guards) (see Chapter 3).

REVIEW OF THE MUSCULOSKELETAL SYSTEM

As described in Chapter 10, the musculoskeletal system and associated neurovascular structures are made up of bones, nerves, vessels, muscles, tendons, ligaments, and joints. To review, the skeletal system contains 206 individual bones. These bones are divided into two categories: the axial skeleton and the appendicular skeleton (Figure 44-1, *A, B*). The axial skeleton consists of the skull, hyoid bone, vertebral column, and thoracic cage. The appendicular skeleton consists of the bones of the upper and lower extremities. It also includes the *girdles*, by which the extremities are attached to the body.

The muscular system provides for movement, postural maintenance (muscle tone), and heat production. The major types of muscles are skeletal, cardiac, and smooth muscle. Skeletal muscle is the most common type of muscle in the body and will be the focus of this chapter (Figure 44-2).

LOOK AGAIN
Chapter 10: Review of Human Systems, pp. 167-171.

CLASSIFICATIONS OF MUSCULOSKELETAL INJURIES

Injuries that result from traumatic forces to the musculoskeletal system include fractures, sprains, strains, and joint dislocations. Patients suspected of having trauma to an extremity should be managed as though a fracture exists. Problems associated with musculoskeletal injuries include the following:

- Hemorrhage
- Instability
- Loss of tissue
- Simple laceration and contamination
- Interruption of blood supply
- Nerve damage
- Long-term disability

CRITICAL THINKING
How could long-term disability result from a musculoskeletal injury?

Musculoskeletal injuries can result from direct trauma (e.g., blunt force applied to an extremity), indirect trauma (e.g., a vertical fall that produces a spinal fracture distant from the site of impact), or pathological conditions such as some forms of arthritis and malignancy (described in Chapter 33). Paramedics should consider kinematics when caring for a patient with a musculoskeletal injury and carefully evaluate the scene (see Chapter 37).

Fractures

A **fracture** is any break in the continuity of bone or cartilage (Figure 44-3). It may be *complete* or *incomplete,* depending on the line of fracture through the bone. Fractures also are classified as *open* or *closed,* depending on the integrity of the skin near the fracture site (Box 44-1). Fractures of long bones may result in moderate to severe hemorrhage within the first 2 hours. As much as 550 mL of blood may be released in the lower leg from a tibial or fibular fracture, 1000 mL of blood in the thigh from a femoral fracture, and 2000 mL of blood from a pelvic fracture.[1]

As described in Chapter 10, the head of long bones in children is separated from the shaft of the bone by the **epiphyseal plate** until the bone stops growing. Fractures

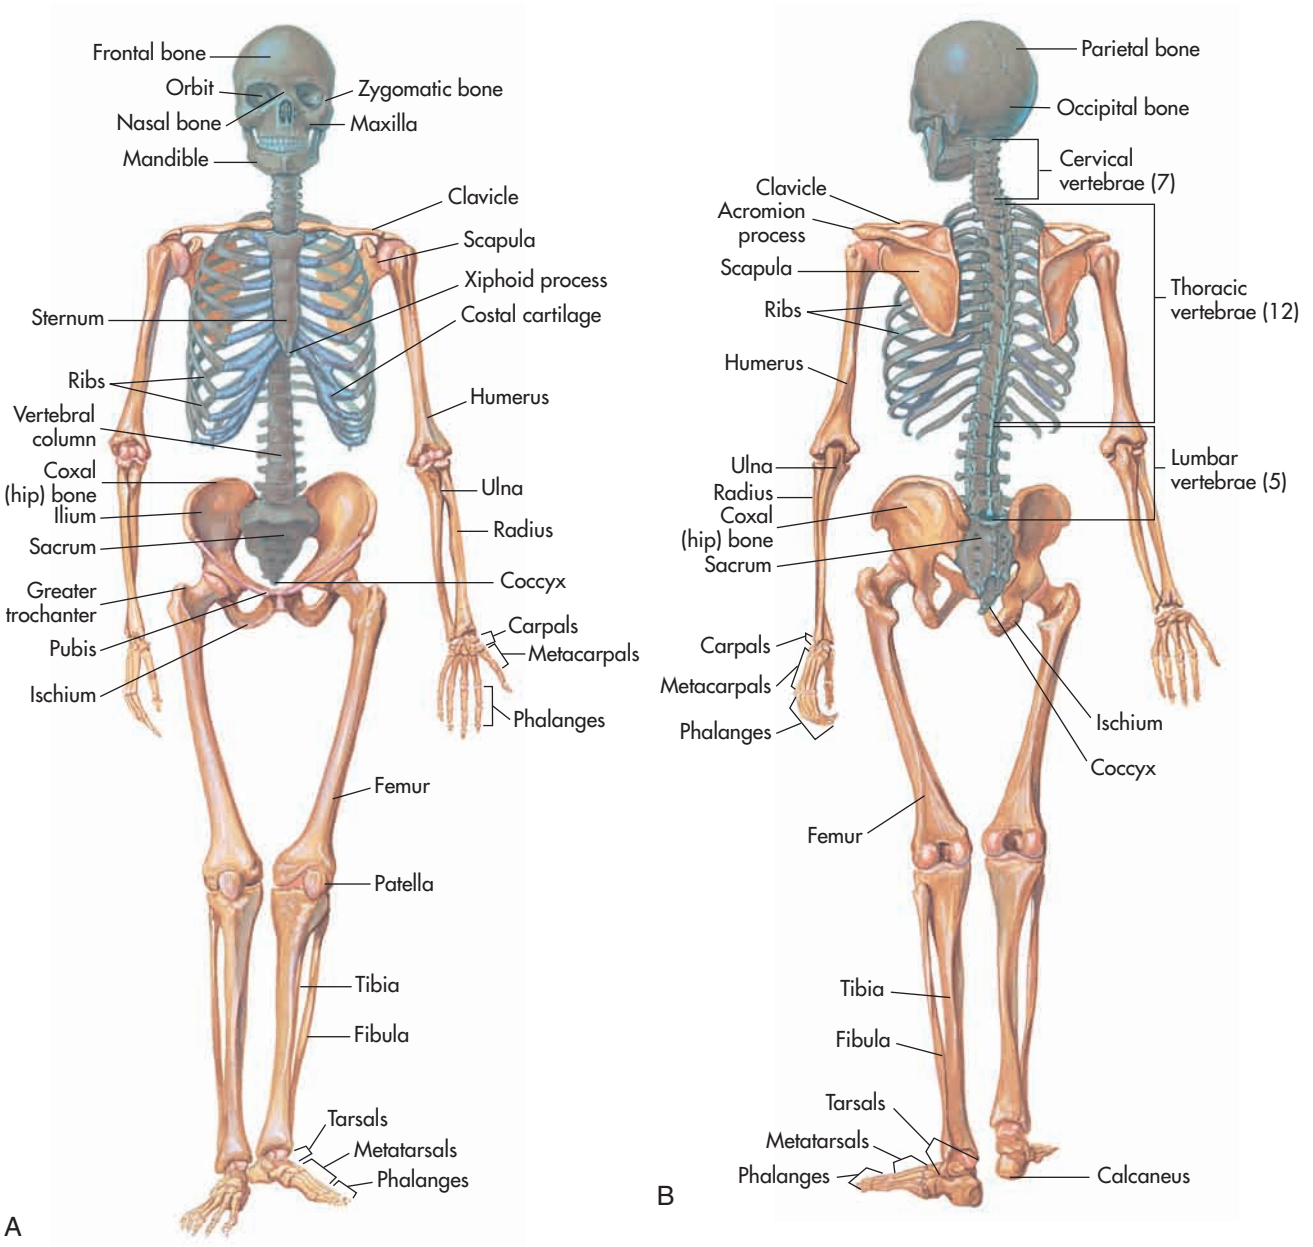

FIGURE 44-1 **A,** Skeleton, anterior view. Axial skeleton is shown in blue. Appendicular skeleton is bone colored. **B,** Skeleton, posterior view. Axial skeleton is shown in blue. Appendicular skeleton is bone colored. (From Christensen BL, et al: *Adult health nursing,* ed 6, St Louis, 2010, Mosby.)

that involve the epiphyseal plate are called **epiphyseal fractures.** These are serious injuries that may result in separation or fragmentation of the growth plate. They also may result in permanent bending or deformity of an extremity. This is known as **torus** (buckling of the cortex of bone) (Figure 44-4).

Sprains

A **sprain** is a partial tearing of a ligament (Figure 44-5). It is caused by sudden twisting or stretching of a joint beyond its normal range of motion (Figure 44-6). Two common areas for sprains are the knee and the ankle. Sprains are graded by severity (Box 44-2). A **first-degree sprain** has no joint instability. This is because only a few fibers of the ligament are torn. Swelling and hemorrhage are minimal. (Repeated first-degree sprains can result in stretching of the ligaments.) A **second-degree sprain** causes more disruption than a first-degree injury. The joint usually is still intact, but swelling and bruising are increased. In a **third-degree sprain** the ligaments are completely torn. If third-degree sprains are accompanied by dislocation, nerve or blood vessel compromise to the extremity is possible. Some

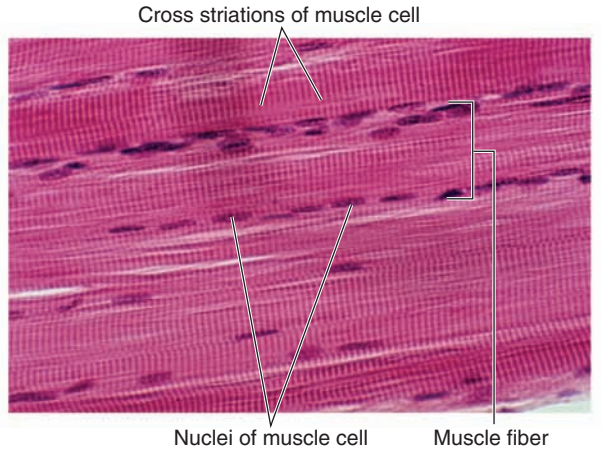

FIGURE 44-2 Skeletal muscle. (From Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 7, St Louis, 2010, Mosby.)

second-degree sprains and most third-degree sprains have the same presentation as a fracture.

The application of ice to an injury during the first 24 hours generally reduces pain and swelling. After that time, heat (e.g., warm soaks) often is prescribed to increase circulation.

NOTE
Orthopedic injuries, including sprains, strains, fractures, and dislocations, can be quite painful for the patient. Per protocol, prehospital care may include the use of analgesics (***morphine, fentanyl, nitrous oxide***) before splinting or moving an injury.

Strains

A **strain** is an injury to the muscle or its tendon from overexertion or overextension. Strains commonly occur in the back and arms and may be accompanied by a significant loss of function. Severe strains may cause an avulsion of bone from the tendon attachment site.

Joint Dislocations

A **joint dislocation** occurs when the normal articulating ends of two or more bones are displaced (Figure 44-7). Joints that often are dislocated are those of the shoulders, elbows, fingers, hips, knees, and ankles. Dislocation should be suspected when a joint is deformed or does not move with normal range of motion. A complete dislocation is called a **luxation;** an incomplete dislocation is called a **subluxation.** All dislocations can result in great damage and instability.

CRITICAL THINKING
Why do dislocations have a high rate of vascular or nerve damage?

BOX 44-1 Classification of Fractures

Open: A break in which a protruding bone or penetrating object causes a soft tissue injury
Closed: A break in the bone that has not yet penetrated the soft tissue or skin
Comminuted: A fracture that involves several breaks in the bone, resulting in multiple bone fragments
Greenstick: A break in which the bone is bent but only broken on the outside of the bend (common in children)
Spiral: A break caused by a twisting motion
Oblique: A break at a slanting angle across a bone
Transverse: A break that occurs at right angles to the long axis of the bone
Stress: A break (especially in one or more of the foot bones) caused by repeated, long-term, or abnormal stress
Pathological: A break resulting from weakness in bone tissue caused by neoplasm or malignant growth
Epiphyseal: A break that involves the epiphyseal growth plate of a child's long bone; may result in permanent angulation or deformity and may cause premature arthritis

BOX 44-2 Grading of Sprains by Severity

First-Degree Sprain
No joint instability
Minimal swelling/hemorrhage

Second-Degree Sprain
Joint usually intact
Increased swelling/ecchymosis

Third-Degree Sprain
Total disruption of ligaments
Possible nerve or vascular compromise

SIGNS AND SYMPTOMS OF EXTREMITY TRAUMA

The signs and symptoms of trauma to an extremity vary. They may be subtle complaints of discomfort. However, they also may include obvious deformity or open fracture. Field evaluation should be rapid, assuming significant injury. Common signs and symptoms of extremity trauma include the following:

- Pain on palpation or movement
- Swelling, deformity
- Crepitus
- Decreased range of motion
- **False movement** (unnatural movement of an extremity)
- Decreased or absent sensory perception or circulation distal to the injury (evidenced by alterations in skin color and temperature, distal pulses, and capillary refill)

CRITICAL THINKING
How can a paramedic differentiate a serious sprain from a fracture in the prehospital setting?

Pediatric fractures are seldom complete breaks. Rather, children's bones tend to bend or buckle because of increased flexibility. This flexibility is due to a thicker periosteum and increased amounts of immature bone.

Greenstick

Break occurs through the periosteum on one side of the bone while only bowing or buckling on the other side. Seen most frequently in forearm.

Spiral

Twisted or circular break that affects the length rather than the width. Seen frequently in child abuse.

Oblique

Diagonal or slanting break that occurs between the horizontal and perpendicular planes of the bone.

Transverse

Break or fracture line occurs at right angles to the long axis of the bone.

Comminuted

Bone is splintered into pieces. This is a rare occurrence in children.

Physeal growth plate injuries: Salter-Harris classification. Epiphyseal fractures are common in children.

Type I

Epiphysis is completely separated from the metaphysis without fracture.

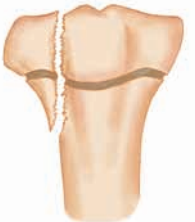
Type II

Transverse fracture extends through the separated epiphyseal plate, producing triangular break.

Type III

Fracture extends through part of the epiphyseal plate into the joint.

Type IV



Fracture extends through the epiphyseal plate and through the metaphysis.

Type V

Epiphyseal plate is crushed, causing cell death in growth plate.

FIGURE 44-3 Bone fractures. **A,** Complete and incomplete. **B,** Comminuted and transverse. **C,** Impacted. **D,** Oblique and spiral. (Courtesy David J. Mascaro and Associates; from McKinney ES, et al: *Maternal-child nursing,* ed 3, St Louis, 2009, Saunders.)

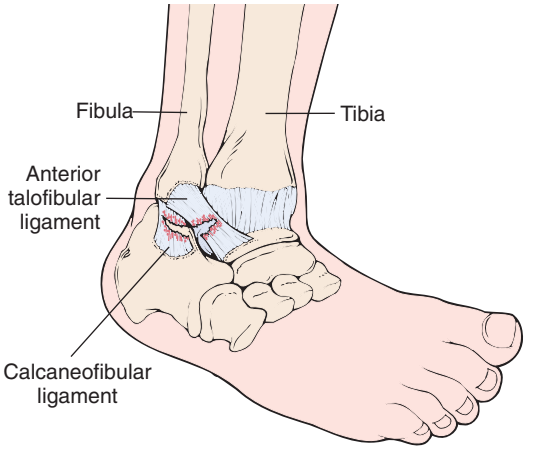

FIGURE 44-5 Ankle sprain. (From Frazier MS, Drzymkowski J: *Essentials of human diseases and conditions,* ed 4, Philadelphia, 2008, Saunders.)

FIGURE 44-6 Swelling and bruising from a sprain of a lateral ligament. (From Ferguson DG, Fodden DI: *Accident and emergency medicine,* London, 1998, Churchill Livingstone.)

ASSESSMENT OF MUSCULOSKELETAL INJURIES

For the purposes of musculoskeletal assessment, patients can be divided into four classes:

- Those with life- or limb-threatening injuries or conditions, including life- or limb-threatening musculoskeletal trauma
- Those with other life- or limb-threatening vascular injuries and only simple musculoskeletal trauma
- Those with no other life- or limb-threatening injuries but with life- or limb-threatening musculoskeletal trauma
- Those with only isolated injuries that are not life or limb threatening

The paramedic should perform a primary survey to determine whether the patient has any conditions that pose a threat to life. Such conditions must be dealt with first. Paramedics must never overlook musculoskeletal trauma. In addition, a grotesque, but noncritical,

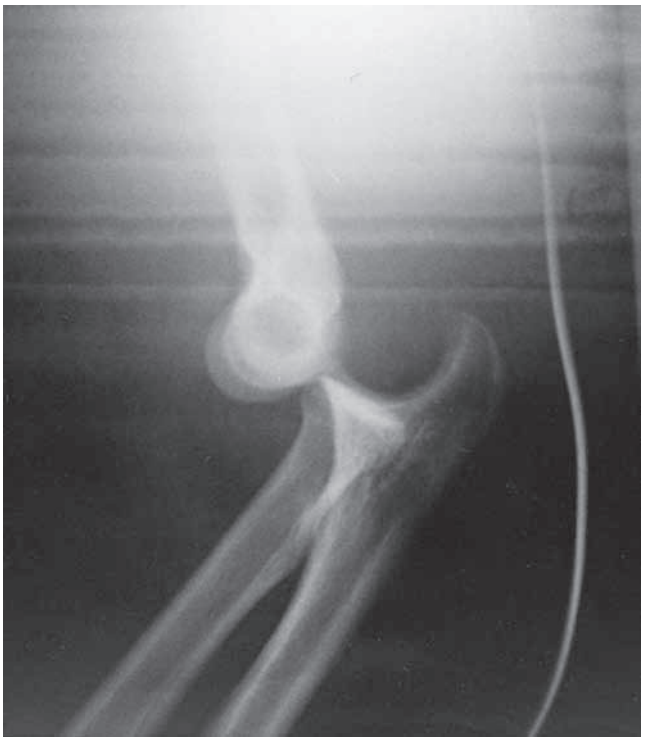

FIGURE 44-7 Posterior elbow dislocation. (From Ferrera PC, Colucciello SA, Marx JA, et al: *Trauma management—an emergency medicine approach,* St Louis, 2001, Mosby.)

musculoskeletal injury should never distract from the priorities of care.

NOTE

Orthopedic trauma can be a very painful injury. The paramedic should follow protocol established by medical direction for the use of analgesics to manage pain.

SHOW ME THE EVIDENCE

Researchers aimed to evaluate the effect of ethnicity, age, income, and gender on the administration of prehospital analgesia for isolated extremity injuries. This was a retrospective cohort study conducted in California in 2005. Of the 953 cases that met inclusion criteria and had complete data, 279 (29%) of the patients received morphine. The researchers found that patients were more likely to receive medication as their income increased. Women were less likely than men to receive prehospital analgesia. They also found a correlation between pain score and transport time—the higher the score and the longer the transport time, the more likely it was for patients to be medicated for pain.

From Michael G, Sporer KA, Youngblood GM: Women are less likely than men to receive prehospital analgesia for isolated extremity injuries, *Am J Emerg Med* 25(8):901-906, 2007.

Evaluation of an injured extremity should always include checking the *"six Ps": pain, pallor, paresthesia, pulses, paralysis,* and *pressure* (Box 44-3). The paramedic also should evaluate

BOX 44-3 Six P's of Musculoskeletal Assessment

Pain or tenderness
Pallor (pale skin or poor capillary refill)
Paresthesia (pins-and-needles sensation)
Pulses (diminished or absent)
Paralysis (inability to move)
Pressure

an extremity's neurovascular status by assessing the distal pulse, motor function, and sensation (before and after movement or splinting). In addition, the injury should be inspected and palpated for surface trauma, tenderness, and swelling. If possible, the assessment should include comparison with the opposite, uninjured extremity. If trauma to an extremity is suspected, the extremity should be splinted (Figure 44-8).

NOTE

This text presents methods to immobilize fractures and dislocations for isolated extremity injuries. Again, seldom does trauma to an extremity pose a threat to life. Therefore patients with multiple-system traumatic injury should first be managed for conditions that compromise the airway, breathing, and circulation (including internal and external hemorrhage in the extremities) and spinal stability. Rapid transport may be indicated by the patient's condition or mechanism of injury. If this is the case, injured extremities can be stabilized by fully immobilizing the patient on a long spine board.

General Principles of Splinting

The goal of splinting is immobilization of the injured body part. Immobilization by splinting helps alleviate pain; decreases tissue injury, bleeding, and contamination of an open wound; and simplifies and facilitates transport of the patient. The general principles of splinting are listed in Box 44-4. It should be noted that the principles of splinting and immobilization are the same for both children and adults. Special considerations for managing pediatric and geriatric patients will be addressed in Chapter 48 and Chapter 49.

TYPES OF SPLINTS

A wide variety of splints and splinting materials are available. Splints can be broadly categorized as rigid splints, soft or formable splints, and traction splints.

The shape of a **rigid splint** cannot be changed. The body part must be positioned to fit the splint's design. Examples of rigid splints include board splints, contoured metal and plastic splints, and some cardboard splints (Figure 44-9). Rigid splints should be padded before use to accommodate for shape and patient comfort.

A **soft splint** or *formable splint* can be molded into a variety of shapes and configurations to accommodate the

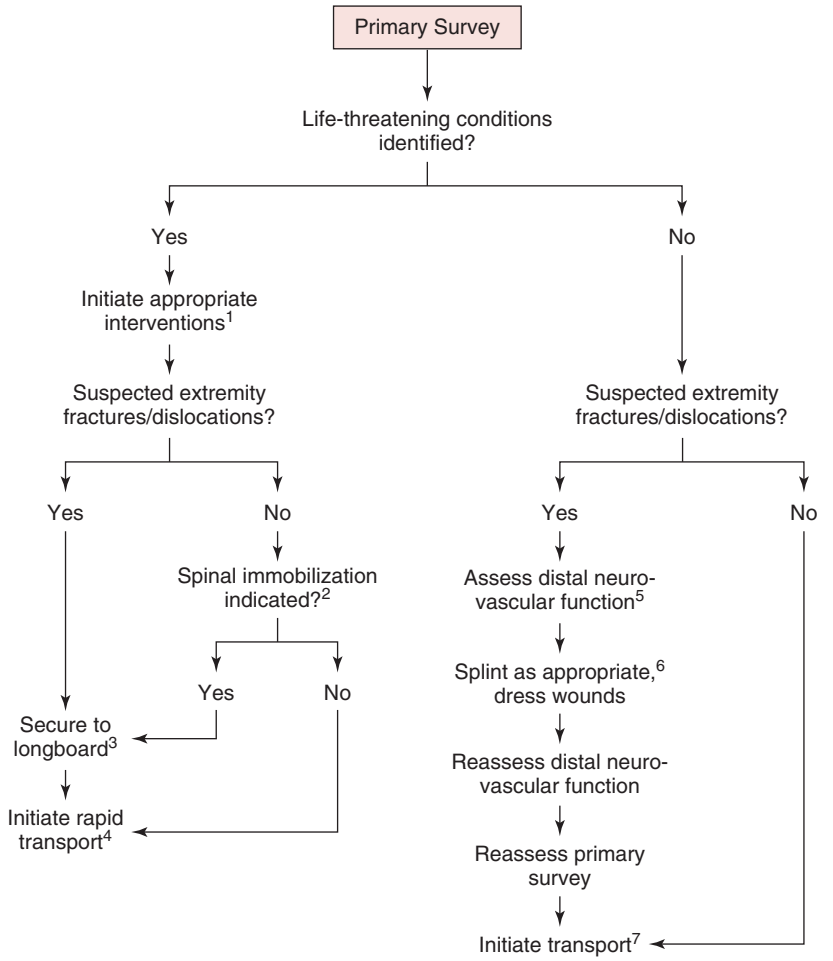

FIGURE 44-8 Evaluating extremity trauma. (From National Association of Emergency Medical Technicians: *PHTLS: prehospital trauma life support,* ed 5, St Louis, 2003, Mosby.)

[1]Airway management, ventilatory support, shock therapy.

[2]See Indications for Spinal Immobilization algorithm.

[3]Injured extremities are immobilized in anatomic position by securing to longboard.

[4]Transport to closest appropriate facility (trauma center, if available); assess distal neurovascular function and apply traction splint (if suspected femur fracture) as time permits.

[5]Assess perfusion (pulses and capillary refilling) and neurologic function (motor and sensory) distal to the suspected fracture or dislocation.

[6]Use appropriate splinting technique to immobilize suspected fracture or dislocation; if suspected midshaft femur fracture, apply traction splint.

[7]Transport to closest appropriate facility.

injured body part. Examples of soft or formable splints include pillows, blankets, slings and swathes, vacuum splints, some cardboard splints, wire ladder splints, and padded, flexible aluminum splints (Figure 44-10). Inflatable air splints also are considered soft or formable splints. However, they are not designed to be used for injuries to the knee or elbow.

A **traction splint** is specifically designed for midshaft femoral fractures. These splints do not apply or maintain enough traction to reduce a femoral fracture. However, they provide enough traction to stabilize and align it. They also are useful to tamponade bleeding and reduce pain. Examples include Thomas half-ring, Hare traction, and Sager traction splints (Figure 44-11).

UPPER EXTREMITY INJURIES

Upper extremity injuries can be classified as fractures or dislocations to the shoulder, humerus, elbow, radius and ulna, wrist, hand, and finger (Figure 44-12). Clavicular injury was discussed in Chapter 42. Most upper extremity vinjuries can be adequately immobilized with a sling and swathe.

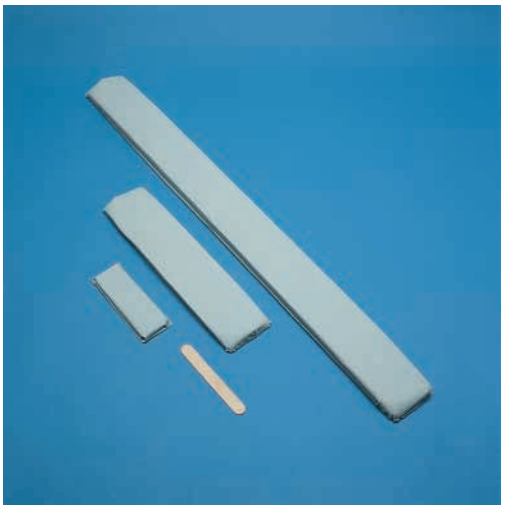

FIGURE 44-9 Rigid splints.

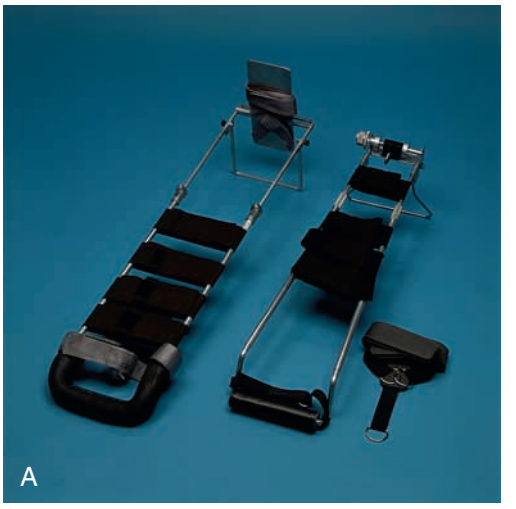

FIGURE 44-11 **A,** Traction splints. **B,** Unipolar traction splint. (B from Aehlert B: *Paramedic practice today: above and beyond,* St Louis, 2010, Mosby.)

BOX 44-4 General Principles of Splinting

1. Splint joints and bone ends above and below the injury.
2. Immobilize open and closed fractures in the same manner.
3. Cover open fractures to minimize contamination.
4. Check and document pulses, sensation, and motor function before and after splinting. Recheck frequently.
5. Stabilize the extremity with gentle in-line traction to a position of normal alignment.
6. Immobilize a long bone extremity in a straight position that can be splinted easily.
7. Immobilize dislocations in a position of comfort; ensure good vascular supply.
8. Immobilize joints as found; joint injuries are aligned only if no distal pulse is felt.
9. Apply cold to reduce swelling and pain. Give analgesics per protocol.
10. Apply compression to reduce swelling.
11. Elevate the extremity if possible.

NOTE: Immobilization requires a minimum of two rescuers. All splints should be well padded for patient comfort.

Shoulder Injury

Shoulder injuries are common in older adults. This is due to a weaker bone structure. Shoulder injuries often result from a fall on an outstretched arm. Patients with an anterior fracture or dislocation (accounting for 90% of cases) often have the affected arm and shoulder close to the chest (with the lateral aspect of the shoulder appearing flat instead of rounded). In addition, a deep depression between the head of the humerus and the acromion laterally ("hollow shoulder") may be visible. Patients with posterior fracture or dislocation may be found with the arm above the head. Other injuries that may affect the shoulder include *sternoclavicular strain* (that results from a direct blow or twisting of an extended arm) and *rotator cuff tendon injuries*. Rotator cuff injuries can be acute or chronic and usually involve the deltoid muscle. Injury to the rotator cuff can occur from a violent pull on the arm or abnormal rotation of the shoulder. They can also result from falls on an outstretched arm that tears and ruptures shoulder tendons. Management of shoulder injuries includes the following:

FIGURE 44-12 **A,** Complete separation of the left acromioclavicular joint. **B,** Anterior dislocation of the left shoulder. **C,** Fracture of the proximal humerus. **D,** Posterior dislocation of the elbow joint with marked deformity. **E,** Severe open fracture of the forearm. **F,** Penetration of the forearm caused by a nail gun. **G,** Greenstick fracture with marked deformity.

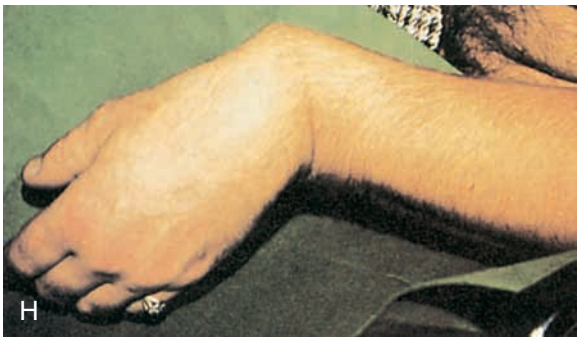

FIGURE 44-12, cont'd **H,** Fracture of the distal radius. **I,** Hand injury from a motorcycle crash. (From Ferguson DG, Fodden DI: *Accident and emergency medicine,* London, 1998, Churchill Livingstone; C-H from London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

1. Assessment of neurovascular status
2. Application of a sling and swathe (Figure 44-13)
3. Application of ice

NOTE
Ice should be placed in a plastic bag and applied for 20-minute periods to the injury site, removed for 20 minutes, and then reapplied. If ice is not available, refreezable packs of gelled solution can be used in the short term, and may provide some comfort and reduce swelling.

Based on the position of the affected arm and shoulder, a makeshift splint may need to be devised to hold the injury in place. For example, with some fractures or dislocations, the paramedic may need to use a rolled blanket with a cravat at the center. The blanket roll is positioned under the elevated arm and secured like a sling. The arm is then swathed to prevent movement. If the patient's arm is positioned above the head, it should be splinted in position.

FIGURE 44-13 Immobilization of the shoulder.

Humeral Injury

Upper arm fractures are common in older adults and children. They often are difficult to stabilize. Radial nerve damage may be present if a fracture occurs in the middle or distal portion of the humeral shaft. A fracture of the humeral neck may cause axillary nerve damage. Internal hemorrhage into the joint also may be a complication. Management includes the following measures:

1. Assessment of neurovascular status
2. Realignment if vascular compromise is present
3. Application of a rigid splint and sling and swathe (Figure 44-14) or splinting of the extremity with the arm extended
4. Application of ice

Elbow Injury

Elbow injuries are common in children and athletes. They are especially dangerous in children. They may lead to ischemic contracture (**Volkmann's contracture**) with serious deformity of the forearm and a claw-like hand. The mechanism of injury usually involves falling on an outstretched arm or flexed elbow. Also, laceration of the brachial artery and radial nerve damage can occur. Management includes the following measures:

1. Assessment of neurovascular status
2. Splinting in the position found with a pillow, blanket, rigid splint, or sling and swathe (Figure 44-15)
3. Application of ice

FIGURE 44-14 Immobilization of the humerus.

FIGURE 44-15 Immobilization of the elbow.

Radial, Ulnar, or Wrist Injury

As with most other upper extremity injuries, injuries to the radius, ulna, and wrist usually are the result of a fall on an outstretched arm. Wrist injuries may involve the distal radius, the ulna, or any of the eight carpal bones. The most common wrist injury is a fracture with a "silver fork" deformity of the distal radius with dorsal angulation (**Colles' fracture**) (Figure 44-16). Forearm injury is common in both children and adults. Management includes the following measures:

1. Assessment of neurovascular status
2. Splinting in the position found with rigid or formable splints or a sling and swathe (Figure 44-17)
3. Application of ice and elevation

NOTE

Subluxation of the radial head **(nursemaid's elbow)** accounts for about 20% of upper extremity injuries in children and is seen in children ages 6 months to 5 years, most often in children in the 1- to 3-year-old age group. History of a pull on the arm or a fall is often reported. The child usually refuses to use the arm but does not seem in pain or distress.[2]

FIGURE 44-16 Colles' fracture (arrow shows dorsal angulation of distal radius fragment).

FIGURE 44-17 Immobilization of the forearm.

CRITICAL THINKING

What effect does a cold pack have on musculoskeletal injuries?

Hand (Metacarpal) Injury

Injury to the hand often results from contact sports, violence (fighting), and work-related crushing injuries. A common metacarpal injury is **boxer's fracture.** This results from direct trauma to a closed fist, resulting in fracture of

the fifth metacarpal bone (Figure 44-18). These injuries also may be associated with hematomas and open wounds. Boxer's fracture is the most common metacarpal fracture, but any of the metacarpals can be fractured, depending on the mechanism of injury. Hand injuries should be splinted in the position of function (as with a hand grasping a football). Rigid or formable splints (previously described for a radial, ulnar, or wrist injury) may be used. Management includes the following measures:

1. Assessment of neurovascular status
2. Splinting with a rigid or formable splint (pillow, blanket) in the position of function
3. Application of ice and elevation

FIGURE 44-18 Boxer's fracture (*arrow*).

Finger (Phalangeal) Injury

Injured fingers may be immobilized with foam-filled aluminum splints or tongue depressors. They also may be immobilized simply by taping the injured finger to an adjacent one ("buddy splinting") (Figure 44-19). Finger injuries are common. However, they should not be considered trivial. Serious injuries include fractures of the thumb. Also, any open or markedly comminuted fractures of the hand or fingers are serious. Management includes the following measures:

1. Assessment of neurovascular status
2. Splinting as previously described
3. Application of ice and elevation

FIGURE 44-19 Immobilization of the finger.

LOWER EXTREMITY INJURIES

Lower extremity injuries include fractures of the pelvis and fractures or dislocations of the hip, femur, knee and patella, tibia and fibula, ankle and foot, and phalanx (Figure 44-20). Compared with upper extremity injuries, lower extremity injuries are associated with greater forces. They also are associated with more significant blood loss. They are more difficult to manage in patients with multiple injuries, and they may be life threatening (e.g., femoral and pelvic fractures).

Pelvic Fracture

As described in Chapter 43, blunt or penetrating injury to the pelvis may result in fracture, severe hemorrhage, and associated injury to the urinary bladder and urethra. The pelvis is surrounded by heavy muscles and other soft tissues. Therefore deformity may be difficult to see (Figure 44-21). Injury to the pelvis should be suspected based on the mechanism of injury or tenderness on palpation of the iliac crests (see Chapter 20). Trauma to the abdomen and pelvic area may be complicated by pregnancy (further described in Chapter 46). Management includes the following measures:

1. Administration of high-concentration oxygen
2. Management for shock (pneumatic antishock garment [PASG] per protocol)
3. Full-body immobilization on a long spine board or scoop stretcher (adequately padded for comfort)
4. Regular monitoring of vital signs
5. Rapid transport (essential)

NOTE

As described in Chapter 36, the pneumatic antishock garment (PASG) may help to arrest hemorrhage by tamponading bleeding vessels in the pelvis or lower extremities. It also may be used to stabilize pelvic and lower extremity fractures in the presence of hypotension (SBP < 90 mm Hg).[3] Decisions on the use of the PASG are made per local protocol and according to medical direction. Commercial pelvic stabilization devices ("pelvic binders") are also available to immobilize unstable pelvic fractures. Examples include the Trauma Pelvic Orthotic Device (T-POD) and the SAM Pelvic Sling (Figure 44-22). Pelvic binders are most appropriate to stabilize pelvic fractures that have been confirmed by x-ray.[6]

(From Ferrera PC, Colucciello SA, Marx JA, et al: *Trauma management—an emergency medicine approach,* St Louis, 2001, Mosby.)

Hip Injury

Hip injuries commonly occur in older adults as a result of a fall. They also are common in younger patients as a result of major trauma. If the hip is fractured at the femoral head and neck, the affected leg usually is shortened and externally rotated. By comparison, with hip dislocation the affected leg is usually shortened and internally rotated (Figure 44-23). (Fractures closer to the head of the femur may manifest similar to an anterior hip dislocation, with a shortened and internally rotated leg.)

Hip fractures are serious injuries, especially in older patients. Complications from the injury can be life threatening. About 25% of older patients die within the first year following injury.[1] Most of these deaths result from venous thromboembolism, pneumonia, and infection. The majority of patients who sustain a hip fracture will require prolonged specialized care, such as a long-term nursing or rehabilitation facility. Less than 30% of patients who sustain a fractured hip will return to their preinjury level of activity.[4] Prehospital management of hip fracture includes the following measures:

1. Assessment of neurovascular status
2. Splinting with a long spine board or scoop stretcher (Figure 44-24) and generously padding the patient for comfort during transport (slight flexion of the knee or padding beneath the knee may improve comfort)
3. Frequent monitoring of vital signs

Femoral Injury

Injury to the femur usually results from major trauma, such as may occur with motor vehicle crashes and pedestrian injuries. It also is a fairly common result of child abuse, accounting for 30% of femur fractures in children younger than 4 years of age.[5]

Fractures of the femur result in powerful thigh muscle contractions. These contractions cause the bone fragments to move back and forth over each other. The patient generally has a shortened leg that is externally rotated and midthigh swelling from hemorrhage, which can be life threatening (Figure 44-25). These fractures should be immobilized in the field with a traction splint. Management includes the following measures:

1. Administration of high-concentration oxygen
2. Management for shock
3. Assessment of neurovascular status
4. Application of a traction splint (Figure 44-26)
5. Regular monitoring of vital signs

NOTE

Traction splints should be used only to immobilize midshaft femoral fractures. They should not be used with fractures of the lower third of the leg, pelvic fractures, hip injury, knee injury, or avulsion or amputation of the ankle and foot. These splints should not be applied if the patient has life-threatening injuries. Rather, the patient should be secured on a long spine board and rapidly transported for definitive care.[6]

When more than one injury contributes to the development of shock, the PASG and traction splint may be used together (per local protocol for the use of the PASG). The traction splint should be applied over the PASG only after it has been inflated. Traction devices placed under the PASG may promote continued hemorrhage, tissue damage, and compromised circulation to the injured extremity.

Knee and Patellar Injury

Fractures of the knee (supracondylar fracture of the femur, intraarticular fracture of the femur or tibia) and fractures and dislocations of the patella commonly result from

FIGURE 44-25 Young man with external rotation, abduction, and shortening of the left femur, consistent with his midshaft fracture. Also note right tibia fracture. (From Ferrera PC, Colucciello SA, Marx JA, et al: *Trauma management—an emergency medicine approach,* St Louis, 2001, Mosby.)

BOX 44-5 Ligament Injuries of the Knee

Injuries to the ligaments around the knee can result from direct blows, from hyperextension, and (more commonly) from twisting or torsion of the knee (e.g., in sports activities). The ligaments outside the knee are the medial collateral ligament and the lateral collateral ligament. They provide the stability for the knee and limit the amount the knee can move from side to side. The medial collateral ligament is on the inner side of the knee and is taut when the leg is straight. It is a strong ligament but can be sprained or completely ruptured (torn) if the straightened knee is twisted at the same time the knee is forced sideways (e.g., during a football tackle). The lateral collateral ligament runs on the outer side of the knee. It connects the distal end of the femur to the top of the fibula. Injury to this ligament seldom occurs as an isolated event. If injured, it is usually associated with another damaged ligament.

The ligaments inside the knee are the anterior cruciate ligament and the posterior cruciate ligament. These ligaments cross over each other. The crisscross formation provides additional stability to the knee, particularly in forward and backward movements of the knee joint (Figure 44-29).

Ligament injuries are managed with rest, ice, compression, and elevation (R-I-C-E); anti-inflammatories and analgesics; and physical therapy. In some cases, surgical repair is required.

motor vehicle crashes, pedestrian injuries, contact sports, and falls on a flexed knee (Figure 44-27). (The popliteal artery is close to the knee joint and may therefore be an associated injury. This is particularly true with posterior dislocations.) Other common knee and patella injuries involve nearby ligaments and tendons (Box 44-5). Management includes the following measures:

1. Assessment of neurovascular status
2. Splinting in the position found with a rigid or formable splint (Figure 44-28) that effectively immobilizes the hip and ankle (traction splints should not be used to immobilize a knee or patellar injury)
3. Application of ice and elevation, if possible

Tibial and Fibular Injury

Injuries to the tibia and fibula may result from direct or indirect trauma. They also may result from twisting injury (Figures 44-29 and 44-30). If the injury is associated with the knee, popliteal vascular injury should be suspected. Management includes the following measures:

1. Assessment of neurovascular status
2. Splinting with a rigid or formable splint (Figure 44-31)
3. Application of ice and elevation

Foot and Ankle Injury

Fractures and dislocations of the foot and ankle may result from a crush injury, a fall from a height, or a violent rotating or twisting force (Figure 44-32). Injuries to nearby tendons also can occur (Box 44-6). The patient with foot or ankle injury usually complains of point tenderness. The person also often is hesitant to bear weight on the extremity. Management includes the following measures:

1. Assessment of neurovascular status
2. Application of a formable splint, such as a pillow, blanket, or air splint (Figure 44-33)
3. Application of ice and elevation

FIGURE 44-28 Immobilization of the knee.

DID YOU KNOW?

Ottawa Ankle Rules

In medicine, the *Ottawa ankle rules* are a set of guidelines used by physicians and other health care professionals to evaluate injuries to the ankle and midfoot. The rules also are used to determine the need for x-rays to identify fractures. (The rules were initially developed for foot and ankle injuries, but similar guidelines have been developed to evaluate the knees [*Ottawa knee rules*].) The Ottawa rules consider bone tenderness and the ability to bear weight when walking four steps. The risk of fracture is highest when there is any pain in the malleolar zone and any one of the following[8]:

- Bone tenderness along the distal 6 cm of the posterior edge of the tibia or tip of the medial malleolus
  or
- Bone tenderness along the distal 6 cm of the posterior edge of the fibula or tip of the lateral malleolus
  or
- An inability to bear weight both immediately and in the emergency department for four steps

Note: Clinical judgment should prevail over the rules if the patient is under the influence of alcohol or other drugs; has other distracting or painful injuries; has diminished sensation in the legs; or has gross swelling that prevents palpation of malleolar bones. The rules have a 98.5% sensitivity for ankle and midfoot fracture in patients 6 years of age and older.[9]

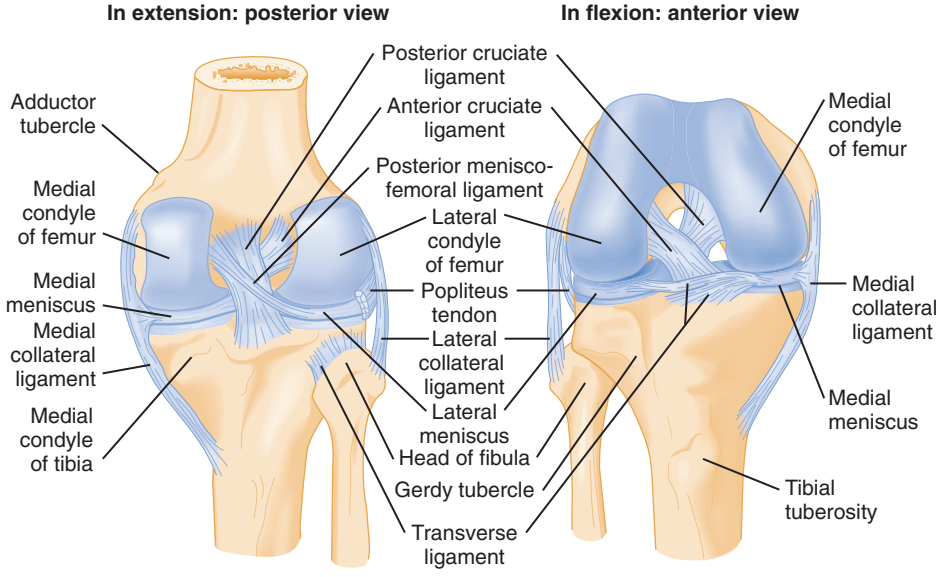

FIGURE 44-29 Anterior and posterior view of the right knee. (From Marx J et al: *Rosen's emergency medicine: concepts and clinical practice*, ed 6, St Louis, 2006, Mosby.)

FIGURE 44-30 Isolated fibular shaft fracture. This patient sustained a direct blow to the lateral leg to produce this transverse fracture. A fracture in this location should arouse suspicion of associated injury to knee ligaments or ankle injury. (From Ferrera PC, Colucciello SA, Marx JA, et al: *Trauma management—an emergency medicine approach,* St Louis, 2001, Mosby.)

FIGURE 44-31 Immobilization of the lower leg.

FIGURE 44-32 Weber B ankle fracture. The fracture lines extend obliquely from the mortise. The medial joint line (between medial malleolus and talus) is somewhat widened. This patient had deltoid ligament rupture and was later treated with surgery. (From Ferrera PC, Colucciello SA, Marx JA, et al: *Trauma management—an emergency medicine approach,* St Louis, 2001, Mosby.)

BOX 44-6 Achilles Tendon Rupture

A common injury to the ankle is a tear or rupture of the Achilles tendon. The Achilles tendon, or *tendon calcaneus,* is the largest tendon in the human body. It is a large ropelike band of fibrous tissue that connects the powerful calf muscles to the calcaneus (heel bone). When the calf muscles contract, the Achilles tendon is tightened, pulling the heel. This allows a person to point the foot and stand on tiptoe. The Achilles tendon is vital to activities, such as walking, running, and jumping. Therefore, it is often a sports-related injury.

A complete tear through the tendon, which usually occurs about 2 inches above the heel, is called an Achilles tendon rupture. This injury usually results from excessive dorsiflexion of the foot. It is common in middle-age male athletes (the "weekend warrior"), in older people, and in those with arthritis and diabetes. Use of corticosteroids and antibiotics also increases the risk for this injury. Treatment may include surgical and nonsurgical therapies as well as foot and ankle casts or braces to prevent movement while the tendon heals.[7]

FIGURE 44-33 Immobilization of the foot and ankle.

Phalangeal Injury

Toe injuries often are caused by "stubbing" the toe on an immovable object. These injuries usually are managed by buddy taping the toe to an adjacent toe. This helps to support and immobilize the injury. Management includes the following measures:

1. Assessment of neurovascular status
2. Buddy splinting
3. Application of ice and elevation

OPEN FRACTURES

Patients with an **open fracture** require special care and evaluation by the paramedic. Fractures may be opened in two ways. They may be opened *from within,* as when a bone fragment pierces the skin, or they may be opened *from without* (e.g., after a gunshot wound). An open fracture also may have made contact with the skin some distance from the fracture site.

Although most open fractures are obvious because of associated hemorrhage, a small puncture wound may not be immediately apparent, and bleeding may be minimal. Therefore the paramedic must consider any soft tissue wound in the area of a suspected fracture to be evidence of an open fracture.

Open fractures are considered a true surgical emergency because of the potential for infection. Most authorities agree that open wounds associated with fractures should be covered with sterile, dry dressings. They should not be irrigated in the field or soaked with any type of antiseptic solution. Hemorrhage should be controlled with direct pressure and pressure dressings.

If a bone end or bone fragment is visible, it should be covered with a dry, sterile dressing and splinted. Bone ends that slip back into the wound during immobilization should be noted and reported to the receiving hospital so that the bone can be cleaned in surgery.

Stages of Fracture Healing

The healing of a fracture proceeds in several different stages. The time required for fracture healing depends on its severity and size. In the earliest stage following the fracture, a hematoma forms at the fracture site. This is followed by the formation of fibrovascular tissue (scar tissue) that replaces the hematoma and stabilizes the fracture area. Genes and proteins in the bone marrow then signal the production of osteoblasts (immature bone cells) and chondrocytes (cartilage cells). Next, the membrane around the bone and the immature bone cells form a callus at the fracture site. Newly formed cartilage cells begin to replace the scar tissue. In the final stage of healing, the immature bone cells held in place by the membrane grow and mature. This newly formed bone replaces the cartilage (*remodeling*) and the healing is completed (Figure 44-34).

The time required for fracture healing depends on how severe and how large it is, where it occurs, how the broken bone is used, and how strong the bone was before the fracture. Some small fractures in the hands heal in a few weeks. Large fractures in the legs or pelvis may take many months to heal (partly because these bones must bear the person's weight). Most fractured bones are immobilized with casts, braces, or surgical fixation devices while they heal. Even after healing, possible complications of fractures include the formation of a fat embolism, nonunion, and osteomyelitis.

STRAIGHTENING ANGULAR FRACTURES AND REDUCING DISLOCATIONS

Angular fractures and dislocations may pose significant problems in splinting and, in some situations, patient extrication and transport. When manipulation of a fracture is required to aid in transport or to improve circulation to the injured extremity, the paramedic should consult with medical direction.

NOTE

Limb-threatening injuries include knee dislocation, fracture or dislocation of the ankle, and subcondylar fractures of the elbow. These serious injuries require rapid transport for evaluation by a physician.

CRITICAL THINKING

Aside from narcotic analgesics, what other drugs may be indicated to relieve muscle spasm, provide anesthesia, and relax the patient while a dislocation or fracture is reduced?

As a rule, fractures and dislocated joints should be immobilized in the position of injury, and the patient should be transported as quickly as possible to the emergency department for x-ray films and realignment (reduction). (Radiographs are often taken of the affected limb to

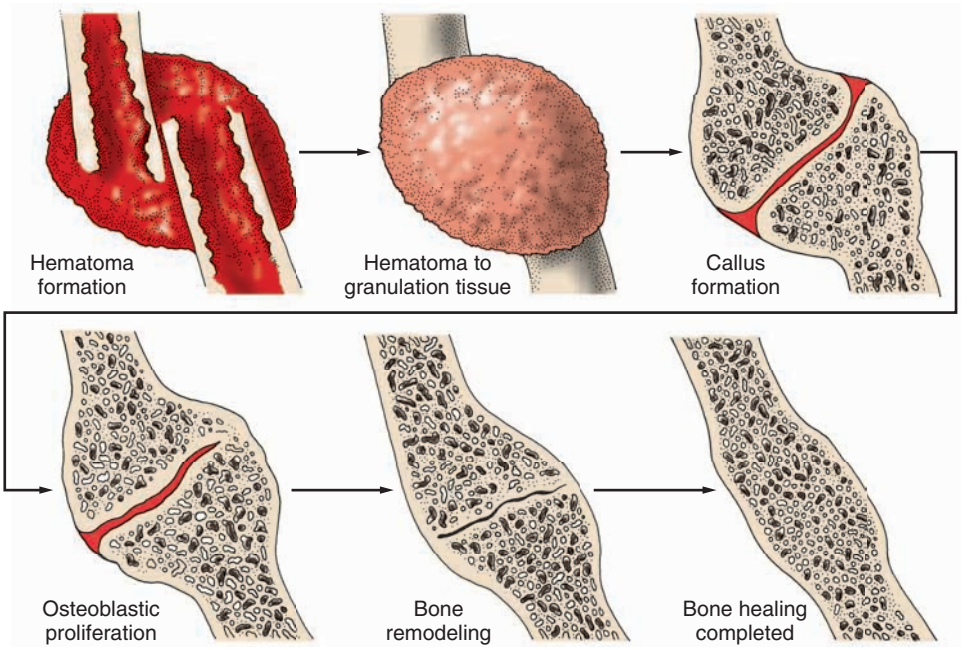

FIGURE 44-34 Stages of fracture healing. (From Linton AD: *Introduction to medical surgical nursing,* ed 4, St Louis, 2007, Saunders.)

rule out bone fragments or other fractures that may complicate reduction.) However, if transport is delayed or prolonged, and if circulation is impaired, an attempt should be made to reposition a grossly deformed fracture or dislocated joint. The exception is the elbow. The elbow should never be manipulated in the prehospital setting. A grossly deformed fracture or dislocation elsewhere often can be realigned if required. This usually can be done without causing more damage or extreme discomfort to the patient. The injury should be handled carefully. Gentle, firm traction should be applied in the direction of the long axis of the extremity. If obvious resistance to alignment is felt, the extremity should be splinted without repositioning.

NOTE

The National Association of EMS Physicians (NAEMSP) recommends reduction of dislocations when transport time is prolonged.[10] The rationale of the Association is that joints are more difficult to reduce if they are left in a dislocated position for a prolonged period; therefore the prehospital care provider can attempt reduction in the field. Before attempting reduction of dislocation in the prehospital setting, the paramedic should be properly trained in appropriate techniques. Attempted reduction should only be undertaken when permitted by written protocols or online medical direction. The procedures should be properly documented.[6]

Specific Techniques for Specific Joints

A brief description of specific techniques for realigning extremity injuries is provided in the following discussion. (Additional training and authorization from medical direction is required.) Only *one* attempt at realignment should be made in the prehospital setting, and *only* if severe neurovascular compromise is present (e.g., extremely weak or absent distal pulses). Moreover, the attempt should be made *only* after consultation with medical direction. Manipulation (if indicated) should be performed as soon as possible after the injury. It should not be performed if the patient has other severe injuries, including the potential for an associated fracture. If not contraindicated by other injuries, IV analgesics (e.g., ***fentanyl, morphine***) and benzodiazepines (e.g., ***midazolam***) should be used before realignment. The paramedic should always assess and document pulse, sensation, and motor function before and after manipulating any injured extremity or joint.

FINGER REALIGNMENT

1. Apply in-line traction along the shaft of the finger.
2. Continue with slow, steady traction until the finger is realigned and the patient feels relief from pain.
3. Immobilize the finger with a splint device or by buddy splinting.

SHOULDER REALIGNMENT

1. Attempt realignment only in the absence of severe back injury.
2. Check circulatory and sensory status.
3. Apply slow, gentle longitudinal traction, with countertraction exerted on the axilla.
4. Slowly bring the extremity to the midline. (Do not apply force.) Realign in the anatomical position while maintaining traction (Figure 44-35).
5. Immobilize with a sling and swathe.

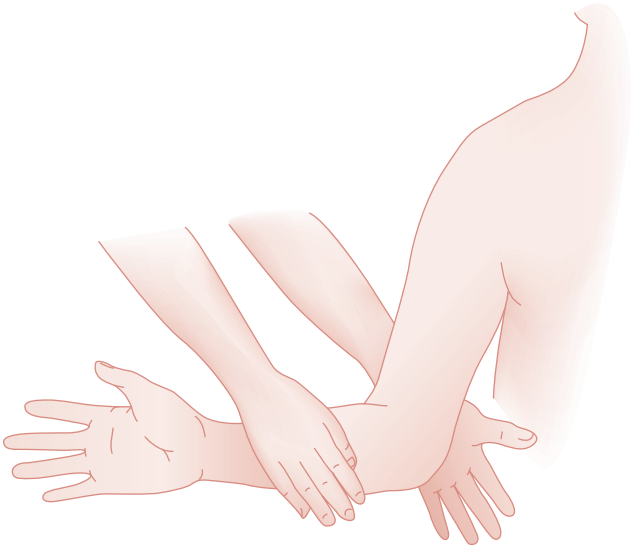

FIGURE 44-35 Traction-countertraction method for reducing anterior shoulder dislocation (From Marx J et al: *Rosen's emergency medicine: concepts and clinical practice*, ed 6, St Louis, 2006, Mosby.)

HIP REALIGNMENT

1. Place the patient supine and stabilize the pelvis.
2. With the knee flexed, apply steady traction in-line with the deformity.
3. Slowly bring the hip to 90 degrees of flexion with slow, steady traction and gentle rotation to relax the muscle spasm (Figure 44-36). Successful realignment is indicated by a "pop" into the joint, a sudden relief of pain, and easy manipulation of the leg to full extension.
4. Immobilize the leg in full extension with the patient positioned on a long spine board. Reevaluate pulses and neurovascular status.
5. If full extension is not achieved, immobilize the leg at a flexion not to exceed 90 degrees with pillows or blankets. Place the patient supine.

KNEE REALIGNMENT

1. Apply gentle, steady traction while moving the injured joint into normal position.
2. Successful realignment is indicated by a "pop" into the joint, resolution of deformity, relief of pain, and increased mobility.
3. Immobilize the leg in full extension (or slight flexion for comfort). Position the patient supine on a long spine board.

NOTE

There is a high incidence of popliteal artery injury with knee dislocation. Therefore, a dislocated knee requires immediate reduction. Placing the hip in flexion and applying longitudinal traction to the leg will facilitate the realignment of the tibia and femur. Angiography *after reduction* is indicated to rule out arterial injury.[11]

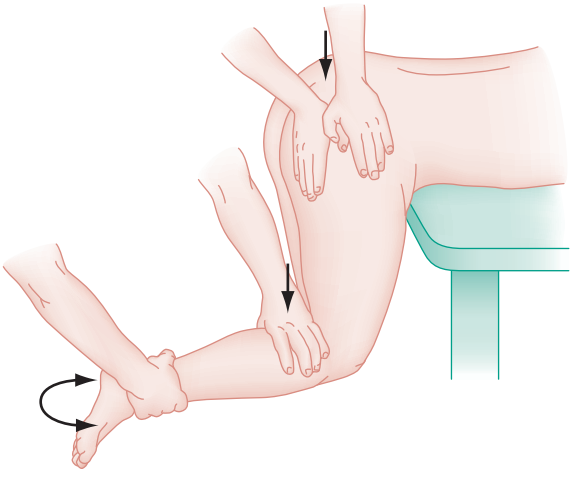

FIGURE 44-36 The Allis technique for hip reduction. (From Marx J et al: *Rosen's emergency medicine: concepts and clinical practice*, ed 6, St Louis, 2006, Mosby.)

ANKLE REALIGNMENT

1. Apply in-line traction on the talus while stabilizing the tibia.
2. Successful realignment is noted by a sudden rotation to a normal position.
3. Immobilize the ankle in the same manner as for a fracture.

REFERRAL OF PATIENTS WITH MINOR MUSCULOSKELETAL INJURY

Some patients with a minor musculoskeletal injury (e.g., a minor sprain) do not require transport by emergency medical services. To make this determination, the paramedic should follow these guidelines:

- Evaluate the need for immobilization.
- Evaluate the need for radiography. This is based on the patient's condition and the mechanism of injury.

CRITICAL THINKING

What should be documented for calls involving minor musculoskeletal injuries?

- Evaluate the need for emergency department assessment versus the patient going to his or her private physician. This is based on the patient's condition and the mechanism of injury.
- Consult with medical direction.

Patients who are not transported to the hospital should be given advice on how to care for the injury. (An instruction sheet should explain techniques for immobilization, elevation, cold or heat application, rest, use of analgesics, and indications for physician follow-up.) If any doubt exists about the seriousness of the patient's injury, the person should be transported to the emergency department for evaluation by a physician.

SUMMARY

- Injuries that can result from traumatic force on the musculoskeletal system include fractures, sprains, strains, and joint dislocations. Problems associated with musculoskeletal injuries include hemorrhage, instability, loss of tissue, simple laceration and contamination, interruption of blood supply, and long-term disability.
- Common signs and symptoms of extremity trauma include pain on palpation or movement, swelling or deformity, crepitus, decreased range of motion, false movement, and decreased or absent sensory perception or circulation distal to the injury.
- Once the paramedic has assessed for life-threatening conditions, the extremity injury should be examined for pain, pallor, paresthesia, pulses, paralysis, and pressure.
- Immobilization by splinting helps alleviate pain; reduces tissue injury, bleeding, and contamination of an open wound; and simplifies and facilitates transport of the patient. Splints can be categorized as rigid, soft or formable, and traction splints.
- Upper extremity injuries can be classified as fractures or dislocations of the shoulder, humerus, elbow, radius and ulna, wrist, hand, and finger. Most upper extremity injuries can be adequately immobilized by application of a sling and swathe.
- Lower extremity injuries include fractures of the pelvis and fractures or dislocations of the hip, femur, knee and patella, tibia and fibula, ankle and foot, and toes.
- Most open fractures are obvious because of associated hemorrhage. However, a small puncture wound may not be initially apparent. In addition, bleeding may be minimal. Therefore the paramedic must consider any soft tissue wound in the area of a suspected fracture to be evidence of an open fracture. Open fractures are considered a true surgical emergency. This is due to the potential for infection.
- Only *one* attempt at realignment should be made. This should be done *only* if severe neurovascular compromise is present (e.g., extremely weak or absent distal pulses). Moreover, it should be done *only* after consultation with medical direction.

CHAPTER

45 Environmental Conditions

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the physiology of thermoregulation.
2. Discuss the risk factors, pathophysiology, assessment findings, and management of specific hyperthermic conditions.
3. Discuss the risk factors, pathophysiology, assessment findings, and management of specific hypothermic conditions and frostbite.
4. Discuss the risk factors, pathophysiology, assessment findings, and management of submersion and drowning.
5. Identify the mechanical effects of atmospheric pressure changes on the body based on knowledge of the basic properties of gases.
6. Discuss the risk factors, pathophysiology, assessment findings, and management of diving emergencies and high-altitude illness.

KEY TERMS

acute mountain sickness A common high-altitude illness that results when an unacclimatized person rapidly ascends to high altitudes.

afterdrop phenomenon A sudden return of cold blood and waste products to the core of the body as a result of rewarming methods used to treat hypothermia.

air embolism The presence of air bubbles in the bloodstream.

barotrauma A physical injury sustained as a result of exposure to increased environmental pressure; also known as *dysbarism*.

barotrauma of ascent A diving illness that occurs through the reverse process of descent; also known as "reverse squeeze."

barotrauma of descent A diving illness that results from the compression of gas in enclosed spaces as the ambient pressure increases with descent under water; also known as "squeeze."

Boyle's law A law pertaining to the properties of gas; it states that if temperature remains constant, the volume of a given mass of gas is inversely proportional to the absolute pressure; that is, when the pressure is doubled, the volume of gas is halved (compressed into a smaller space), and vice versa.

central thermoreceptors Nerve endings located in or near the anterior hypothalamus that are sensitive to heat.

conduction The direct movement of heat from a warmer object to a cooler one (simple transfer).

convection The transfer of heat by mass motion of a fluid such as air or water.

core body temperature The temperature of deep structures of the body as compared with the temperatures of peripheral tissues.

Dalton's law A law pertaining to the pressure of gas; it states that the pressure exerted by each gas in a mixture of gases is the same pressure that the gas would exert if it alone occupied the same volume.

decompression sickness A multisystem disorder that results when nitrogen in compressed air converts back from solution to gas, forming bubbles in the tissues and blood.

demarcation The visible boundary between living tissue and necrotic tissue.

drowning A mortal event in which a submersion victim is pronounced dead at the scene of the attempted resuscitation or within 24 hours after arrival in the emergency department or hospital.

dysbarism Describes illnesses that result directly or indirectly from changes in ambient atmospheric pressure and the pressure of gases within the body.

frostbite A localized injury that results from environmentally induced freezing of body tissues.

frostnip A cold injury manifested by transient numbness and tingling that resolves after rewarming.

heat cramps Brief, intermittent, and often severe muscular cramps that frequently occur in muscles fatigued by heavy work or exercise.

heat exhaustion A form of heat illness characterized by minor aberrations in mental status, dizziness, nausea, headache, and a mild to moderate increase in the core body temperature.

heat stroke A syndrome that occurs when the thermoregulatory mechanisms normally in place to meet the demands of heat stress break down entirely. As a result, the body temperature increases to extreme levels. Multisystem tissue damage and physiological collapse also occur.

Henry's law A law of gas pressure that states that, at a constant temperature, the solubility of a gas in a liquid solution is proportionate to the partial pressure of the gas.

high-altitude cerebral edema The most severe form of acute high-altitude illness. It is characterized by a progression of global cerebral signs in the presence of acute mountain sickness.

high-altitude illness Refers to illness that principally occurs at altitudes 8200 feet or more above sea level.

high-altitude pulmonary edema A high-altitude illness thought to be caused at least partly by an increase in pulmonary artery pressure that develops in response to hypoxia.

hyperthermia Abnormal elevation of body temperature.

hypothermia An abnormal body temperature below 95° F (35° C).

mammalian diving reflex A reflex stimulated by cold water that shunts blood to the brain and heart from the skin, gastrointestinal tract, and extremities.

nitrogen narcosis An illness associated with scuba diving in which nitrogen becomes dissolved in solution as a result of greater than normal atmospheric pressure; also known as rapture of the deep.

Osborn wave A positive deflection at the J point on an ECG, characteristically seen in hypothermia; also known as a J wave.

peripheral thermoreceptors Nerve endings sensitive to heat, located in the skin and some mucous membranes; they usually are categorized as cold or warm receptors.

pulmonary overpressurization syndrome A condition that results from expansion of trapped air in the lungs; it may lead to alveolar rupture and extravasation of air into extraalveolar locations.

radiation The direct release of body heat to cooler surroundings.

recompression The use of elevated pressure (including hyperbaric oxygen therapy) to treat conditions within the body caused by a rapid decrease in pressure.

submersion An incident in which a person experiences some swimming-related distress that is sufficient to require support in the prehospital setting and transportation to a medical facility for further observation and treatment.

thermogenesis The production of heat, especially by the cells of the body.

thermolysis The dissipation of heat by means of radiation, evaporation, conduction, or convection.

thermoregulation The maintenance of body temperature, even under a variety of external conditions.

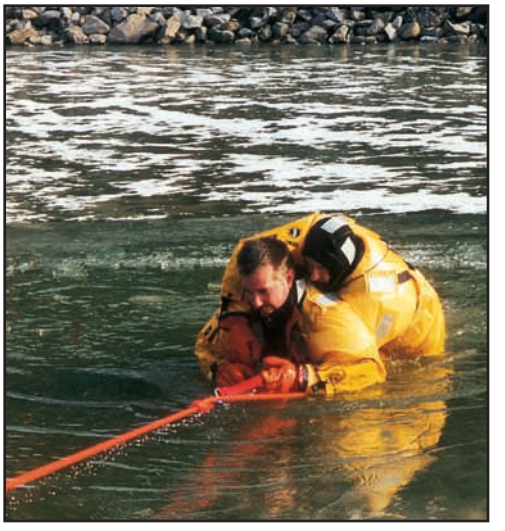
trench foot An injury that occurs from prolonged exposure to cold, but not freezing, water.

Exposure to elements in the environment can produce many types of emergencies. Paramedics must be prepared to recognize and manage these conditions. This requires being knowledgeable about the causative factors and the pathophysiology of specific disorders.

THERMOREGULATION

Thermoregulation is the maintenance of body temperature, even under a variety of external conditions. Body temperature is regulated in the brain by a thermoregulatory center.

This center is located in the posterior hypothalamus. It receives information from **central thermoreceptors** in or near the anterior hypothalamus and from **peripheral thermoreceptors** in the skin and some mucous membranes. Peripheral thermoreceptors are nerve endings usually categorized as cold receptors and warm receptors. Cold receptors are stimulated by lower skin-surface temperatures. Warm receptors are stimulated by higher skin-surface temperatures. Information from these receptors is transmitted by the spinal cord to the posterior hypothalamus. The posterior hypothalamus responds with appropriate signals to help the body reduce heat loss and increase heat production (cold receptor stimulation) or increase heat loss and reduce heat production (warm receptor stimulation).



(Courtesy Creve Coeur Fire Protection District.)

CRITICAL THINKING
The body has many more cold receptors than heat receptors. Why do you think this is true?

Central thermoreceptors are neurons that are sensitive to changes in temperature. These neurons react directly to changes in the temperature of the blood. They send messages to the skeletal muscle through the central nervous system (CNS). They affect vasomotor tone, sweating, and the metabolic rate through sympathetic nerve output to skin arterioles, sweat glands, and the adrenal medulla.

As discussed in Chapter 20, the thermoregulatory center has an inherent set point. This maintains a relatively constant **core body temperature** (CBT) of 98.6° F (37° C). To maintain an optimum environment for normal cell metabolism (homeostasis), the body must keep the CBT fairly constant, even when external and internal conditions tend to raise or lower it. Body temperature can be increased or decreased in two ways. One way is through the regulation of heat production **(thermogenesis).** The other way is through the regulation of heat loss **(thermolysis).**

Regulating Heat Production

The body can generate heat in response to cold. It does this through mechanical, chemical, metabolic, and endocrine activities. Several physiological and biochemical factors affect the direction and magnitude of these compensatory responses. Such factors include the person's age, general health, and nutritional status.

Heat is controlled chemically by cellular metabolism (oxidation of energy sources). Every tissue contributes to this type of heat production. However, skeletal muscles produce the largest amount of heat, particularly when shivering occurs. Along with shivering, which is often associated with chattering of the teeth, vasoconstriction occurs to conserve as much heat as possible. Shivering is the body's best defense against cold. It can increase heat production by as much as 400%.[1]

CRITICAL THINKING
What fuels does the body need to increase heat production through the mechanism of shivering?

Endocrine glands also regulate heat production. They do this through the release of hormones from the thyroid gland and adrenal medulla. Sympathetic discharge of epinephrine and norepinephrine (along with the activity of sympathetic nerves that lead to adipose tissue) increases metabolism. This results in an increase in heat production. Box 45-1 presents examples of ways the body regulates heat production.

Regulating Heat Loss

Heat is lost from the body to the external environment through the skin, lungs, and excretions. The skin is the most important of these in regulating heat loss. Radiation, **conduction**, **convection**, and evaporation are the major mechanisms of heat loss (Figure 45-1).

Radiation is the direct release of body heat to cooler surroundings. The surface of the human body constantly emits heat in the form of infrared rays. If the surface of the body is warmer than the environment, heat is lost through radiation.

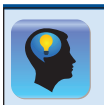
Conduction is the direct movement of heat from a warmer object to a cooler one (simple transfer). Heat moves from a higher temperature to a lower temperature. Thus the body surface loses or gains heat by direct contact with cooler or warmer surfaces, including air. If the ambient air temperature is lower than the skin temperature, body heat is lost to the surrounding air by conduction. The greater the temperature difference between two objects, the more quickly heat is transferred between them.

Convection is similar to conduction; however, in convection the two objects in contact are also moving relative to one another. It is heat transfer by mass motion of a fluid such as air or water. For example, if air or water next to the body is heated, moves away, and is replaced by cool air or water, heat loss occurs by convection. Convection can be greatly aided by external forces such as wind or fans. It promotes conductive heat exchange by continuously maintaining a supply of cool air. Factors that contribute to the cooling effects of convection are the speed of air currents and the temperature of the air.

BOX 45-1 Compensatory Mechanisms for Regulating Heat Production

Mechanisms That Decrease Heat Loss
Peripheral vasoconstriction
Reduction of surface area by body position (or clothing)
Piloerection (not effective in humans)

Mechanisms That Increase Heat Production
Shivering
Increased voluntary activity
Increased hormone secretion
Increased appetite



CRITICAL THINKING
How does wearing the fully enclosed hazardous materials suit affect your body's ability to regulate temperature?

Evaporation is a process by which fluid changes from a liquid to a gas, and lowers the temperature on the surface where the evaporation occurred. When fluid evaporates, it absorbs heat from surrounding objects and air. The temperature of the surrounding air and the relative humidity greatly affect the amount of heat lost as a result of evaporation of moisture from the skin or the respiratory tract

(breathing). The relative humidity is 100% when the air is fully saturated with moisture. Sweating can markedly increase evaporative heat loss as long as the humidity is low enough to allow the sweat to evaporate. At humidity levels above 75%, evaporation decreases. At levels approaching 90%, evaporation essentially ceases.[2] Box 45-2 presents other examples of ways the body regulates heat loss.

External Environmental Factors

Some factors in the environment can contribute to a medical emergency. They also may affect rescue and transport. These elements include the climate, season, weather, atmospheric pressure, and terrain. When the potential for an environmental emergency exists, the paramedic must consider the following factors:

- Localized prevailing weather norms and any deviations
- Characteristics of seasonal variation in climate
- Weather extremes (wind, rain, snow, humidity)
- Barometric pressure (e.g., at altitude or under water)
- Terrain that can complicate injury or rescue

The patient's health also is a factor related to environmental stressors. It can also worsen other medical or traumatic conditions. Examples include the patient's age, predisposing medical conditions, use of prescription and over-the-counter medications, use of alcohol or recreational drugs, and previous rate of exertion.

BOX 45-2 Compensatory Mechanisms for Regulating Heat Loss

Mechanisms That Increase Heat Loss

Vasodilation of skin vessels
Sweating

Mechanisms That Decrease Heat Production

Decreased muscle tone and voluntary activity
Decreased hormone secretion
Decreased appetite

FIGURE 45-1 Mechanisms of heat loss. (From McSwain N, Paturas J: *The basic EMT: comprehensive prehospital patient care,* ed 2, St Louis, 2001, Mosby.)

HYPERTHERMIA

Hyperthermia, or heat illness, results from one of two basic causes: One cause is temperature-regulating mechanisms that are overwhelmed by high temperatures in the environment or, more commonly, by excessive exercise in moderate to extremely high temperatures. The second cause is temperature-regulating centers that fail, usually in older adults or in ill or incapacitated patients. Either cause can result in heat illness such as heat cramps, heat exhaustion, and heat stroke.

Heat Cramps

Heat cramps are brief, intermittent, and often severe muscular cramps that occur in hot environments. They often affect muscles fatigued by heavy work or exercise. The primary cause of heat cramps is sodium and water loss.

People who suffer from heat cramps sweat profusely and drink water without adequate salt. During times of high environmental temperatures, 1 to 3 L of water per hour can be lost through sweating. Each liter contains 30 to 50 mEq of sodium chloride. The water and sodium deficiency together cause muscle cramping. This normally occurs in the most heavily exercised muscles, including the calves and arms, although any muscle can be involved. The patient is usually alert and has hot, sweaty skin, tachycardia, and a normal blood pressure. The CBT is normal.

Heat cramps are easily managed by removing the patient from the hot environment. Also, sodium and water should be replaced. In more serious cases, medical direction may recommend intravenous (IV) infusion of a balanced sodium chloride solution. Oral salt additives (e.g., salt tablets) can cause gastrointestinal irritation, ulceration, and vomiting. This worsens the electrolyte imbalance. Paramedics should follow local protocol with regard to providing a carbohydrate- and salt-containing beverage (e.g., Gatorade and Powerade) to help rehydrate patients.

Heat Exhaustion

Heat exhaustion is a more severe form of heat illness. It is characterized by dizziness, nausea, headache, and mild to moderate elevation of the CBT (up to 103° F [39° C]). In severe cases, dizziness caused by significant intravascular volume loss, as well as fainting, may occur. This orthostatic dizziness occurs when the patient changes from a lying position to a sitting or standing position.

Like heat cramps, heat exhaustion more often is associated with a hot environment and results in profuse sweating. Loss of water and salt, electrolyte imbalance, and difficulty maintaining blood pressure contribute to inadequate peripheral and cerebral perfusion. The person usually recovers rapidly when removed from the hot environment, given replacement fluids, and cooled with a cool water spray. Patients with significant fluid loss or orthostatic hypotension may require IV administration of a balanced sodium chloride solution. Heat exhaustion can progress to heat stroke if left untreated.[2]

Heat Stroke

Heat stroke occurs when the body's temperature-regulating mechanisms break down entirely. As a result of this failure, the body temperature rises to 105.8° F (41° C) or higher. This damages tissue in all the body systems and results in total body collapse. Heat stroke is a true medical emergency. The syndrome commonly is classified into two types: classic heat stroke and exertional heat stroke.

NOTE

Increased body temperature caused by failure of the temperature-regulating mechanisms should not be confused with fever associated with a response to inflammation or infection. With fever, the effect on the hypothalamus is caused by endogenous pyrogens released by phagocytic leukocytes. Antipyretic drugs can reverse these effects, returning the set point of the hypothalamus to normal.

Classic heat stroke occurs during periods of sustained high ambient temperatures and humidity. The illness commonly affects the very young, older adults, and those who live in poorly ventilated homes without air conditioning. An example is a young child left in an enclosed car on a hot afternoon. Another example is an older person confined to a hot room during a heat wave. Victims of classic heat stroke also often suffer from chronic diseases. Some of these include diabetes, heart disease, alcoholism, or psychiatric disorders. These diseases predispose the individual to the syndrome. Many patients who are susceptible to classic heat stroke take prescribed medications for other conditions. These may include diuretics, antihypertensives, psychotropics (antipsychotics, phenothiazines), antihistamines, and anticholinergics. These drugs further impair a person's ability to tolerate heat stress. In these patients the illness develops from poor dissipation of environmental heat.

NOTE

The autoimmune neuropathy associated with diabetes can interfere with vasodilation, perspiration, and thermoregulatory input. Some cardiac drugs (e.g., anticholinergics, beta blockers, diuretics) can predispose a patient to dehydration, can interfere with vasodilation, and can reduce the body's ability to increase the heart rate in response to a volume loss.

In contrast to patients with classic heat stroke, patients with *exertional heat stroke* are usually young and healthy. Athletes, military recruits, and firefighters who work or exercise in the heat and humidity often are affected. In these situations, heat builds up more rapidly in the body than it can be dispersed into the environment. Preventive measures to reduce the risk of exertional heat illness for all age groups include the following:

- Avoiding or limiting exercise in hot environments, especially on consecutive days
- Maintaining an adequate fluid intake

- Achieving acclimatization, which results in more perspiration with a lower salt concentration, thereby increasing fluid volume in the body

CLINICAL MANIFESTATIONS

As described previously, the temperature-regulating centers in the brain receive their information largely from the temperature of circulating blood in the deep and superficial veins and from the skin. In response to hypothalamic stimulation, a number of physiological events occur: (1) the respiratory rate quickens to increase heat loss through exhaled air; (2) cardiac output increases to provide more blood flow through skin and muscle to enhance heat radiation; and (3) sweat gland activity increases to enhance evaporative heat loss. These compensatory mechanisms require a normally functioning CNS to properly respond to the temperature extreme. They also require a working cardiovascular system to move excess heat from the core to the surface of the body. Problems in either or both of these systems lead to a rapidly increasing CBT.

Central Nervous System Manifestations. The CNS manifestations of heat stroke vary. Some patients may be in frank coma. Others may show confusion and irrational behavior before collapse. Convulsions are common. They can occur early or late in the course of the illness. Because the brain stores little energy, it depends on a constant supply of oxygen and glucose. Decreased cerebral perfusion pressure results in cerebral ischemia and acidosis. Increased temperatures markedly increase the metabolic demands of the brain as well. The extent of brain damage depends on the severity and duration of the hyperthermic episode. Fever from illness (e.g., infection) and an increased CBT from heat stroke produce similar symptoms, especially in the central nervous system. The paramedic should obtain a thorough history (if available) so as to distinguish between the two syndromes. If unsure of the cause, the paramedic should treat the patient for heat stroke.

CRITICAL THINKING

What other conditions can demonstrate the types of mental status changes seen with heat stroke?

Cardiovascular Manifestations. A rise in skin temperature reduces the thermal gradient between the core and the skin. This causes an increase in skin blood flow (peripheral vasodilation), which gives the skin a flushed appearance. About 50% of victims of exertional heat stroke have persistent sweating,[2] which results from increased release of catecholamines. In classic heat stroke, sweating usually is absent. This is due to dehydration, drug use that impairs sweating, direct thermal injury to sweat glands, or sweat gland fatigue. Therefore the presence of sweating does not rule out the diagnosis. Also, the cessation of sweating is not the cause of heat stroke. Peripheral vasodilation results in decreased vascular resistance and shunting as the illness progresses. High-output cardiac failure is common. It is manifested by extreme tachycardia and hypotension. Cardiac output initially can be four to five times normal. However, as temperatures continue to rise, myocardial contractility begins to decrease. Also, the central venous pressure rises. In any age group, the presence of hypotension and decreased cardiac output points to a poor prognosis. Other systemic manifestations associated with heat stroke include:

- Pulmonary edema (accompanied by systemic acidosis, tachypnea, hypoxemia, and hypercapnia)
- Myocardial dysfunction
- Gastrointestinal bleeding
- A reduction in renal function (secondary to hypovolemia and hypoperfusion)
- Hepatic injury
- Clotting disorders
- Electrolyte abnormalities

MANAGEMENT

Heat stroke almost invariably leads to death if left untreated. The factors most important to a successful outcome are initiation of basic life support (BLS) and advanced life support (ALS) measures, rapid recognition of the heat illness, and rapid cooling of the patient. After ensuring an adequate airway and ventilatory and circulatory support, the paramedic should manage the patient with heat stroke as follows[3]:

1. Move the patient to a shady environment and remove restrictive clothing. If available, use hyperthermic thermometers (e.g., rectal probes) to monitor the CBT. Take and record the temperature at least every 5 minutes during the cooling process. This ensures adequate rates of cooling. It also helps to prevent inadvertent (rebound) hypothermia. Rebound hypothermia can best be avoided by stopping the cooling measures when the patient's CBT reaches about 102° F (39° C).
2. Begin cooling by fanning the patient while keeping the skin wet. Continue lowering the body temperature by this method en route to the hospital. If transport is delayed, complete immersion (victim is placed in cold water up to the chin) or spraying tepid water (60° F [16° C]) over the body surface is recommended. Shivering should be controlled with IV ***diazepam***.

NOTE

Submersion in ice water or cold water is an effective means to rapidly lower core body temperature.[3] The use of these methods is controversial. Some authorities believe they may lead to patient discomfort, shivering, frank shaking, peripheral vasoconstriction, and convulsions, which act to increase the CBT as the body temperature is lowered. Other authorities recommend ice water submersion after other methods prove unsuccessful within 30 minutes of treatment.[4] Paramedics should follow the recommendations established by medical direction.

3. If hypovolemia is present, administer IV fluids per medical direction. (Ideally, 1 to 2 L of fluid should be administered during the first hour after collapse and additional fluids administered according to the level of hydration.) In most patients the blood pressure rises to a normal range during the cooling process. This occurs as large volumes of blood from the skin move back to the central circulation. Rapid cooling directly improves cardiac output. Be very cautious with fluid replacement. Also, closely monitor the patient for signs of fluid overload. The administration of too much fluid can cause pulmonary edema, especially in older adults.
4. Administer medications as prescribed by medical direction. Depending on the patient's status and response to cooling methods, these drugs may include ***diazepam*** or ***lorazepam*** for sedation and seizure control, ***mannitol*** to promote renal blood flow and diuresis, and glucose to manage hypoglycemia.

HYPOTHERMIA

Hypothermia (CBT less than 95° F [35° C]) can result from a decrease in heat production, an increase in heat loss, or a combination of these two processes.

Hypothermia can have metabolic, neurological, traumatic, toxic, and infectious causes. However, it most often is seen in cold climates and in exposure to extremely cold conditions in the environment. Failure to recognize and properly treat hypothermia can increase the rate of morbidity and mortality.

Pathophysiology

Exposure to cold produces a chain of events in the body aimed at conserving core heat. Initially, immediate vasoconstriction in the peripheral vessels occurs. At the same time, the rate of metabolism by the CNS increases. The blood pressure and the heart and respiratory rates also increase dramatically. As cold exposure continues, muscle tone increases. The body generates heat in the form of shivering. Shivering continues until the CBT reaches about 86° F (30° C), glucose or glycogen is depleted, or insulin is no longer available for glucose transfer. When shivering stops, cooling is rapid. A general decline then begins in the function of all body systems.

With continued cooling, respirations decline slowly; the pulse rate and blood pressure decrease; the blood pH drops; and significant electrolyte imbalances emerge. Hypovolemia can develop from a shift of fluid out of the vascular space, with increased loss of fluid through urination (*cold diuresis*). After early tachycardia, progressive bradycardia develops. This often does not respond to ***atropine.*** Significant electrocardiographic (ECG) changes occur. These include prolonged PR, QRS, and QT intervals; and obscure or absent P waves.[2] In addition, the J point (**Osborn wave**) may be present at the junction of the QRS complex and ST segment (Figure 45-2). These events generally are followed by cardiac and respiratory arrest as the CBT approaches 68° F (20° C).

The progression of clinical signs and symptoms of hypothermia is divided into three classes based on the CBT[5]: mild, moderate, and severe. *Mild hypothermia* is classified as a CBT between 93.2° and 96.8° F (34° and 36° C); *moderate hypothermia* as a CBT between 86° and 93° F (30° and 34° C); and *severe hypothermia* as a CBT below 86° F (30° C). The signs and symptoms of the three classes of hypothermia are listed in Table 45-1.

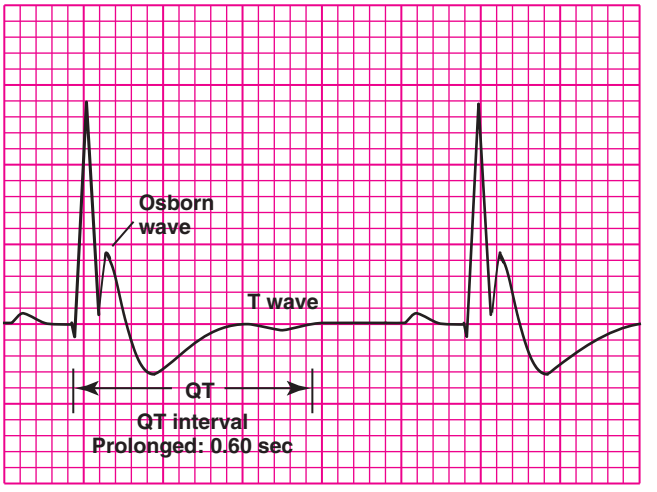


FIGURE 45-2 Osborn wave of hypothermia. (From Wesley K: *Huszar's basic dysrhythmias and acute coronary syndromes: interpretation and management*, ed 4, St Louis, 2012, Mosby.)

TABLE 45-1 Progression of Clinical Signs and Symptoms of Hypothermia*

Classification	Core Body Temperature	Signs and Symptoms
Mild	96.8° F (36° C)	Increased metabolic rate, maximum shivering, thermogenesis
	93.2° F (34° C)	Impaired judgment, slurred speech
Moderate	86° F (30° C)	Respiratory depression, myocardial irritability, bradycardia, atrial fibrillation, Osborn waves
Severe	<86° F (<30° C)	Basal metabolic rate 50% of normal, loss of deep tendon reflexes, fixed and dilated pupils, spontaneous ventricular fibrillation

*Often no reliable correlation is seen between clinical signs and symptoms and a specific core body temperature.

Those at increased risk for developing unintentional hypothermia are outdoor enthusiasts (e.g., campers, hikers, hunters, and fishermen), older adults, the very young, and individuals with concurrent medical or psychiatric illness. Thermoregulatory mechanisms also can be impaired by brain damage caused by trauma, hemorrhage, hypoxia, and CNS depression from drug overdose or intoxicants. Drugs known to impair thermoregulation include alcohol, antidepressants, antipyretics, phenothiazines, sedatives, and various pain medicines (including ***aspirin,*** acetaminophen, and nonsteroidal antiinflammatory drugs [NSAIDs]). Acid-base imbalances, such as those that occur during ketoacidosis, also can affect the body's ability to stabilize body temperature. This occurs when the imbalances cause a decrease in heat production or an increase in heat loss.

CRITICAL THINKING

What group of people is especially vulnerable to hypothermia as a result of their environmental, medical, and social situation?

Management

The first step in managing hypothermia is to maintain a high degree of suspicion for its presence. When the exposure is obvious (e.g., a victim involved in an avalanche or cold water immersion), diagnosis is simple. However, in some situations, signs and symptoms may be subtle (e.g., hunger, nausea, chills, and dizziness). When hypothermia is suspected, the paramedic's immediate action is to extricate and evacuate the patient to a site of warm shelter; remove cold, wet clothing; prevent a further drop in the victim's CBT; survey for traumatic injuries; cover the patient with warm blankets and increase the temperature in the ambulance; and rapidly and gently transport the patient for definitive care.

Rewarming techniques for managing patients with hypothermia are classified as *passive, active external,* and *active internal.* Passive rewarming includes measures such as moving the patient to a warm environment, removing wet clothing, and applying warm blankets. Active rewarming techniques refer to heating methods or devices such as radiant heat, forced hot air, and warm water packs. Active internal rewarming is invasive. Some of these procedures can be performed in the field, such as administering warmed IV fluids and providing warm, humidified oxygen. Other procedures are reserved for in-hospital care. Examples include peritoneal and/or pleural lavage with warm fluids; use of esophageal rewarming tubes; cardiopulmonary bypass (active core rewarming); and extracorporeal circulation (blood warming with partial bypass).

NOTE

Rewarming methods such as hot water immersion can cause hypotension from peripheral vasodilation (rewarming shock) and a sudden return of cold, acidotic blood and waste products to the body's core **(afterdrop phenomenon).** Therefore active rewarming techniques in the prehospital setting generally are avoided unless patient transportation is to be delayed.

Mild Hypothermia

In mild cases of hypothermia, removal of the victim from the cold environment and passive rewarming may be all that is necessary to manage the cold exposure. The paramedic can accomplish this by removing wet clothing (wet clothes allow five times as much heat loss as dry clothes) and wrapping the victim in a dry blanket to prevent further chilling and help retain the patient's body heat. If the victim is conscious, warm drinks and sugar sources can support a gradual rise in CBT and help correct any dehydration present. Patients should not be permitted to smoke, which causes vasoconstriction; to drink alcoholic beverages, which produce peripheral vasodilation and increase heat loss from the skin; or to drink caffeine-containing beverages, which cause vasoconstriction and diuresis. These patients may be lethargic and somewhat dulled mentally but generally are oriented with no marked mental derangements.

Moderate Hypothermia

At CBTs below 93° F (34° C), mental derangements are invariably present and include disorientation, confusion, and lethargy proceeding to stupor and coma. Patients with moderate hypothermia usually have lost their ability to shiver, and their uncoordinated physical activity renders them unable to perform meaningful tasks. Management of patients with moderate hypothermia begins with ensuring adequate airway, ventilatory, and circulatory support and maintaining body temperature. The paramedic should first employ passive rewarming techniques and should not permit these patients to move about independently or physically exert themselves. Even minor physical activity can trigger dysrhythmias, including ventricular fibrillation. External rewarming (e.g., heated blankets, forced air, and warmed IV infusion) and rapid and gentle transportation for definitive care are indicated for these patients. Careful monitoring of the patient's mental status, ECG, and vital functions is crucial.

NOTE

Paramedics should not delay urgent procedures in patients who are hypothermic. Airway management should begin with basic manual procedures (head-tilt, chin-lift) and ventilatory assistance. The use of oral or nasal adjuncts, including oral and nasal intubation, may be necessary to control the airway and provide ventilatory support.

Severe Hypothermia

If the patient's CBT is below 86.4° F (30° C), he or she usually is unconscious. The patient should be gently moved to a warm environment if vital signs are present. The paramedic should institute passive and external rewarming, administer oxygen, and transport the patient to an appropriate medical facility.

If the patient with moderate-to-severe hypothermia is in cardiac arrest (ventricular fibrillation [VF] or pulseless ventricular tachycardia [VT]), the paramedic should begin CPR and attempt defibrillation once. If the patient does not respond to one shock, further defibrillation attempts should be deferred. Care should be focused on providing effective CPR, rewarming the patient, and ensuring rapid transport to the emergency department. In-hospital active internal rewarming will be required for these patients. If a patient with severe hypothermia is pulseless, cyanosis, fixed and dilated pupils, and stiff and rigid muscles (simulating rigor mortis) may be present. Prolonged resuscitation can be beneficial in these patients, and CPR is indicated even if signs of death are present.[6] (Resuscitation may be withheld, however, if the victim has obvious lethal injuries or if the body is frozen so that the nose and mouth are blocked by ice and chest compression is impossible.) Some physicians will not presume a hypothermic patient to be dead until a near-normal CBT has been achieved and resuscitation efforts are still unsuccessful.

SPECIAL CARE CONSIDERATIONS FOR PATIENTS WITH HYPOTHERMIA

Prehospital care for patients with hypothermia should focus on airway, breathing, and circulation with some modification in approach. These modifications are listed below[6]:

1. Pulse and respirations may be difficult to detect. These vital signs (including ECG readings) should be assessed for 30 to 45 seconds to confirm the need for CPR. If there is any doubt about the presence of a pulse, begin CPR immediately.
2. For unresponsive patients and those in arrest, advanced airway management is indicated. This will serve two purposes: (1) it will enable provision of effective ventilation with warm, humidified oxygen (if available); and (2) it will isolate the airway to reduce the likelihood of aspiration.
3. The hypothermic heart may be unresponsive to cardiovascular drugs. In addition, drug metabolism may be reduced, allowing for toxic accumulation of the drug in the peripheral tissues. For these reasons, IV drugs were often withheld when the CBT was less than 30°C. Without sufficient data to support these theories, the American Heart Association has stated it may be reasonable to consider administration of a vasopressor during cardiac arrest according to the standard ACLS algorithm, concurrent with rewarming strategies (Class IIb).
4. Sinus bradycardia may be protective in severe hypothermia. This rhythm may maintain sufficient oxygen delivery when hypothermia is present. Cardiac pacing usually is not indicated or successful.

SHOW ME THE EVIDENCE

Researchers evaluated 170 patients in Cambodia and Iraq injured by landmines. Of that group 30 received prehospital hypothermia prevention measures and 140 did not. Hypothermia prevention measures for this study included removing wet clothing, using buddy warming, wrapping in blankets, protecting from wind, and administering warmed (40° C, 104° F) IV fluids. For the purpose of the study hypothermia was a body temperature less than 36° C (97° F) measured orally. In the intervention group 21% were hypothermic when first evaluated (mean 35.1° C; 95.2° F). In the prevention group one patient had hypothermia on hospital admission versus 18.6% of the control group. The risk of hypothermia increased with extended transport time. The researchers conclude that simple measures in the prehospital setting can reduce the incidence of posttraumatic hypothermia and its attendant complications.

FROSTBITE

Frostbite is a localized injury. It results from environmentally induced freezing of body tissues. It often occurs in the lower extremities, particularly the toes and feet. Less often it occurs in the upper extremities (the fingers and hands). Frostbite also occurs on the ears, nose, and other body areas not protected from environmental extremes.

Pathophysiology

Frostbite occurs as ice crystals form in tissue. This produces macrovascular and microvascular damage and direct cellular injury. The freezing depth depends on the intensity and duration of cold exposure. Severe freezing can also occur in tissue exposed to volatile hydrocarbons (e.g., from industrial injuries) at low temperatures.

Under most conditions of frostbite, ice crystals form in the extracellular tissue. This draws water out of the cells and into the extravascular spaces. As a result, the electrolyte concentration in the cell can reach toxic levels. The ice crystals can also expand and cause direct mechanical destruction of tissue. This leads to damage to blood vessels (particularly the endothelial cells), partial shrinkage and collapse of the cell membrane, loss of vascular integrity, local edema, and disruption of nutritive blood flow. Ischemia often produces the most damaging effects of frostbite.

When frozen tissue thaws, blood flow through the capillaries is initially restored. However, blood flow declines within minutes after thawing. This occurs as the arterioles and venules constrict and release emboli, which travel through the small vessels. Progressive tissue loss results from thrombosis and hypoxia. The endothelium is damaged and results in deterioration of the microvasculature and dermal necrosis. The process of thawing and refreezing is more harmful to tissue than allowing the frostbitten part to remain frozen until it can be warmed with minimal risk of refreezing. In addition to extreme temperature, wind, and humidity, predisposing factors for frostbite include the following:

- Lack of protective clothing
- Poor nutrition
- Preexisting injury or medical or psychiatric illness
- Fatigue
- Decrease in local tissue perfusion
- Tobacco use
- Atherosclerosis
- Tight, constrictive clothing (especially socks and boots)
- Increased vasodilation
- Alcohol or other drug consumption in hypothermic patients
- Use of medications
- History of previous cold injury

Classifications and Symptoms

Cold injury can be subdivided into a number of classifications. For example, cold injury commonly is divided into two categories: frostnip and frostbite. Initial evaluation of the severity of the frostbite is difficult. This is because the injury does not always reflect the underlying vascular changes.[2] Regardless of the depth of injury, the area may appear to be frozen. Palpation may help the paramedic to distinguish between superficial and deep injury. With superficial injury, the underlying tissue springs back on compression. With deep injury, the underlying tissue is hard and cannot be compressed.

FROSTNIP

Frostnip is manifested by transient numbness and tingling that resolves after rewarming. This cold injury does not represent true frostbite, because no tissue destruction occurs. The initial symptoms are coldness and numbness in the affected area.

FROSTBITE

Frostbite can be graded as first-, second-, and third-degree injuries, based on the severity of exposure. Affected areas may include the dermal and shallow subcutaneous layers as well as the subdermal layers and deep tissues. All grades involve at least some tissue loss. The disrupted nutritional capillary flow is never restored to the damaged tissue. With severe injuries, the affected area remains cold, mottled, and blue or gray after rewarming. After rewarming, edema usually appears within 3 hours. This is followed by the formation of vesicles within 3 to 24 hours (Figure 45-3). The blisters begin to resolve within 1 week, after which the skin blackens into a hard eschar. Eventually the blackened tissue peels away **(demarcation)** (Figure 45-4). This reveals shiny, red skin beneath. This tissue is sensitive to heat and cold and often remains susceptible to repeated frostbite injury.

Management

Prehospital care for frostbite is limited to support of the patient's vital functions, elevation and protection of the affected extremity (jewelry should be removed), pain management, and rapid transport to a medical facility. Vigorous rubbing or massage is ineffective and harmful. Partial, slow rewarming with blankets or other warm objects can worsen the injury. If the frostbite involves the patient's lower extremities, the person should not be allowed to walk. During transport, all restrictive and wet clothing should be removed from the patient. These should be replaced with warm, dry clothing and blankets to guard against hypothermia. The patient should not be permitted to consume alcohol or smoke tobacco. Rapid rewarming of the frozen part by immersion in hot water (maximum of 104° F [40° C]) is the most effective therapeutic measure for preserving viable tissue. Because of the risk of refreezing, this method of rewarming should not be used in the prehospital setting if transport to a medical facility will be delayed (e.g., backwoods rescue, natural disasters).

FIGURE 45-3 Edema and blister formation 24 hours after frostbite injury in an area covered by a tightly fitting boot. (From Auerbach PS: *Management of wilderness and environmental emergencies*, ed 5, St Louis, 2007, Mosby.)

FIGURE 45-4 Gangrenous necrosis 6 weeks after a frostbite injury. (From Auerbach PS: *Management of wilderness and environmental emergencies*, ed 5, St Louis, 2007, Mosby.)

NOTE

Trench foot (immersion foot) is similar to frostbite. However, it occurs from prolonged exposure to cold, but not freezing, water. The signs and symptoms of this condition are similar to those of frostbite. They include pain and the formation of blisters with rewarming. The paramedic should cover the affected area with sterile dressings and keep it dry and warm.

SUBMERSION

Drowning was the fifth leading cause of unintentional death in the United States in 2006. It was the second leading cause of unintentional injury or death among children and youths. About 80,000 submersion incidents are reported each year. Of these, 85% of the victims are male, and two thirds of the victims are nonswimmers.[7]

Classifications

As recommended by the American Heart Association, the World Health Organization, and the Utstein definition and style of data reporting, the term drowning is defined as "a process resulting in primary respiratory impairment from submersion/immersion in liquid."[5,8] (The term *submersion* usually refers to the head being below water, whereas *immersion* refers to the head being above water. The two terms often are used interchangeably.[9]) The definition further requires that a liquid/air interface be present at the entrance of the victim's airway, preventing the victim from breathing air. According to this definition, the victim may live or die after this process, but whatever the outcome, he or she has been involved in a drowning event. Victims of submersion incidents usually fall into one of two categories:

- Conscious patients, such as nonswimmers, exhausted swimmers, river canoeists who become trapped by roots or strong currents, individuals who fall overboard or off a dock, and motor vehicle crash victims who are trapped in submerged vehicles; also included in this category are conscious patients who fall into extremely cold water and who do not resurface (*sudden submersion syndrome*)
- Unconscious patients, such as those who suffer a stroke or cardiac arrest while swimming and those who fall into water and die as a result of hypothermia

Pathophysiology

Drowning begins with intentional or unintentional submersion. After submersion, the victim realizes he or she is in distress. An example of this is a nonswimmer who panics or a swimmer who becomes fatigued. Drowning begins with the conscious victim taking in several deep breaths. This is an attempt to store oxygen before breath-holding (Figure 45-5). The victim holds the breath until breathing reflexes override the breath-holding effort. As water is aspirated, laryngospasm occurs. Laryngospasm and aspiration produce severe hypoxia. This results in serious hypoxemia and acidosis, which lead to cardiac dysrhythmias and CNS anoxia. The physiological events that follow are partly determined by the type and amount of water aspirated. Regardless of the type of water aspirated, the pathophysiology of drowning is characterized by hypoxia, hypercapnia, and acidosis, which result in cardiac arrest.

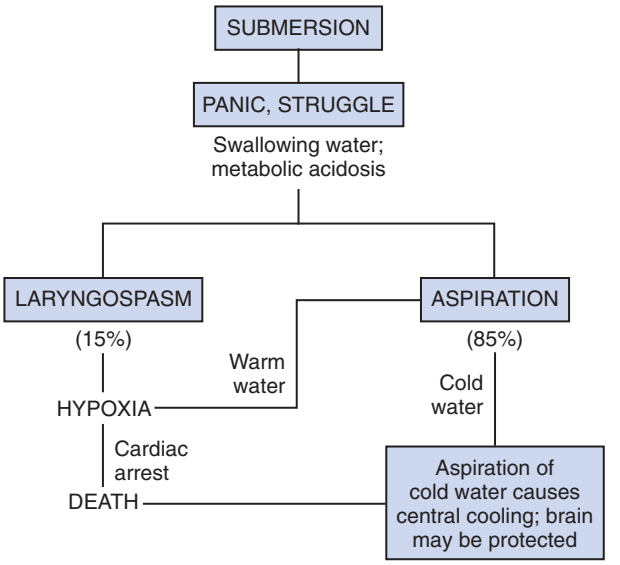

FIGURE 45-5 Progression of the drowning incident. (Modified from Auerbach PS: *Management of wilderness and environmental emergencies,* ed 5, St Louis, 2007, Mosby.)

Drowning can occur in almost any type of water. Victims of submersion aspirate salt water or fresh water, tap water, or contaminated water (such as water containing sewage, chemicals, algae, bacteria, or sand). In theory, different fluids have different effects. However, these differences are not clinically significant in prehospital care. They should not be considered in the initial management of submersion patients. The single most important factors that determine outcome are the duration of submersion and the duration and severity of hypoxia.[1]

Pulmonary Pathophysiology Secondary to Drowning

Respiratory failure, hypoxia, and acidosis are the life-threatening complications of submersion. Hypoxia can result from the following factors:

- Fluid in the alveoli and interstitial spaces
- Loss of surfactant
- Contaminant particles in the alveoli and tracheobronchial tree
- Damage to the alveolar-capillary membrane and vascular endothelium

Poor perfusion and hypoxemia lead to metabolic acidosis in most patients. In those who survive the incident, acute respiratory failure may occur. This includes the development of acute respiratory distress syndrome (ARDS). ARDS (described in Chapter 24) reduces lung compliance and increases ventilation-perfusion mismatches and intrapulmonary shunting. The onset of symptoms can be delayed for as long as 24 hours after the submersion (*secondary drowning*).

CRITICAL THINKING
Do other swimmers or onlookers often "hear" a person who is drowning?

LOOK AGAIN
See Chapter 24: Respiratory, pp. 757-758.

In addition to pulmonary effects, submersion can affect other body systems. For example, cardiovascular derangements can occur as a result of hypoxia and acidosis, leading to dysrhythmias and decreased cardiac output. CNS dysfunction and nerve damage result from cerebral edema and anoxia. The paramedic also must be suspicious of spinal injury in drowning victims. Renal dysfunction is not a common complication. However, when it does occur, it can progress to acute renal failure. This is usually the result of hypoxic injury or hemoglobinuria, leading to acute tubular necrosis.

Factors That Affect the Clinical Outcome

The following four factors can affect the clinical outcome of a submersion incident:

1. *Duration of submersion.* The longer the time submersed, the less likely the patient is to survive. When rescue takes longer than 30 minutes, victims rescued from warm water in summer months or in warm southern waters usually do not survive. Submersion in cold water for up to 66 minutes in children has been associated with survival, including intact brain function. (Most children rescued from cold water should receive resuscitation even with prolonged submersion.) Resuscitation is indicated for all patients unless physical evidence of death is present (e.g., putrefaction, dependent lividity, and rigor mortis). Submersion victims who have spontaneous circulation and breathing when they reach the hospital usually recover, with good outcomes.[5]
2. *Cleanliness of the water.* Contaminants in water have an irritant effect on the pulmonary system. This may lead to bronchospasm and poor gas exchange. These can cause a secondary pulmonary infection with delayed severe respiratory compromise.
3. *Temperature of the water.* Submersion in cold water can have beneficial and negative effects. The rapid onset of hypothermia can serve a protective function. This is especially the case with brain viability in patients who have undergone prolonged submersion. An incident in which a child was submerged for 66 minutes in a creek with a water temperature of 37° F (5° C) is the longest documented submersion with a good neurological outcome.[10] This phenomenon is not fully understood. A contributing factor may be the **mammalian diving reflex** in infant and child submersions. This is a reflex stimulated by cold water. It shunts blood to the brain and heart from the skin, gastrointestinal tract, and extremities. This reflex occurs in seals and lower mammals. It also occurs in humans to some extent. As described in Chapter 22, hypothermia may slow brain cell death and organ demise that can lead to permanent neurological damage. Likewise, hypothermia can also contribute to neurological recovery after prolonged submersion by reducing the metabolic needs of the brain. (Hypothermia also may develop secondary to submersion and later heat loss through evaporation during attempts at resuscitation. In these cases, the hypothermia is not protective.) The relative contributions of the diving reflex and hypothermia are not clear. The adverse effects of submersion in cold water include severe ventricular dysrhythmias.
4. *Age of the victim.* The younger the patient or victim, the better the chance for survival.

Management

At the site of a submersion incident, the safety of the EMS crew is paramount. Only personnel trained in water rescue should try to intervene (see Chapter 55). Depending on the type and duration of submersion, the patient's symptoms may vary from an asymptomatic presentation to cardiac arrest. After gaining access to the victim, the paramedic should take spinal precautions while the victim is still in the water only if spinal injury is suspected (e.g., diving injury, obvious injury, alcohol consumption) (see Chapter 41). Rescue breathing (if needed) should be initiated as soon as possible. The use of subdiaphragmatic thrusts to remove water from the airways is ineffective and dangerous and may cause vomiting and aspiration**.** Subdiaphragmatic thrusts are indicated, however, if foreign body airway obstruction is suspected.[2]

After removing the patient from the water, the paramedic should evaluate the patient to ensure an adequate airway. Ventilatory and circulatory support should be provided as needed. Other forms of initial patient care include administration of high-concentration oxygen, pulse oximetry, ECG monitoring, and establishment of an IV line. Patients who are in cardiac arrest should be managed with standard BLS and ALS protocols.

Victims of submersion incidents often are at risk for hypothermia; heat loss in water can be up to 32 times greater than that in air. Hypothermia can make resuscitation more difficult. It requires special consideration with regard to gentle handling, the administration of drugs, and defibrillation. As with all other victims of hypothermia, the paramedic should remove the patient's wet clothing. The patient then should be dried and wrapped in blankets to conserve body heat. External warming and the administration of heated, humidified oxygen at the scene and during transport should be considered. All patients suspected of having hypothermia should be managed as described earlier.

According to the AHA, "all victims of drowning who require any form of resuscitation (including rescue breathing alone) should be transported to the hospital."[5] Asymptomatic patients also require transport for physician evaluation. They should be given oxygen and carefully monitored to guard against aspiration pneumonia and

undetected hypoxia that can result from submersion. Oxygen is the most important treatment needed by submersion victims.

CRITICAL THINKING

What are the risks to rescuers on a call involving submersion victims?

DIVING EMERGENCIES

The United States has more than 4 million recreational scuba divers,[11] and more than 400,000 new sport divers are certified each year. Emergencies unique to pressure-related diving include those caused by the mechanical effects of pressure (barotrauma), air embolism, and the breathing of compressed air (decompression sickness and nitrogen narcosis).

NOTE

The term *scuba* is actually an acronym. It stands for self-contained underwater breathing apparatus. This equipment allows divers to breathe underwater. Scuba gear typically consists of one or two compressed air tanks. These are strapped to the diver's back and connected by a hose to a regulator.

Basic Properties of Gases

The weight of the atmosphere exerts a pressure of 14.7 pounds per square inch (psi) of force at sea level. (14.7 psi is equal to 760 mm Hg.) This means that a 1-inch column of air as tall as the atmosphere would weigh 14.7 pounds. This weight is commonly referred to as *1 atmosphere of pressure* (1 atm). Water weighs considerably more than air and can exert much more pressure. For example, a 1-inch column of seawater needs to be only 33 feet tall to weigh 14.7 pounds. This means that at a depth of 33 feet, the total pressure is 29.4 psi, or 2 atm of pressure (1 atm from the air and 1 atm from the 33 feet of water [2 × 14.7 = 29.4]). This is referred to as *ambient pressure* or *absolute pressure*. Every additional 33 feet of seawater adds another 14.7 pounds of pressure, or another 1 atm.

LAWS PERTAINING TO GASES

Three laws of the properties of gases underpin all pressure diving-related emergencies (and some high-altitude illnesses). These are Boyle's law, Dalton's law, and Henry's law. The following properties of gases can aid comprehension of these laws: *increased pressure dissolves gases into the blood; oxygen metabolizes, and nitrogen dissolves.*

NOTE

The term **dysbarism** describes illnesses that result directly or indirectly from changes in ambient atmospheric pressure and the pressure of gases within the body.

Boyle's Law. Boyle's law states that, if temperature remains constant, the volume of a given mass of gas is inversely proportional to the absolute pressure; that is, when the pressure is doubled, the volume of gas is halved (compressed into a smaller space), and vice versa. This can be expressed by the equation $PV = K$, in which P is pressure, V is volume, and K is a constant. Boyle's law explains the "popping" or "squeezing" sensation in the ears that a person may feel when traveling by air. It is the basic mechanism for all types of barotrauma: *trapped gases expand as pressure decreases.* For example, when a diver uses a scuba tank of pressurized air, the lung volumes remain constant at various depths. If the diver ascends but does not exhale, water pressure decreases and the gas in the lungs expands. This greatly increases the pressure in the lungs.

NOTE

Gas expands as pressure decreases. This fact applies to increases in altitude that occur during air transportation. For example, in a patient transported by air, gas can expand in the respiratory system, gastrointestinal system, or sinuses as altitude increases and pressure decreases. Medical equipment also can be affected by an increase in air volume. Examples include endotracheal tube cuffs and air splints.

Dalton's Law. Dalton's law states that the pressure exerted by each gas in a mixture of gases is the same pressure that the gas would exert if it alone occupied the same volume. On the other hand, the total pressure of a mixture of gases equals the sum of the partial pressures that make up the mixture. This law is expressed by the equation $P_t = PO_2 + PN_2 + P_x$, where P_t is the total pressure, PO_2 is the partial pressure of oxygen, PN_2 is the partial pressure of nitrogen, and P_x is the partial pressure of the remaining gases in the mixture.

To simplify, the air we breathe is about 80% nitrogen and 20% oxygen; that is, about 80% of the pressure of the air (i.e., the gas mixture) is exerted by the nitrogen in the mixture. About 20% of the pressure is exerted by the oxygen in the mixture. This means that at sea level, the pressure exerted on us by the nitrogen in the air is 80% of 14.7, or 11.76 psi; the pressure from the oxygen is 20% of 14.7, or 2.94 psi. Together, these account for the 14.7 psi of pressure at the surface. Even though the gas mixtures remain with normal percentages of nitrogen and oxygen, the partial pressures of these gases change at different altitudes above sea level or at depths below sea level. The principles of this law explain problems that can arise from the breathing of compressed air: *gas expansion causes the partial pressure of oxygen to drop as gas molecules move farther apart, reducing the available oxygen.*

Henry's Law. Henry's law states that, at a constant temperature, the solubility of a gas in a liquid solution is proportionate to the partial pressure of the gas. This means that more gas can be dissolved into a liquid at a higher pressure, and less gas can be dissolved into the liquid when

that pressure is released. For example, when a container of a carbonated beverage (pressurized with dissolved carbon dioxide gas) is opened, a "pop" is heard and bubbles form on the liquid. This occurs because the pressure in the container is no longer great enough to hold the dissolved gas inside. Henry's law is expressed by the equation: $\% X = P_x/P_t \times 100$, where $\% X$ is the amount of gas dissolved in a liquid, P_x is the partial pressure of the gas, and P_t is the total atmospheric pressure. This law explains why more nitrogen, which makes up almost 80% of air, dissolves in a diver's body as ambient pressure increases with descent. This dissolved nitrogen is released from the tissues on ascent as pressure decreases.

Barotrauma

Barotrauma is tissue injury caused by a change in pressure, which compresses or expands gas contained in various body structures. The type of barotrauma depends on whether the diver is in descent or ascent. Barotrauma is the most common injury of scuba divers.

BAROTRAUMA OF DESCENT

Barotrauma of descent (also known as *squeeze*) results from the compression of gas in enclosed spaces as the ambient pressure increases with descent under water. Air trapped in noncollapsible chambers is compressed. This leads to a vacuum-type effect that results in severe, sharp pain caused by the distortion; vascular engorgement; edema; and hemorrhage of the exposed tissue (Box 45-3). As a rule, squeeze usually results from a blocked eustachian tube or from failure of the diver to clear (open) the eustachian tube with exhalation during descent. The ears and paranasal sinuses are most likely to be affected. Squeeze occurs in the ears, sinuses, lungs and airways, gastrointestinal tract, thorax, teeth (pulp decay, recent extraction of sockets or fillings), or added air spaces (face mask or diving suit).

The management of barotrauma of descent involves slowly returning the diver to shallower depths. Prehospital care is mainly supportive. After the patient has been evaluated by a physician, definitive care may include bed rest with the head elevated, avoidance of strain and strenuous activity, use of decongestants and possibly antihistamines and antibiotics, and perhaps surgical repair.

CRITICAL THINKING

What preexisting illness can make a diver more susceptible to squeeze?

BAROTRAUMA OF ASCENT

Barotrauma of ascent occurs through the reverse process of descent ("reverse squeeze"). Assuming that the air-filled cavities of the body have equalized pressure during the diver's descent, the volume of air trapped in this pressurized space expands as ambient pressure decreases with ascent (Boyle's law). If air is not allowed to escape because of obstruction (e.g., breath-holding, bronchospasm, or mucous plug), the expanding gases distend the tissues surrounding them. The most common cause of this type of barotrauma is breath-holding during ascent.

Problems from reverse squeeze are rare. However, one type of reverse squeeze (**pulmonary overpressurization**

BOX 45-3 Signs and Symptoms of Diving-Related Conditions

Squeeze
Pain
Sensation of fullness
Headache
Disorientation
Vertigo
Nausea
Bleeding from the nose or ears

Pulmonary Overpressurization Syndrome (POPS)
Gradually increasing chest pain
Hoarseness
Neck fullness
Dyspnea
Dysphagia
Subcutaneous emphysema

Air Embolism
Focal paralysis or sensory changes (strokelike symptoms)
Aphasia
Confusion
Blindness or other visual disturbances
Convulsions
Loss of consciousness
Dizziness
Vertigo
Abdominal pain
Cardiac arrest

Decompression Sickness
Shortness of breath
Itching
Rash
Joint pain
Crepitus
Fatigue
Vertigo
Paresthesias
Paralysis
Seizures
Unconsciousness

Nitrogen Narcosis
Impaired judgment
Sensation of alcohol intoxication
Slowed motor response
Loss of proprioception
Euphoria

syndrome [POPS]) can occur as a result of the expansion of trapped air in the lungs and can lead to alveolar rupture. It also can lead to leakage of air into areas outside the alveoli. The clinical syndromes associated with barotrauma of ascent include pneumomediastinum, subcutaneous emphysema, pneumopericardium, pneumothorax, pneumoperitoneum, and systemic arterial air embolism. Except for tension pneumothorax (a rare complication that may require needle or tube decompression) and air embolism, which may require hyperbaric recompression therapy (Box 45-4), POPS usually requires only administration of oxygen, observation, and transport for evaluation by a physician.

AIR EMBOLISM

Air embolism is the most serious complication of pulmonary barotrauma. It is a major cause of death and disability among sport divers. Divers risk this condition when they ascend too rapidly or hold their breath during ascent. The classic description of a dive causing an air embolism is rapidly ascending to the surface because of panic.

Air embolism results as the expanding air disrupts tissues and air is forced into the circulatory system. The air bubbles pass through the left side of the heart and become lodged in small arterioles. This occludes distal circulation. The syndrome usually manifests as the diver surfaces and exhales. Exhaling releases the high intrapulmonic pressure that resulted from lung overexpansion. With the decrease in intrathoracic pressure, bubbles advance into the left side of the heart and enter the systemic arterial supply. This results in a dramatic presentation. The clinical manifestations depend on the site of systemic arterial occlusion. The most common presentation of air embolism is similar to that of stroke and includes vertigo, confusion, loss of consciousness, visual disturbances, and focal neurological deficits.

Air embolism should be suspected if a diver suddenly loses consciousness immediately after surfacing. Paramedics should begin BLS and ALS measures, and the patient should be rapidly transported for recompression treatment. Also, the patient should be thoroughly evaluated for signs of POPS, such as a pneumothorax.

A patient suspected of having an air embolism should be transported in a horizontal, neutral position.[2,12] This position helps to avoid aggravating cerebral edema that may develop. If air transport is to be used, the patient should be transported by an aircraft that is pressurized to sea level. The patient also can be transported by a rotary wing aircraft that flies at low altitude. This prevents existing intraarterial air bubbles from expanding further. The flight altitude must be as low as possible if the internal cabin pressure cannot be maintained at sea level. Ideally, it should never be over 1000 feet above sea level.

Recompression. Recompression is the use of elevated pressure (including hyperbaric oxygen therapy) to treat conditions within the body caused by a rapid decrease in pressure (e.g., air embolism). Recompression takes place in a hyperbaric oxygen chamber (Figure 45-6). As described in Chapter 33, hyperbaric chambers allow for the delivery of oxygen at a higher than normal atmospheric pressure. The process is used to overcome the natural limit of oxygen solubility in blood. It thus reduces the intravascular bubble volume and restores tissue perfusion. Slow decompression helps to prevent bubbles from re-forming. Paramedics should know the location of the nearest hyperbaric treatment facility and should follow the protocol established by medical direction. Ground transportation to a hyperbaric facility is preferred over air transportation. This is because the increase in altitude lowers the ambient pressure and allows microbubbles to expand. Recompression is not required for diving injuries such as ear or facial barotrauma, nitrogen narcosis, pneumothorax, pneumomediastinum, or subcutaneous emphysema.[2]

CRITICAL THINKING
Where is the nearest hyperbaric chamber in your area?

BOX 45-4 Hyperbaric Oxygen Therapy

Altering the surrounding air pressure for medical treatment is a practice that dates back to the seventeenth century. At that time, "fevers and inflammations" were treated in crude chambers that were pressurized using hand bellows. Today, hyperbaric oxygen therapy (HBOT) is carried out in single-person chambers (mono chamber). These are monoplace chambers. The treatment also can be done in larger multiplace chambers (dual chamber), which can house several patients and the attending hyperbaric health care workers. HBOT has proved to be effective in the treatment of a wide variety of medical disorders. These include air embolism and decompression sickness; carbon monoxide poisoning and smoke inhalation; carbon monoxide poisoning complicated by cyanide poisoning; clostridial myonecrosis (gas gangrene); crush injury, compartment syndrome, and other acute traumatic ischemias; intracranial abscesses; and thermal burns. It also has been shown to enhance the healing of certain problem wounds.

FIGURE 45-6 Hyperbaric oxygen chamber. (From Auerbach PS: *Management of wilderness and environmental emergencies*, ed 5, St Louis, 2007, Mosby.)

NOTE
The Diver's Alert Network, a nonprofit organization operated by Duke University Medical Center, specializes in diving-related illnesses. It offers consultation and referral services. The telephone number is 1-800-446-2671.

DECOMPRESSION SICKNESS

Decompression sickness is also known as *the bends, dysbarism, caisson disease,* and *diver's paralysis.* It is a multisystem disorder. It results when nitrogen in compressed air (dissolved into tissues and blood from the increase in the partial pressure of the gas at depth) converts back from solution to gas. This results in the formation of bubbles in the tissues and blood. The syndrome occurs when the ambient pressure decreases (Henry's law). The cause is an ascent that is too rapid. In such an ascent, the balance between the dissolved nitrogen in tissue and blood and the partial pressure of nitrogen in the inspired gas cannot be reached. Because the nitrogen bubbles can form in any tissue, *lymphedema* (the accumulation of lymph in soft tissues), cellular distention, and cellular rupture also can occur. The net effect of all these processes is poor tissue perfusion and ischemia. The joints and the spinal cord are most often affected. Signs and symptoms of decompression sickness may initially include rashes, itching, and a complaint of "bubbles under the skin." Pulmonary complaints may include chest pain, cough, and shortness of breath.

Failure to make recommended decompression "stops" during ascent usually causes decompression sickness. (Stops are based on diving tables and charts that consider depth, the duration of the dive, and previous dives completed.) Making stops during the ascent allows more time for safe *off-gassing.* Many hyperbaric professionals advise a 3- to 5-minute safety stop at 15 to 20 feet for any dive.[13] For dives below 60 feet, another safety stop at 30 feet may be of value. If possible, the paramedic should ask the diver about safety stops made during ascent.

NOTE
Compressed gas at 33 feet (2 atmospheres) doubles in volume when the diver moves to the surface (1 atmosphere). This is because the pressure is half of 33 feet. The last 6 feet of ascent have the greatest potential for volume expansion. This is considered the most dangerous depth.

The paramedic should suspect decompression sickness in any patient who has symptoms within 12 to 36 hours after a scuba dive. These will be symptoms that cannot be explained by other conditions. (An example is a patient with unexplained joint pain who had been diving within the previous 24 hours.) Prehospital care includes support of vital functions, administration of high-concentration oxygen, fluid resuscitation, and rapid transportation for recompression. The patient transport and air evacuation guidelines described for air embolism should also be used with these patients.

NITROGEN NARCOSIS

Nitrogen narcosis ("rapture of the deep") is a condition in which nitrogen becomes dissolved in the blood. This is caused by a higher than normal partial pressure of nitrogen. Dissolved nitrogen crosses the blood-brain barrier. It produces depressant effects similar to those of alcohol. This can seriously impair the diver's thinking and lead to lethal errors in judgment. Symptoms of nitrogen narcosis usually become evident at depths of 75 to 100 feet. At depths below 300 feet, with standard air (an oxygen-nitrogen mixture), the diver loses consciousness. Nitrogen narcosis affects all divers, but is better tolerated by experienced divers. It is more likely to occur if the diver is cold, fatigued, or frightened. Helium-oxygen mixtures are used to improve the nitrogen complication (improving mental clarity) for deep dives. (Examples of these mixtures are TriMix and Heliox.) The narcotic effects of nitrogen are reversed with ascent.

NOTE
The depressant effect of pressurized nitrogen has been compared to drinking one dry martini on an empty stomach every 10 minutes (the "martini rule"). The theory is that being 15 meters under water is equivalent to drinking one martini; at 30 meters, two martinis; at 45 meters, three martinis, and so on.

Nitrogen narcosis is a common factor in diving accidents, and it may be responsible for memory loss. Prehospital care is mainly supportive. The paramedic should assess the patient for injuries that may have occurred during the dive, and the patient should be transported for evaluation by a physician.

NOTE
Less common diving-related illnesses may result from oxygen toxicity (usually seen with prolonged exposure to oxygen or exposure to excessive concentrations of oxygen), breathing of contaminated gases (e.g., carbon monoxide in the compressed air), hypercapnia, and hyperventilation.

HIGH-ALTITUDE ILLNESS

High-altitude illness principally occurs at altitudes 8200 feet or more above sea level.[2] It is attributed directly to exposure to reduced atmospheric pressure (described previously), which results in hypobaric hypoxia. Activities associated with these syndromes include mountain climbing, aircraft or glider flight, riding in hot air balloons, and the use of low-pressure or vacuum chambers.

NOTE
Worldwide, it is estimated that about 40 million people live above 8000 feet, and 25 million live above 12,000 feet.[14] Most cases of high-altitude illness are not associated with these groups who are acclimated to high altitudes. Those most affected by illness from high altitudes are people who occasionally ascend into mountainous regions, such as mountain sport enthusiasts and tourists.[2]

DID YOU KNOW?

Normal PaO_2 at High Altitude

Altitude also affects the normal, expected PaO_2. High altitude decreases barometric pressure and therefore the inspired PO_2. Up to an altitude of 10,000 feet above sea level, barometric pressure decreases about 24 mm Hg per 1000 feet of elevation. For example, in Denver, where the elevation is 5280 feet, barometric pressure is about 633 mm Hg. At 10,000-feet elevation barometric pressure is only 523 mm Hg. The general formula for changing observed sea-level PaO_2 values to PaO_2 values at a different barometric pressure is as follows:

Expected PO_2 at high altitude =

(High-altitude barometric pressure/760 mm Hg) × sea level PO_2

According to this calculation, if a normal person's sea-level PaO_2 is 95 mm Hg, the PaO_2 in Denver is about 79 mm Hg; at 10,000-feet elevation, it is only 65 mm Hg.[15]

The high-altitude syndromes discussed in this chapter are acute mountain sickness (AMS), high-altitude pulmonary edema, and high-altitude cerebral edema. Emergency care for all forms of high-altitude illness includes airway, ventilatory, and circulatory support and descent to a lower altitude. In addition, a physician should evaluate all patients with high-altitude illness. Strategies for preventing high-altitude illness include the following[16]:

1. Gradual ascent (days)
2. Limited exertion
3. Decreased sleeping at altitude
4. Adequate fluid intake to prevent dehydration
5. High-carbohydrate diet
6. Medications (all are controversial)
   - Acetazolamide (to speed acclimatization and reduce the incidence of AMS)
   - Nifedipine (used solely by those with a history of high-altitude pulmonary edema [HAPE] to prevent recurrence upon ascent)
   - Steroids

Exposure to high altitude can worsen chronic medical conditions. This is the case even without apparent altitude sickness. (Examples of such conditions include angina pectoris, congestive heart failure [CHF], chronic obstructive pulmonary disease [COPD], sickle cell disease, and hypertension.) These conditions can worsen as a result of a low partial pressure of oxygen. A low partial pressure of oxygen means that less oxygen is inhaled with each normal respiratory volume.

Acute Mountain Sickness

Acute mountain sickness (AMS) is a common high-altitude illness. It results when an unacclimatized person ascends rapidly to high altitudes. The illness usually develops within 4 to 6 hours of reaching a high altitude and reaches maximum severity within 24 to 48 hours (Box 45-5). It abates on the third or fourth day after exposure with gradual acclimatization.

BOX 45-5 Signs and Symptoms of High-Altitude Illness

Acute Mountain Sickness (AMS)

Headache (most common symptom) attributed to subacute cerebral edema or to spasm or dilation of cerebral blood vessels secondary to hypocapnia or hypoxia
Malaise
Anorexia
Vomiting
Dizziness
Irritability
Impaired memory
Dyspnea on exertion

High-Altitude Pulmonary Edema (HAPE)

Shortness of breath
Dyspnea
Cough (with or without frothy sputum)
Generalized weakness
Lethargy
Disorientation

High-Altitude Cerebral Edema (HACE)

Headache
Ataxia
Altered consciousness
Confusion
Hallucinations
Drowsiness
Stupor
Coma

The physical findings with AMS vary. They include tachycardia, bradycardia, postural hypotension, and ataxia (impaired ability to coordinate movement). Ataxia is a key sign of the progression of the illness. As AMS becomes severe, the victim may experience alterations in consciousness, disorientation, and impaired judgment. Emergency care includes administration of oxygen. It also includes descent to as low an altitude as needed to achieve relief. Definitive treatment after evaluation by a physician may involve the use of diuretics to treat fluid retention associated with AMS, steroids to reduce associated cerebral edema, and hyperbaric therapy.

High-Altitude Pulmonary Edema

High-altitude pulmonary edema (HAPE) is caused at least partly by increased pulmonary artery pressure that develops in response to hypoxia. The increased pressure results in the release of leukotrienes. These increase the permeability of pulmonary arterioles. The increased pressure also results in the leakage of fluid into extravascular space. The initial symptoms of HAPE usually begin 24 to 72 hours after the exposure to high altitudes. The symptoms often are preceded by vigorous exercise.

Physical findings in patients with HAPE include hyperpnea, crackles, rhonchi, tachycardia, and cyanosis. Emergency care includes administration of oxygen to increase arterial oxygenation and reduce pulmonary artery pressure. It also includes descent to a lower altitude. After evaluation by a physician, the patient may be hospitalized for observation.

Portable hyperbaric chambers (e.g., the Gamow bag and Gamow tent) are commercially available. These may temporarily reverse the effects of high-altitude pulmonary and cerebral edema. They are used by some EMS agencies in high-risk areas when immediate descent is not possible.

High-Altitude Cerebral Edema

High-altitude cerebral edema (HACE) is the most severe form of acute high-altitude illness. It is characterized by a progression of global cerebral signs in the presence of AMS. These signs probably are related to an increase in intracranial pressure caused by cerebral edema and swelling. Therefore the distinctions between AMS and HACE are inherently blurred. The progression from mild AMS to unconsciousness associated with HACE can occur quickly (i.e., within 12 hours). However, it usually requires 1 to 3 days of exposure to high altitudes.

NOTE

The symptoms of mild AMS are similar to a "hangover," and usually include headache and slurred speech. Patients with HACE will have symptoms of mild AMS plus ataxia (an impaired ability to coordinate movements) and mental status changes.[17]

HACE must be managed promptly, because without treatment the syndrome rapidly progresses to stupor, coma, and death. As with other forms of high-altitude illness, emergency care focuses on airway, ventilatory, and circulatory support and descent to a lower altitude.

SUMMARY

- Body temperature is regulated by a thermoregulatory center in the posterior hypothalamus. The body temperature can be increased or decreased in two ways. One of these ways is through the regulation of heat production. (This is known as thermogenesis.) The other way is through the regulation of heat loss. (This is known as thermolysis.)
- Heat illness results from one of two basic causes. First, the normal temperature-regulating functions can be overwhelmed by conditions in the environment. These conditions can include heat stress. More often, though, they involve excessive exercise in moderate to extreme environmental conditions. The other cause is failure of the body's thermoregulatory mechanism. This may occur in older adults or ill or debilitated individuals. Heat cramps are brief, intermittent, and often severe. They are muscular cramps that occur in muscles fatigued by heavy work or exercise. Heat exhaustion is characterized by minor aberrations in mental status, dizziness, nausea, headache, and a mild to moderate rise in the core body temperature (CBT) (up to less than 103° F [39° C]). Heat stroke occurs when the temperature-regulating functions break down entirely. This failure results in body temperature increasing to 105.8° F (41° C) or higher. Temperatures this high damage all tissues and lead to collapse.
- Hypothermia (a CBT lower than 95° F [35° C]) can result from a decrease in heat production, an increase in heat loss, or a combination of these two factors. The progression of clinical signs and symptoms of hypothermia is divided into three classes based on the CBT: mild (CBT between 93.2° and 96.8° F [34° and 36° C]), moderate (CBT between 86° and 93° F [30° and 34° C]), and severe (CBT below 86° F [30° C]). Severely hypothermic patients have no vital signs, including respiratory effort, pulse, and blood pressure.
- Frostbite is a localized injury. It results from environmentally induced freezing of body tissues. This freezing leads to the damage to blood vessels. Ischemia often produces the most damaging effects of frostbite. In deep frostbite this can include mummification and sloughing of nonviable skin and deep structures.
- Drowning is a process that results in primary respiratory impairment from submersion/immersion in a liquid medium that prevents the person from breathing air. Regardless of the type of water aspirated, the pathophysiology of drowning is characterized by hypoxia, hypercapnia, and acidosis, which result in cardiac arrest.
- The three laws pertaining to the basic properties of gases that are involved in all pressure-related diving emergencies are Boyle's law, Dalton's law, and Henry's law. Increased pressure dissolves gases into blood; oxygen metabolizes, and nitrogen dissolves.
- Barotrauma is tissue damage. It results from compression or expansion of gas spaces when the gas pressure in the body differs from the ambient pressure. The type of barotrauma depends on whether the diver is in descent or ascent. Air embolism is the most serious complication of pulmonary barotrauma. It is a major cause of death and disability among sport divers.
- High-altitude illness results from exposure to reduced atmospheric pressure, which results in hypoxia. Forms of high-altitude illness include acute mountain sickness, high-altitude pulmonary edema, and high-altitude cerebral edema.

Chapter 50: Abuse and Neglect
Chapter 51: Patients with Special Challenges
Chapter 52: Acute Interventions for Home Care

CHAPTER

46 Obstetrics

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the basic anatomy and physiology of the reproductive system during pregnancy.
2. Outline fetal development from ovulation through birth.
3. Explain normal maternal physiological changes that occur during pregnancy and describe how they influence prehospital patient care and transportation.
4. Describe appropriate information to be elicited during the obstetrical patient's history.
5. Describe specific techniques for assessment of the pregnant patient.
6. Describe the general prehospital care of the pregnant patient.
7. Discuss the special implications of trauma in pregnancy.
8. Outline principles of care for a pregnant patient in cardiac arrest.
9. Recognize and begin treatment for complications of pregnancy such as hyperemesis gravidarum, Rh sensitization, diabetes mellitus, and infection.
10. Describe the assessment and management of patients with preeclampsia and eclampsia.
11. Explain the pathophysiology, signs and symptoms, and management of vaginal bleeding in pregnancy.
12. Outline the physiological changes that occur during the stages of labor.
13. Describe the role of the paramedic during normal labor and delivery.
14. Compute an Apgar score.
15. Describe assessment and management of postpartum hemorrhage.
16. Discuss the identification, implications, and prehospital management of complicated deliveries.

KEY TERMS

abruptio placentae A partial or full detachment of a normally implanted placenta at more than 20 weeks' gestation.

amniotic fluid Fluid in the amniotic sac; primarily produced by the fetal urine and placenta.

amniotic fluid embolism An embolism that occurs when particulate matter in amniotic fluid forms an embolus and gains access to maternal circulation during labor or delivery or immediately after delivery.

amniotic sac A thin-walled bag that contains the fetus and amniotic fluid during pregnancy.

Apgar score The evaluation of a newborn's physical condition, usually performed at 1 minute and 5 minutes after birth, including heart rate, respiratory effort, muscle tone, reflex irritability, and color.

Braxton-Hicks contractions Irregular tightening of the pregnant uterus that begins in the first trimester and increases in frequency, duration, and intensity as pregnancy progresses.

breech presentation The intrauterine position of the fetus in which the buttocks or feet present, rather than the head.

cephalopelvic disproportion An obstetrical condition in which a newborn's head is too large or a mother's birth canal too small to permit a normal vaginal delivery.

cesarean delivery A surgical procedure in which the abdomen and uterus are incised and the baby is delivered transabdominally.

Chadwick's sign The bluish coloration of the vulva and vagina that develops after the sixth week of pregnancy as a normal result of local venous congestion; an early sign of pregnancy.

chorioamnionitis An inflammatory reaction in the amniotic membranes caused by infection in the amniotic fluid.

cord presentation A presentation that occurs when the cord slips down into the vagina or appears externally after the amniotic membranes have ruptured.

crowning The phase at the end of labor in which the fetal head is seen at the opening of the vagina.

ductus arteriosus A vascular channel in the fetus that joins the pulmonary artery directly to the descending aorta.

eclampsia A grave form of pregnancy-induced hypertension, characterized by convulsions, coma, proteinuria, and edema.

ectopic pregnancy A pregnancy that occurs when a fertilized ovum implants anywhere other than the uterus.

embryo In human beings the stage of prenatal development between the time of implantation of the fertilized ovum until the end of the seventh or eighth week.

erythroblastosis fetalis A life-threatening blood disorder caused by maternal antibodies directed against the fetus' erythrocytes, secondary to ABO or Rh incompatibility between the mother and the fetus.

estimated date of confinement Delivery date for the fetus.

fetus Unborn young, from the third month of the intrauterine period until birth.

first stage of labor The stage of labor that begins with contractions and ends when the cervix is fully dilated at 10 cm; divided into *early labor*, *active labor*, and *transition*.

foramen ovale An opening in the septum between the right and left atria in the fetal heart; it provides a bypass for blood that would otherwise flow to the fetal lungs.

fundal massage The application of external pressure to the uterus to stop postpartum bleeding.

gestation The period from fertilization of the ovum until birth.

gestational diabetes mellitus A disorder characterized by impaired ability to metabolize carbohydrates, usually caused by a deficiency of insulin; it occurs in pregnancy and disappears after delivery but in some cases returns years later.

gestational hypertension Hypertension that occurs during the latter stages of pregnancy (>20 weeks) without any other features of preeclampsia, and resolves during the postpartum period; recognized by a new blood pressure reading of 140/90 mm Hg or higher.

gravida The number of all current and past pregnancies.

HELLP syndrome A severe form of preeclampsia with *H*, hemolysis; *EL*, elevated liver enzymes; and *LP*, low platelet count.

hydrops fetalis A fetal condition characterized by the accumulation of fluid throughout body tissues, including the lungs, heart, and abdominal organs.

hyperemesis gravidarum A condition of pregnancy characterized by severe nausea, vomiting, weight loss, and electrolyte disturbance; sometimes referred to as "a severe case of morning sickness."

iatrogenic Caused by treatment or diagnostic procedures.

lochia A normal postpartum vaginal discharge that contains blood, mucus, and placental tissue from the lining of the uterus.

mucous plug A collection of cervical mucus that fills and seals the cervical canal during pregnancy. It is discharged from the vagina during childbirth.

multiple gestation A pregnancy with more than one fetus.

ovum An egg in the ovary of a female.

para The number of past pregnancies that have remained viable to delivery.

parturition The process by which an infant is born.

placenta A highly vascular fetal-maternal organ through which the fetus absorbs oxygen, nutrients, and other substances and excretes carbon dioxide and other wastes.

placenta previa Placental implantation in the lower uterine segment partially or completely covering the cervical opening.

postpartum hemorrhage Blood loss of more than 500 mL after delivery of the newborn.

precipitous delivery A rapid, spontaneous delivery of less than 3 hours from onset of labor to birth; it results from overactive uterine contractions and little maternal soft tissue or bony resistance. Childbirth that occurs with such speed that usual preparations cannot be made.

preeclampsia An abnormal disease of pregnancy characterized by the onset of acute hypertension associated with proteinuria after the twentieth week of gestation.

premature infant An infant who is born before 37 weeks' gestation.

premature rupture of the membranes Rupture of the amniotic sac before the onset of labor, regardless of gestational age.

prolapsed umbilical cord An umbilical cord that protrudes beside or ahead of the presenting part of the fetus.

Rh disease An immune disorder that develops in a fetus, when IgG antibodies directed against Rh-positive red blood cells are produced by the mother and pass through the placenta.

Rh sensitization A condition that can occur during pregnancy if an Rh-negative woman is pregnant with a baby who has Rh-positive blood. If this occurs, the immune system reacts to the Rh factor by producing antibodies to destroy it.

second stage of labor The stage of labor that is measured from full dilation of the cervix to delivery of the infant.

shoulder dystocia An obstacle to delivery that occurs when the fetal shoulders press against the maternal symphysis pubis, blocking shoulder delivery.

shoulder presentation The presentation that results when the long axis of the fetus lies perpendicular to that of the mother; also known as *transverse presentation*.

spontaneous abortion The nontherapeutic termination of pregnancy that usually occurs before 20 weeks' gestation; the lay term is *miscarriage*.

third stage of labor The stage of labor that begins with delivery of the infant and ends when the placenta is expelled and the uterus has contracted.

third-trimester bleeding Vaginal bleeding that occurs in the third trimester of pregnancy.

TORCH infections An acronym for a special group of infections that may be acquired by a woman during pregnancy: **T**oxoplasmosis, **O**ther infections (namely, hepatitis B, syphilis, and herpes zoster), **R**ubella, **C**ytomegalovirus, **H**erpes simplex virus.

trimester One of three periods of approximately 3 months into which pregnancy is divided.

umbilical cord A flexible structure connecting the umbilicus of the fetus with the placenta and giving passage to the umbilical arteries and vein.

uterine atony The lack of uterine tone.
uterine inversion A rare event in which the uterus turns inside out after birth.
uterine rupture A spontaneous or traumatic rupture of the uterine wall.
zygote The developing ovum from the time it is fertilized until it is implanted in the uterus as a blastocyst.

Childbirth is common in the prehospital setting. Most often, paramedics only assist in this natural process. However, obstetrical emergencies can develop suddenly and have life-threatening consequences. The paramedic must be prepared to recognize and manage these events and sometimes assist in abnormal deliveries. This chapter presents the causes and treatment of obstetrical emergencies. It also discusses the normal and abnormal events associated with childbirth.

REVIEW OF FEMALE REPRODUCTIVE ANATOMY

As described in Chapter 10 and in Chapter 31, the female reproductive system is composed of external and internal anatomical structures that allow for pregnancy. To review, the external genitalia are the labium minora and majora, the vagina, and the clitoris. The internal organs that lie within the pelvis include the uterus, ovaries, uterine (or fallopian) tubes, and cervix (Figure 46-1).

The female reproductive cycle (described in Chapter 31) is under the control of the endocrine system and its hormones. For women of child-bearing age, the cycle usually is a monthly event that begins with menstruation (shedding of the endometrium or uterine lining). The cycle ends with pregnancy or, in the absence of fertilization, with another menstrual cycle.

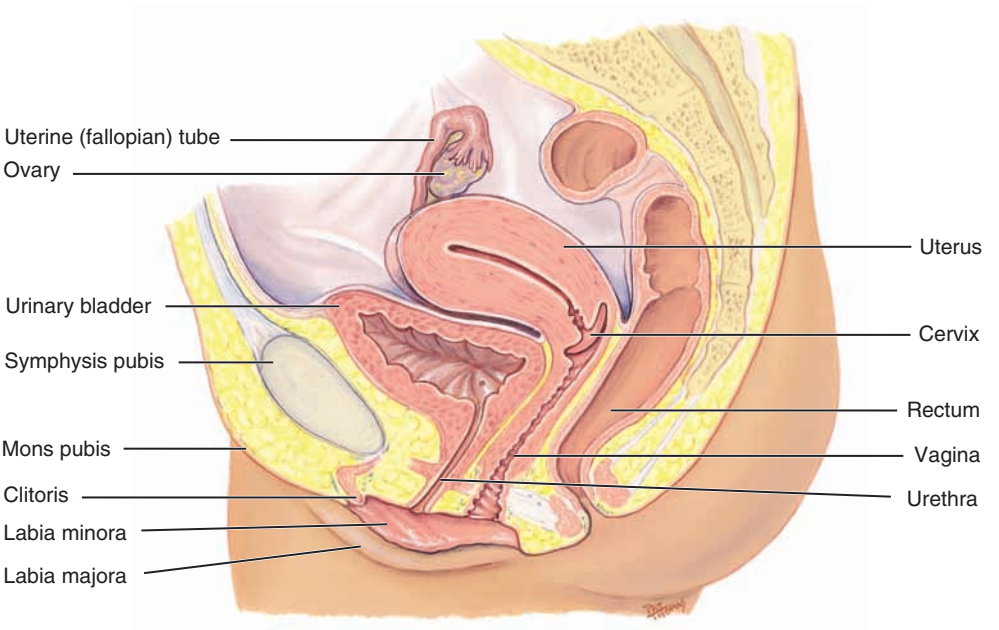

FIGURE 46-1 Organs of the female reproductive system. (From Applegate E: *The anatomy and physiology learning system,* ed 3, St Louis, 2006, Saunders.)

See Chapter 10: Review of Human Systems, pp. 202-205, and Chapter 31: Gynecology, pp. 930-931.

NOTE
In 2006, there were 435,436 births to mothers ages 15 to 19 years in the United States (a birth rate of 41.9 per 1000 women in this age group). Nearly two thirds of these births were to mothers under 18 years of age; more than half were among mothers ages 18 to 19 years; most births were unintended. Teen pregnancy, birth, and abortion rates in the United States are considerably higher than most other developed countries.[1] The possibility of pregnancy should always be considered when caring for patients of childbearing age.

DID YOU KNOW?
Cultural Values That May Affect Pregnancy
Pregnancy is a universal event that is embedded in a cultural context, both from expectant parents and from surrounding family members. Common to all cultures is the fear that there may be a negative outcome from the pregnancy or that the baby or the mother may die during childbirth. A universal ideal of pregnancy is that the baby will be born healthy and eager to thrive. Although cultural values rarely affect medical care, the beliefs of all pregnant mothers should be respected. Below is a sampling of cultural values about pregnancy[2]:

- The predominant U.S. culture treats pregnancy like an illness, with frequent visits to a physician, many laboratory tests, and hospitalization for delivery with various medical interventions. Other cultures, however, may see pregnancy as a natural condition that does not require medical care.
- Some Hispanic women believe that wearing proper clothing will ensure a safe birth.
- Some Puerto Rican women are indulged by their families during pregnancy. Exercise is considered inappropriate.
- Some American Indian women avoid tying knots or braids during pregnancy to prevent complications involving the umbilical cord.
- Some Sephardic Jewish women delay having baby showers until after birth to prevent a stillbirth.
- Some Cuban women avoid loud noises or looking at people with deformities during pregnancy.
- Some Japanese women may believe that if they are happy during pregnancy it will cause good fortune for the fetus (who is learning from the mother).
- Some Cambodian women may avoid standing in doorways to prevent the baby from becoming stuck in the birth canal.
- In many cultures, women must avoid contact with illness and death and may not attend funerals during pregnancy.
- Many Navajo families do not choose a name for the baby until after birth because they fear it will harm the infant.
- Some Jewish families select items needed for the new baby, but do not bring them into the home until after the birth.

NORMAL EVENTS OF PREGNANCY

Fertilization normally occurs in the fallopian tube when the head of a sperm penetrates a mature **ovum.** After penetration the nuclei of the sperm and ovum fuse. At this time the newly fertilized ovum becomes a **zygote.** The zygote undergoes repeated cell divisions as it passes down the fallopian tube. After a few days of rapid cell division, a ball of cells called a *morula* is formed with cell differentiation between the inner layer of cells (blastocyst cells) and the outer layer of cells (trophoblast cells). Trophoblast cells attach to the endometrium lining of the uterus. Implantation begins within 7 days after fertilization. Implantation is completed when the trophoblast cells make contact with maternal circulation. (This is about day 12.) Trophoblast cells go on to make various life support systems for the embryo (placenta, amniotic sac, umbilical cord); blastocyst cells develop into the embryo itself (Figure 46-2).

SPECIALIZED STRUCTURES OF PREGNANCY

The placenta, the umbilical cord, and the amniotic sac and its fluid provide nutrients for the developing embryo. They also are part of fetal circulation.

Placenta

The trophoblast cells continue to develop and form the placenta for about 14 days after ovulation. The **placenta** is a disklike organ composed of interlocking fetal and maternal tissues. The placenta is the organ of exchange between the mother and fetus and is responsible for the following five functions:

1. *Transfer of gases.* The diffusion of oxygen and carbon dioxide through the placental membrane is similar to the diffusion that occurs in the lungs. Dissolved oxygen in maternal blood passes through the placenta into fetal blood. This takes place as a result of the increase in the partial pressure of oxygen in the mother's blood compared to that of the fetus. Conversely, as fetal carbon dioxide pressure (P_{CO_2}) increases, a low-pressure gradient of carbon dioxide develops across the placental membrane. The carbon dioxide then diffuses from fetal blood to maternal blood.

CRITICAL THINKING
What happens to diffusion of gases if the mother becomes hypoxic?

2. *Transport of nutrients.* Other metabolic substrates that the fetus needs diffuse into fetal blood in the same manner as oxygen. For example, glucose levels in fetal blood are about 20% to 30% lower than those in maternal blood. This results in a rapid diffusion of glucose to the fetus. Diffusion also transports other substrates, such as fatty acids, potassium, sodium, and chloride. The placenta also actively absorbs some nutrients from maternal blood.

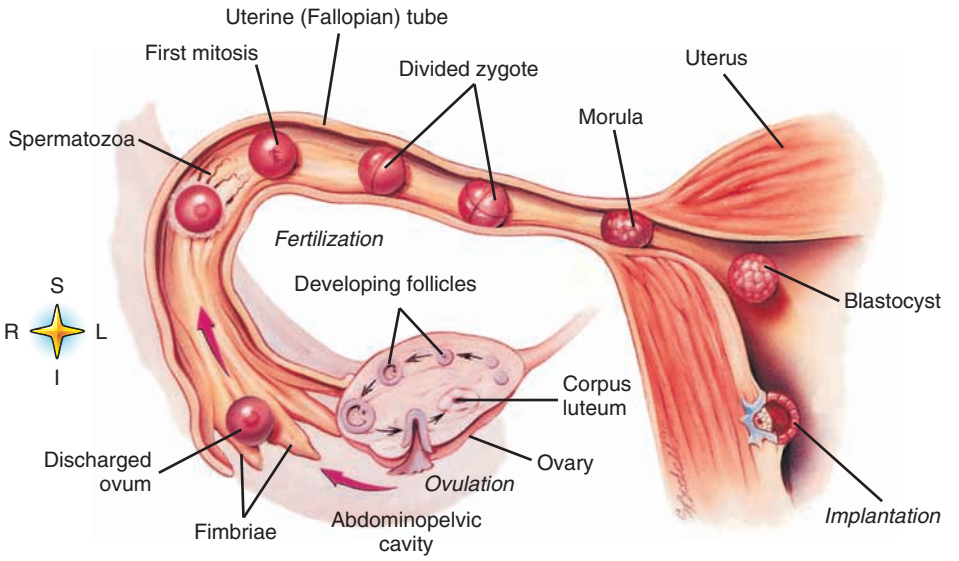

FIGURE 46-2 Fertilization and implantation. At ovulation the ovary releases an ovum, which begins its journey through the uterine tube. While the ovum is in the tube, a sperm fertilizes the ovum to form the single-celled zygote. After a few days of rapid cell division, a ball of cells called a *morula* forms. After the morula develops into a hollow ball (blastocyte), implantation occurs. (From Thibodeau G, Patton K: *Anatomy and physiology,* ed 5, St Louis, 2003, Mosby.)

3. *Excretion of wastes.* Waste products diffuse from fetal blood into maternal blood. Examples of such products are urea, uric acid, and creatinine. They are excreted with the waste products of the mother. Wastes transfer from fetal circulation to maternal circulation by moving osmotically from a higher concentration to a lower concentration, in the same manner as carbon dioxide.
4. *Hormone production.* The placenta becomes a temporary endocrine gland. It secretes estrogen and progesterone. By the third month of fetal development the corpus luteum (described in Chapter 31) on the ovary no longer is needed to sustain the pregnancy. Estrogen, progesterone, and other hormones maintain the uterine lining, prevent the occurrence of menses, and stimulate changes in the pregnant woman's breasts, vagina, cervix, and pelvis that prepare her body for delivery and lactation.
5. *Formation of a barrier.* The placenta forms a barrier against some harmful substances in the mother's circulation (e.g., bacteria and certain drugs). The placental barrier is only partially selective and does not fully protect the fetus. Certain medications easily cross the placenta. Among these are steroids, narcotics, anesthetics, and some antibiotics.

Umbilical Cord

The umbilical cord connects the umbilicus with the placenta. (The average umbilical cord is about 55 cm long with a diameter of 1 to 2 cm.) Blood flows from the fetus to the placenta through two umbilical arteries in the cord. These arteries carry deoxygenated blood. Oxygenated blood returns to the fetus through the umbilical vein. Fetal circulation is independent of and separated from the maternal circulation. Anatomical structures unique to fetal circulation are the ductus venosus, the foramen ovale, and the ductus arteriosus. The ductus venosus is a continuation of the umbilical cord. It serves as a shunt to allow most blood returning from the placenta to bypass the immature liver of the embryo. The ductus venosus allows blood to empty directly into the inferior vena cava. The foramen ovale and the ductus arteriosus allow blood to bypass the embryo's lungs. The lungs remain collapsed until birth.

The **foramen ovale** is a shunt from the right atrium into the left atrium. The **ductus arteriosus** connects the pulmonary artery to the aorta. Thus the well-oxygenated blood from the placenta enters the left side of the heart directly from the right side, bypassing the lungs. The left ventricle pumps the oxygenated blood mainly into vessels of the head and forelimbs. The blood entering the right atrium from the superior vena cava progresses downward through the tricuspid valve into the right ventricle. Most of this blood is deoxygenated blood from the head of the fetus. The blood is pumped by the right ventricle into the pulmonary artery. The deoxygenated blood passes from the pulmonary artery, through the ductus arteriosus, into the descending aorta, through the two umbilical arteries, and into the placenta for oxygenation. At birth the various arteriovenous shunts close in most infants (Figure 46-3).

Amniotic Sac and Amniotic Fluid

The **amniotic sac** completely surrounds the embryo. It contains **amniotic fluid,** which is primarily produced by the fetal urine and by the placenta. The fluid is continually produced. It amounts to about 175 to 225 mL by the fifteenth week of pregnancy and about 1 L at birth. The amniotic sac may rupture before or at the time of delivery. There may be a large loss of fluid (gross rupture) or a small trickle (leaking of membranes).

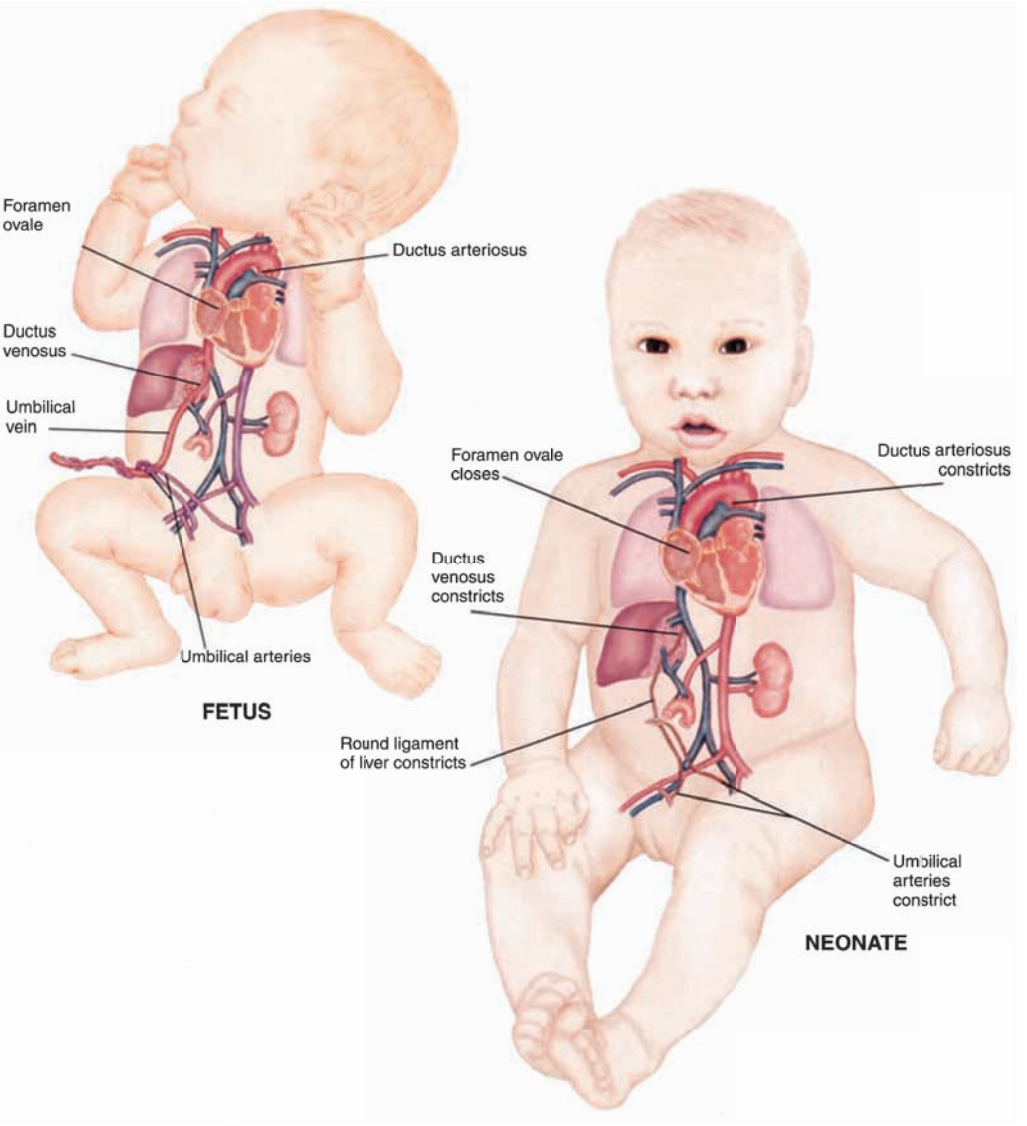

FIGURE 46-3 Fetal circulation and changes in circulation after birth. (From McKinney ES, Ashwill JW, et al: *Maternal-child nursing,* Philadelphia, 2000, Saunders.)

FETAL GROWTH AND DEVELOPMENT

The developing ovum is called an **embryo** during the first 8 weeks of pregnancy. Thereafter and until birth, it is called a **fetus.** The period during which the fetus grows and develops within the uterus is known as **gestation.** Gestation averages 40 weeks from the time of fertilization to delivery of the newborn. Gestation is divided into **trimesters.** The calculated *delivery date* is referred to as the **estimated date of confinement** (EDC). Rapid fetal growth and development characterize the period of gestation (Figure 46-4 and Box 46-1).

Infant Adaptations After Birth

At birth, the infant loses the placental connection with the mother. The fetal circulation changes almost immediately to permit adequate blood flow through the lungs (see later). A newborn usually begins to breathe spontaneously at birth. This occurs when the chest exits the birth canal or with some external stimulation. At birth, the surface tension of the viscid fluid that fills the alveoli holds the walls of the alveoli together. The newborn's first breaths need to be powerful enough to open the alveoli and to allow subsequent respirations to occur with less effort.

The ductus venosus, ductus arteriosus, and foramen ovale allow blood flow to bypass the immature liver and lungs of the developing fetus. When blood flow through the placenta ceases at birth, there is a resultant increase in systemic vascular resistance and an increase in pressure in the aorta, left ventricle, and left atrium. In addition, pulmonary vascular resistance decreases greatly because of lung expansion. This reduces the pulmonary arterial, right ventricular, and right atrial pressures. As a result of these changes in pressure, the arteriovenous shunts close normally within a few hours after birth. They eventually

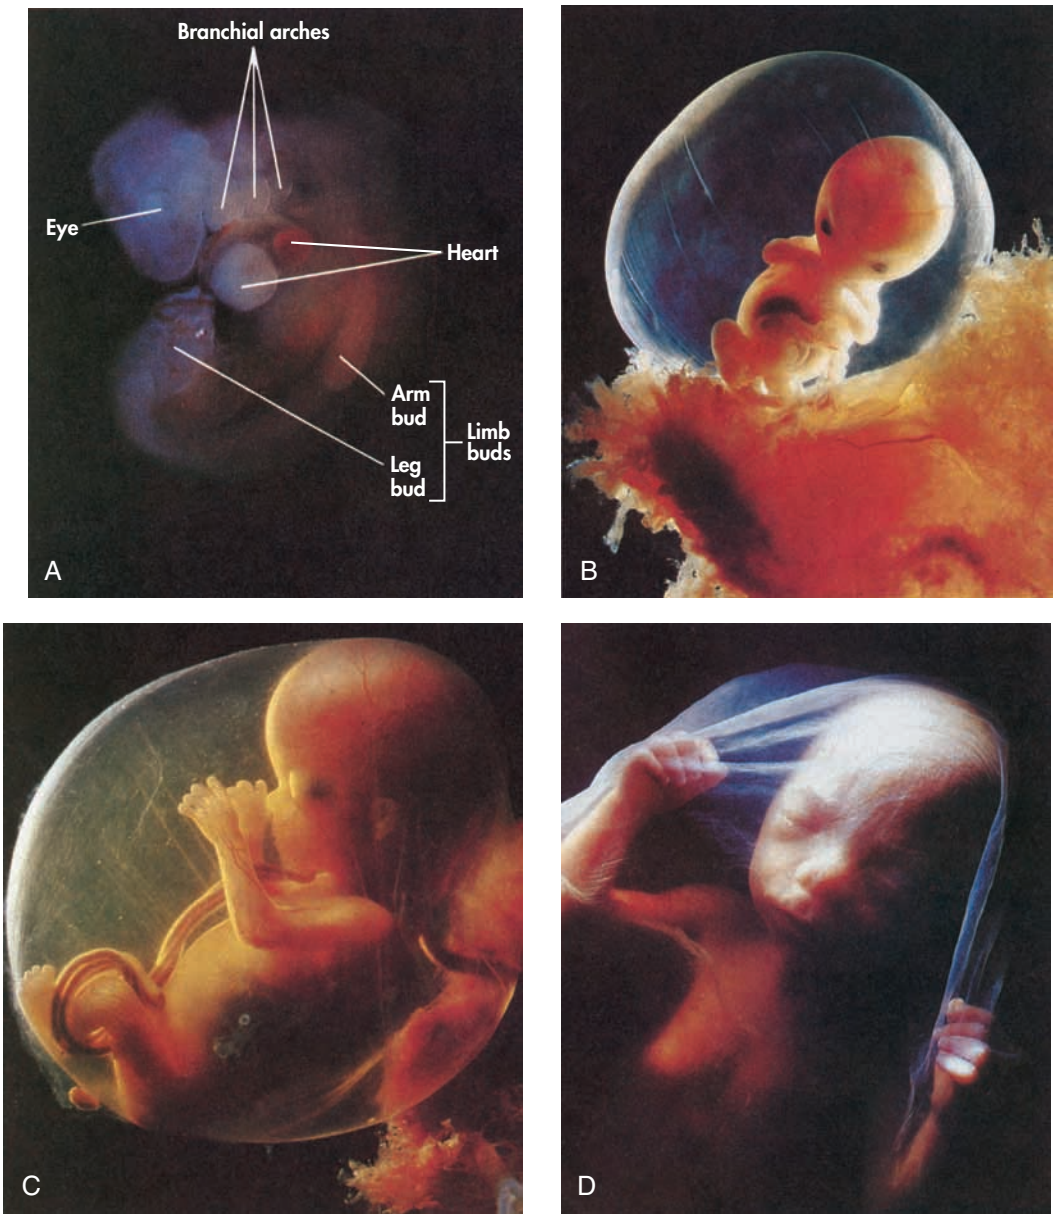

FIGURE 46-4 Human embryos and fetuses. **A,** At 35 days. **B,** At 49 days. **C,** At the end of the first trimester. **D,** At 4 months. (From Thibodeau G, Patton K: *Structure and function of the body,* ed 9, St Louis, 1992, Mosby.)

close completely and are covered with a growth of fibrous tissue.

CRITICAL THINKING
Do newborn heart tones sound normal if you auscultate them immediately after birth?

PREGNANCY TERMINOLOGY (GTPAL)

GTPAL is an acronym that stands for *Gravida, Term, Preterm, Abortions*, and *Living*. Gravida is the number of times a woman has been pregnant. Term is the number of term deliveries. Preterm is the number of preterm deliveries. Abortions is the number of spontaneous or induced abortions. Living is the number of living children.

Pregnant patients are described by their gravid and parous states. As just stated, gravida refers to the number of times the woman has been pregnant, including the present pregnancy. Para refers to the number of infants born after 20 weeks' gestation. For example, a woman who is pregnant for the first time is gravida 1, para 0 (Box 46-2). A woman who has had two or more deliveries is multipara. A woman who has never delivered a child is nullipara.

PATIENT ASSESSMENT

The paramedic must be familiar with the normal physiological changes that occur in the pregnant woman. This will help the paramedic to assess a pregnant patient.

BOX 46-1 Embryo and fetal Development in Utero for Each Lunar Month (28 Days)

First Lunar Month
- Foundations form for the nervous system, genitourinary system, skin, bones, and lungs.
- Buds of arms and legs begin to form.
- Rudiments of eyes, ears, and nose appear.

Second Lunar Month
- The head is disproportionately large because of brain development.
- Gender differentiation begins.
- The centers of bones begin to ossify.

Third Lunar Month
- Fingers and toes are distinct.
- The placenta is complete.
- Fetal circulation is complete.

Fourth Lunar Month
- Gender is differentiated.
- Rudimentary kidneys secrete urine.
- Heartbeat is present.
- Nasal septum and palate close.

Fifth Lunar Month
- Fetal movements are felt by the mother.
- Heart sounds are perceptible with a fetoscope.

Sixth Lunar Month
- The skin appears wrinkled.
- Eyebrows and fingernails develop.

Seventh Lunar Month
- The skin is red.
- The pupillary membrane disappears from the eyes.
- If born, the infant cries and breathes but frequently dies.

Eighth Lunar Month
- The fetus is viable if born.
- The eyelids open.
- Fingerprints are set.
- Vigorous fetal movement occurs.

Ninth Lunar Month
- The face and body have a loose, wrinkled appearance because of subcutaneous fat deposits.
- Amniotic fluid decreases slightly.

Tenth Lunar Month
- Skin is smooth.
- Eyes are uniformly slate colored.
- The bones of the skull are ossified and nearly together at sutures.

BOX 46-2 Obstetrical Terminology

Antepartum: The maternal period before delivery
Grand multipara: A woman who has had seven deliveries or more
Multigravida: A woman who has had two or more pregnancies
Multipara: A woman who has had two or more deliveries
Nullipara: A woman who has never delivered
Perinatal: Occurring at or near the time of birth
Postpartum: The maternal period after delivery
Prenatal: Existing or occurring before birth
Primigravida: A woman who is pregnant for the first time
Primipara: A woman who has given birth only once
Term: A pregnancy that has reached 40 weeks' gestation

Maternal Changes During Pregnancy

In addition to cessation of menstruation and obvious enlargement of the uterus, the pregnant woman undergoes many other physical changes. These changes affect the genital tract, breasts, gastrointestinal system, cardiovascular system, respiratory system, and metabolism.[3]

GENITAL TRACT

Uterus
- Uterine size increases from 70 g (nongravid) to 1000 g by term.
- The uterus triples in size and weight by 8 weeks of pregnancy.
- The uterus occupies the entire pelvic cavity. It may be palpated suprapubically by 12 weeks of pregnancy.
- The uterus becomes an abdominal organ and the top of the uterus (fundus) reaches the level of the umbilicus by 20 weeks' gestation.
- The uterine fundus descends a little when the fetus descends into the pelvis. This occurs close to term between 38 and 40 weeks' gestation.

Cervix
- Increased uterine blood volume and lymphatic fluid cause pelvic congestion and edema. This results in softening and bluish discoloration of the cervix (**Chadwick's sign**).

Vagina
- The vagina develops a violet color from increased vascularity.
- The vaginal mucosa increases in thickness and vaginal secretions increase.
- The pH of vaginal secretions decreases to about 3.5 because of the increased production of lactic acid from glycogen in the vaginal epithelium. Acidic pH reduces the growth of some pathogens.

Bladder
- Early in the first trimester, frequency of urination occurs mainly from pressure of the expanding uterus on the bladder. Physiological increases in blood volume and cardiac output of the mother may also play a role. Urinary frequency disappears when the

uterus rises out of the pelvis. It returns once again when the fetal head engages in the pelvis near term.

BREASTS

- The breasts become tender in the early weeks of pregnancy.
- The breasts increase in size as a result of hypertrophy of the mammary alveoli by the second month of pregnancy.
- The nipples become larger, more deeply pigmented, and usually more erectile early in pregnancy.
- As breast glands proliferate, the nipples may secrete a clear fluid by the tenth week of pregnancy if stimulated.

GASTROINTESTINAL SYSTEM

- Morning sickness and nausea may occur at any time. They usually begin by the sixth and abate by the fourteenth week of pregnancy. The cause of morning sickness is unknown but may be related to the high serum levels of chorionic gonadotropin in early pregnancy.
- The enlarging uterus displaces the mother's stomach and intestines upward and laterally. This may cause indigestion and gastroesophageal reflux disease (GERD) and may increase the risk for aspiration in unconscious patients.
- The liver is displaced backward, upward, and to the right.
- The tone and motility of the gastrointestinal tract decrease, leading to prolonged gastric emptying and relaxation of the pyloric sphincter. Heartburn and constipation are common.

CRITICAL THINKING

Consider an unconscious pregnant woman who has sustained trauma. What are problems associated with the gastrointestinal changes of pregnancy?

CARDIOVASCULAR SYSTEM

Heart

- Elevation of the diaphragm displaces the heart to the left and upward. Flat or negative T waves may be present in lead III on the electrocardiogram.
- Cardiac output increases by 30% by the thirty-fourth week of pregnancy.
- The pulse rate may increase 15 to 20 beats/min above baseline late in the third trimester.
- Pulmonic systolic and apical systolic murmurs are common. This is because lowered blood viscosity and increased flow lead to turbulence in the great vessels.

Circulation

- Total blood volume increases by 30%. Plasma volume increases by 50%. As a result, hemodilutional anemia is possible beginning at 28 weeks.
- Blood pressure decreases 10 to 15 mm Hg during the second trimester. This is because of the reduction in peripheral resistance. Blood pressure gradually increases to prepregnancy levels toward term.
- The enlarged uterus interferes with venous return from the legs, resulting in peripheral edema in the ankles. Hemorrhoids and varicose veins may be present.
- The supine position may cause the uterus to compress the inferior vena cava. This can produce decreased cardiac filling and decreased cardiac output (*supine hypotension syndrome*). The patient may become faint and hypotensive while lying on her back after the first or second trimester.

Blood

- The leukocyte count increases.
- Fibrinogen levels increase by 50% because of the influence of estrogen and progesterone.

RESPIRATORY SYSTEM

- Tidal volume and minute ventilation increase by 30% to 40% in late pregnancy.
- Functional residual capacity decreases by about 25%.
- The respiratory rate may be normal or may increase because of elevation of the diaphragm by the enlarged uterus.
- P_{CO_2} normally decreases because of an increased respiratory rate. P_{CO_2} changes from 40 to 30 torr to provide a gradient for fetal carbon dioxide. This may cause dizziness and a sensation of shortness of breath for the pregnant woman.

METABOLISM

- The mother normally will experience a weight gain of 15 to 30 pounds.
- Increased water retention produces an increase in hydrostatic pressure within the capillaries. This favors filtration from the vascular bed and can result in edema.
- The metabolic rate and caloric demand (especially for protein) increase.
- Glucose escapes into the urine because of increased glomerular filtration.
- Maternal gestational diabetes mellitus (GDM) may result from an impaired ability to metabolize carbohydrates. Gestational diabetes mellitus is further described later in this chapter.
- Fetal demands for calcium and iron may deplete maternal stores if the patient does not supplement them through diet.

History

When obtaining a history from an obstetrical patient, the paramedic first should gather details about the chief complaint. This complaint may not be related to the pregnancy. If possible, paramedics should solicit information about the onset of signs and symptoms and examine the patient in privacy. After ruling out life-threatening illness or injury, the paramedic should interview the patient to obtain relevant information. The history for a pregnant patient must incorporate the following eight points:

1. Obstetrical history
   a. Length of gestation
   b. Parity and gravidity
   c. Previous cesarean delivery
   d. Maternal lifestyle (alcohol or other drug use, smoking history)
   e. Infectious disease status
   f. History of previous gynecological or obstetrical complications (e.g., eclampsia, GDM, premature labor, or ectopic pregnancy)
2. Presence of pain
   a. Onset (gradual or sudden)
   b. Character
   c. Duration and evolution over time
   d. Location and radiation
3. Presence, quantity, and character of vaginal bleeding
4. Presence of abnormal vaginal discharge
5. Presence of "show" (expulsion of the mucous plug in early labor) or rupture of membranes
6. Current general health and prenatal care (none, physician, nurse, midwife)
7. Allergies and medications taken (especially the use of narcotics in the last 4 hours)
8. Maternal urge to bear down or sensation of imminent bowel movement, indicating imminent delivery

NOTE

Pregnancy may aggravate some preexisting medical conditions. Examples are diabetes, heart disease, hypertension, and seizure disorders. And some medications (e.g., antihypertensive agents and oral hypoglycemic drugs) used to manage these disorders cannot be taken by the mother during her pregnancy. This is due to the potential harm to the fetus. Thus a thorough patient history is vital. The history will help the paramedic anticipate care that may be required at the scene and during patient transport.

Physical Examination

The patient's chief complaint determines the extent of the examination. The goal in examining an obstetrical patient is to identify acute life-threatening conditions rapidly. A part of this goal is to identify imminent delivery. If delivery is near, the paramedic must take the proper management steps.

The paramedic should assess the patient's general appearance and skin color. If she is very pale, hemorrhage should be suspected. Sunken cheeks, cracked lips, or hollow eyes with a history of vomiting indicate dehydration. Vital signs should be monitored often during the care. Orthostatic vital signs may indicate the early presence of significant bleeding or fluid loss. The paramedic should recall that normal physiological changes in the pregnant patient can produce variations in vital signs. Examples are mild tachycardia, a slight fall in systolic and diastolic blood pressures, and an increase in respiratory rate.

The patient's abdomen should be examined for scars and gross deformities. Gentle palpation may reveal the presence of masses, enlarged organs, intestinal distention, or a distended bladder. In late pregnancy, though, these may be difficult to recognize. During the examination, it may be possible to discern peritoneal irritation. Peritoneal irritation is diagnosed by the presence of tenderness, guarding, or rebound tenderness. If the patient is obviously pregnant, the paramedic may need to assess uterine size and monitor the fetus.

EVALUATION OF UTERINE SIZE

The uterine contour usually is irregular between 8 and 10 weeks' gestation. Thus early uterine enlargement may not be symmetrical and may be deviated to one side. The uterus is above the symphysis pubis at 12 to 16 weeks' gestation. The uterus is at the level of the umbilicus at 20 weeks and near the xiphoid process at term. Figure 46-5 shows changes in fundal height at the various weeks of gestation.

FETAL MONITORING

Fetal heart sounds can be auscultated beginning at 12 weeks' gestation. (They may be difficult to hear in a noisy environment.) They can be auscultated by use of a

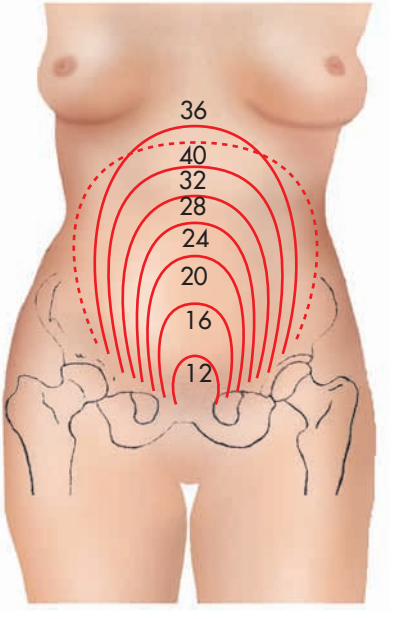

FIGURE 46-5 Changes in fundal height during pregnancy. *Weeks 10 to 12:* The uterus is within the pelvis, and fetal heartbeat can be detected with a Doppler probe. *Week 12:* The uterus is palpable just above the symphysis pubis. *Week 16:* The uterus is palpable just between the symphysis pubis and umbilicus. *Week 20:* The uterine fundus is at the lower border of the umbilicus. A fetal heartbeat can be auscultated with a fetoscope. *Weeks 24 to 26:* The uterus becomes ovoid, and the fetus is palpable. *Week 28:* The uterus is about halfway between the umbilicus and xiphoid process, and the fetus is easily palpable. *Week 32:* The uterine fundus is just below the xiphoid. *Week 40:* Fundal height drops as the fetus begins to engage in the pelvis. (From Seidel HM, et al: *Mosby's guide to physical examination,* ed 2, St Louis, 1991, Mosby.)

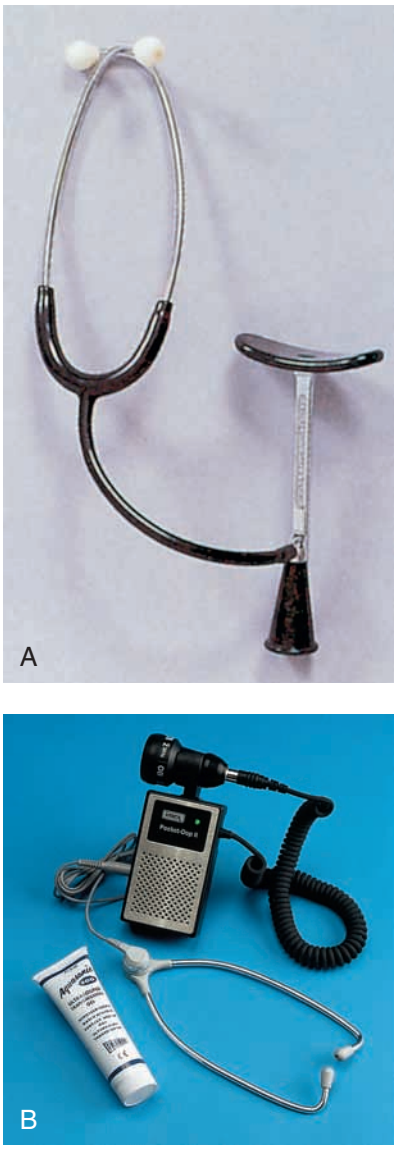

FIGURE 46-6 **A,** Fetoscope. **B,** Doppler probe. (From Seidel HM, et al: *Mosby's guide to physical examination,* ed 2, St Louis, 1991, Mosby.)

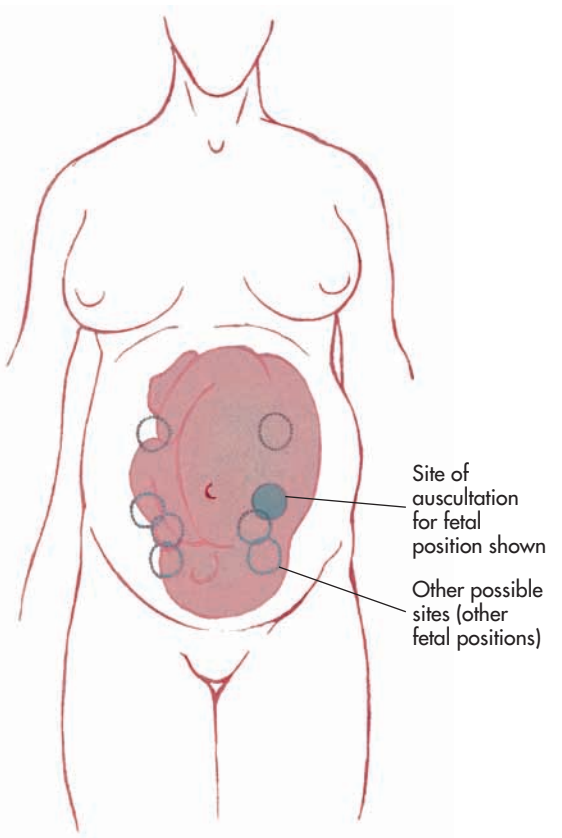

FIGURE 46-7 Sites for auscultation of fetal heart tones.

stethoscope, fetoscope, or Doppler probe (Figure 46-6). The purpose of checking heart tones is to assess fetal well-being. The paramedic should monitor the fetal heart rate and maternal vital signs every 5 to 10 minutes.

When auscultating the fetal heart rate (FHR), the paramedic should position the high-intensity diaphragm of the stethoscope (the bell of the fetoscope or the microphone of the Doppler probe) firmly on the mother's abdominal wall. If more than 20 weeks' gestation, the paramedic should palpate for the fetal back (defined by a structure that is firm and hard versus small body parts). The diaphragm is then moved in a circular pattern of 6 to 8 inches in diameter around the woman's umbilicus until fetal heart tones can be heard (Figure 46-7). If using a Doppler, it should be placed below the umbilicus on the side of the fetal back. Once the paramedic locates the tones, the fetal heart rate is measured in beats per minute. Because fetal heart tones can often be difficult to hear, one should not spend too much time trying to find them, particularly in a patient who is seriously sick, in active labor, or otherwise unstable.

NOTE
At 12 to 15 weeks' gestation, the fetal heart rate can be heard directly above the mother's symphysis pubis, or slightly to the right or left. At 15 to 26 weeks' gestation, fetal heart rate should be monitored halfway between the mother's symphysis pubis and umbilicus.

The normal fetal heart rate is 120 to 160 beats/min. A fetal heart rate that remains above 160 beats/min (*fetal tachycardia*) or below 110 beats/min (*fetal bradycardia*) for more than 60 seconds may be an early sign of fetal distress. It also may be a sign of fetal or maternal hypoxia. Intermittent, short-term increases or decreases in the fetal heart rate usually are normal. Variation can occur at any time and is a sign of fetal suckling. Short-term periodic changes in fetal heart rate are common during fetal sleep, fetal movement, and contractions associated with labor and delivery.

General Management of the Obstetrical Patient

If birth is not imminent, care for the healthy patient should be limited to basic treatment modalities (airway, ventilatory, and circulatory support) and transportation for physician evaluation. In the absence of distress or injury, the patient should be transported in a comfortable position. (This is usually left lateral recumbent.) The paramedic may need to monitor the electrocardiogram, administer oxygen (5 to 7 L/min), and monitor the fetus based on patient assessment and vital sign determinations. Medical direction may advise intravenous (IV) access in some patients. Most drugs usually are inappropriate because they can mask symptoms of a worsening condition.

NOTE

Complications associated with pregnancy can result from trauma (including abuse), medical conditions, prior disease processes that the pregnancy can aggravate or mask, the pregnancy itself (vaginal or intraperitoneal hemorrhage), spontaneous abortion, or problems associated with labor and delivery. Often the patient with gynecological or obstetrical complaints is embarrassed, apprehensive, and, if pregnant, concerned about the unborn child. Tact, understanding, and a caring, supportive attitude from the paramedic are important when managing these patients.

TRAUMA DURING PREGNANCY

About 1 in every 12 pregnancies is complicated by physical trauma.[4] When a pregnant woman is severely injured, the fetus is at high risk for death. The anatomical and physiological changes of pregnancy can alter the pregnant woman's response to injury. This may necessitate modified assessment, treatment, and transportation strategies.

Maternal Injury

The causes of maternal injury in decreasing order of frequency are vehicular crashes, falls, and penetrating objects. These injuries can result in trauma to the gravid uterus and to the maternal bladder, liver, and spleen. In addition, an injury that results in a pelvic fracture can produce massive hemorrhage and damage to the fetal skull. As described in Chapter 37, the severity of any injury depends on many factors and may involve multiple organ systems.

During pregnancy, the fetus is well protected within the uterus; amniotic fluid surrounds the fetus. This fluid serves as an excellent shock absorber. Because of this protection the fetus rarely experiences physical trauma except as a result of direct penetrating wounds or extensive blunt trauma to the maternal abdomen. The greatest risk of fetal death is from interruption of blood flow to the placenta from trauma to or death of the mother. This can cause fetal distress and intrauterine demise. Thus when dealing with a pregnant trauma patient, the paramedic promptly should assess and intervene on behalf of the mother. Severe abdominal injury can result in premature separation of the placenta, premature labor or abortion, rupture of the uterus, and fetal death. Causes of fetal death from maternal trauma include death of the mother, separation of the placenta, maternal shock, uterine rupture, and fetal head injury. Although direct life-threatening fetal injury is uncommon in blunt trauma, in penetrating trauma direct injury to the fetus can cause fetal death, even if the mother's injuries are not life threatening.

Assessment and Management

The priorities in assessing and managing a pregnant trauma patient are the same as those for a nonpregnant patient: adequate airway, ventilatory, and circulatory support with spinal precautions; hemorrhage control; and rapid assessment, stabilization, and rapid transportation to a medical facility. Resuscitating the mother is key to the survival of the mother and fetus. Thus during the first stages of assessment and management, the mother's status should be the focus. Despite the severity, all pregnant trauma patients should be given high-concentration oxygen and transported for physician evaluation.

The examination should be thorough. The paramedic must detect, identify, and manage injuries that contribute to hypovolemia or hypoxia. With the normal increase in maternal blood volume, the mother can tolerate more blood loss before showing signs and symptoms of shock. A 30% to 35% reduction in blood volume can produce minimal changes in blood pressure but reduce uterine blood flow by 10% to 20%.[5] Thus the mother may maintain adequate blood pressure at the expense of the fetus. The true amount of blood loss may be difficult to detect. Fetal monitoring is the best available indicator of fetal well-being after trauma. However, patient transport should never be delayed to assess fetal heart rate.

NOTE

Any traumatic injury to the uterus causing blood loss can result in massive hemorrhage much more quickly than in nonpregnant patients. Any vaginal bleeding after injury should be addressed immediately.

Accelerations of fetal heart rate above baseline are associated with fetal movement and contractions. However, this also may be an early sign of fetal distress. Decreased fetal movement and increased fetal heart rate can indicate maternal shock.

Decelerations in fetal heart rates (below the baseline) result from a decrease in cardiac output and hypoxia. A hypoxic fetus in metabolic acidosis cannot accelerate his or her heart rate. Thus the fetus becomes bradycardic (a heart rate of less than 100 beats/min). Sustained fetal bradycardia (lasting 10 minutes or more) may be a response to increased parasympathetic tone. The fetus can tolerate this only for a short time before becoming acidotic. Fetal

bradycardia may be a late sign of maternal hypotension, hypoxia, or decreased maternal circulating volume. It also is a sign of fetal distress attributable to umbilical cord compression or prolonged decelerations in heart rate.

CRITICAL THINKING
What might be some common feelings of traumatized pregnant females?

Special Management Considerations

Special considerations in managing the pregnant trauma patient include oxygenation, volume replacement, and hemorrhage control. Labor is a complication of trauma in pregnancy. The paramedic crew should be ready to manage delivery or spontaneous abortion (described later in this chapter).

Oxygenation

- Adequate maternal airway maintenance and oxygenation are essential to prevention of fetal hypoxemia.
- Oxygen requirements are 10% to 20% greater than in the normal, nonpregnant patient. Fetal hypoxia may occur with even small changes in maternal oxygenation. The paramedic should administer oxygen at 5 to 7 L/min.
- Pulse oximetry should be used to monitor oxygen saturation.

Volume Replacement

- Signs and symptoms of hypovolemia may not be present until the blood loss is large.
- Blood is shunted preferentially from the uterus to preserve maternal blood pressure.
- Bleeding also may occur inside the uterus. The pregnant uterus can sequester up to 2000 mL of blood after separation of the placenta with little or no evidence of vaginal bleeding.[5]
- Crystalloid fluid replacement is indicated, even when blood pressure remains normal.
- Vasopressors generally are not recommended. They decrease uterine blood flow and fetal oxygen delivery. Vasodilators sometimes are given to patients with severe preeclampsia who are hypertensive.

Hemorrhage Control

- External hemorrhage should be controlled by using the same techniques as for a nonpregnant patient.
- The use of the pneumatic antishock garment is controversial in trauma, and is rarely used today. Most studies suggest that the role of the pneumatic antishock garment for internal hemorrhage is very limited.[8] If the pneumatic antishock garment is to be applied, only the leg compartments should be inflated. This is because use of the abdominal compartment may increase blood loss from pelvic injury. The abdominal compartment can be inflated (by order of medical direction) when maternal and fetal deaths are imminent. However, this is rarely done.
- Vaginal bleeding may point to placental separation, placenta previa, or uterine rupture.
- Avoid a vaginal examination. It may increase bleeding and trigger delivery. This may be the case especially if unsuspected placenta previa is present (described later in this chapter).
- Document the amount and color of vaginal bleeding.
- Collect and transport any expelled tissue with the patient to the facility.

Transportation Strategies

Pregnant patients more than 3 to 4 months' gestation should not be transported in a supine position because of the potential for supine hypotension. In the absence of suspected spinal injury, the patient should be transported in a left lateral recumbent position. If spinal injury is suspected, the patient should be prepared for transportation in the following manner:

1. Fully immobilize the patient on a long spine board.
2. After immobilization, carefully tilt the board on its left side by logrolling the secured patient 10 to 15 degrees.
3. Place a blanket, pillow, or towel under the right side of the board to move the uterus to the left side.

CRITICAL THINKING
Which facilities in your community are prepared to manage high-risk deliveries?

CARDIAC ARREST IN THE PREGNANT PATIENT

Cardiac arrest can occur in pregnant women from a number of causes (Box 46-3). However, many cardiovascular problems associated with pregnancy are related to changes in anatomy that produce a decrease in the return of venous blood.[6] Key interventions to prevent cardiac arrest in a distressed or compromised pregnant patient include placing the patient in the left lateral position or *manually* and *gently* displacing the uterus to the left, administering 100% oxygen, and giving a fluid bolus. The key to resuscitation of the fetus is often resuscitation of the mother. The mother cannot be resuscitated until blood flow to her right ventricle is restored.

An aggressive resuscitation effort is justified in patients who are near term. This can allow for a **cesarean delivery** at the hospital. Fetal survival improves if the time between maternal death and delivery is less than 5 minutes. Survival is poor if the time is longer than 20 to 25 minutes.[6] Alerting the emergency department staff of the possibility of the need for an emergency cesarean section is critical to infant survival.

BOX 46-3 Causes of Cardiac Arrest Associated With Pregnancy

Events That Occur at the Time of Delivery

Amniotic fluid embolism
Drug toxicity (e.g., because of magnesium sulfate or epidural anesthetic)
Eclampsia

Events That Occur from Complex Physiological Changes Associated with Pregnancy

Possible Contributing Factors (BEAU-CHOPS)
- Bleeding/DIC
- Embolism: coronary/pulmonary/amniotic fluid embolism
- Anesthetic complications
- Uterine atony
- Cardiac disease (MI/ischemia/aortic dissection/cardiomyopathy
- Hypertension/preeclampsia/eclampsia
- Other: differential diagnosis of standard ACLS guidelines
- Placenta abruptio/previa
- Sepsis

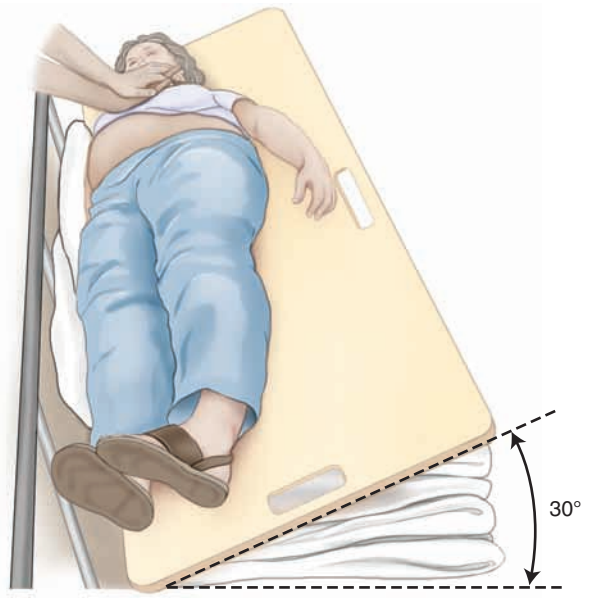

FIGURE 46-8 Patient positioning to displace the uterus.

NOTE

A cesarean delivery or *C-section* is the delivery of a newborn through a surgical incision in the abdominal wall and uterus. A cesarean delivery is performed for a variety of fetal and maternal indications that can complicate childbirth. It may also be the preferred method of delivery by the mother. Cesarean delivery occurs in about 27% of deliveries in the United States.[7]

If cardiac arrest occurs, the paramedic should institute cardiopulmonary resuscitation (CPR) with a few modifications[6]:

- Relieve pressure on the aorta and the inferior vena cava. This can be done by placing the hands on the abdomen to move the uterus to the patient's right or left side. Displacement can also be accomplished by placing the patient in a left lateral tilt of 20 to 30 degrees, using blankets, pillows, or a wedge to support the pelvis and thorax (Figure 46-8).
- Generally perform chest compressions higher on the sternum (that ensures a palpable pulse wave) to adjust for the shifting of the pelvic and abdominal contents toward the head.

Other patient management considerations that are unique to the pregnant patient in cardiac arrest include establishing intravenous access above the diaphragm to enhance the systemic circulation of fluids and drugs, and managing maternal hypotension (systolic blood pressure <100 mm Hg or <80% of baseline) to avoid reduced placental perfusion. In addition, the paramedic should anticipate a difficult airway because of changes in airway mucosa that occur during pregnancy. Standard drug doses and defibrillation therapies are recommended.[6]

NOTE

Magnesium sulfate toxicity in pregnant patients may result in prolonged PR, QRS and QT intervals, nodal block, bradycardia, hypotension, and cardiac arrest. Should this occur, the magnesium sulfate drip should be discontinued and calcium chloride should be given.[6]

MEDICAL CONDITIONS AND DISEASE PROCESSES THAT CAN COMPLICATE PREGNANCY

Pregnancy can mask or worsen certain medical conditions and diseases. These include hypertension, diabetes, infection, neuromuscular disorders, and cardiovascular disease. These conditions and diseases should be considered as part of the paramedic's differential diagnosis. Pregnancy can also cause certain conditions to present atypically, such as acute appendicitis and acute cholecystitis. Specific medical conditions and disease processes discussed in this section include hyperemesis gravidarum, Rh sensitization, hypertensive disorders specific to pregnancy, and infection.

Hyperemesis Gravidarum

Hyperemesis gravidarum (HG) is a condition of pregnancy characterized by severe nausea, vomiting, weight loss, and electrolyte disturbance. It is sometimes referred to as "a severe case of morning sickness." In women who have HG, symptoms begin within 2 to 5 weeks after conception. The nausea and vomiting generally eases after the first trimester and typically stops before 20 weeks' gestation. About 10% to 20% of mothers will have nausea and vomiting until delivery, though it is usually less severe. HG in previous pregnancies often follows a similar pattern of duration and

severity in future pregnancies. The exact cause of HG is unknown. However, it is likely due to several factors that may include[9]:

- Sensitivity of the brain to motion
- Slow gastric emptying
- Insufficient fluids or nutrition
- Rapidly changing hormone levels during pregnancy, because of the rapidly growing placenta
- Gastrointestinal reflux
- Physical and emotional stress of pregnancy
- Vitamin deficiencies

MANAGEMENT

HG can lead to dehydration, weight loss, and malnutrition that can harm both the mother and the fetus. HG is usually managed with antiemetics to control the nausea and vomiting and rehydration therapy. Vitamin and mineral supplements also may be prescribed. Antidepressants are sometimes needed to manage depression that may accompany the illness. Severe cases may require hospitalization and fluid therapy to manage dehydration. Prehospital care is primarily supportive.

Rh Sensitization

As described in Chapter 11, people with Rh-negative blood do not carry the Rh marker on their red blood cells; people with Rh-positive blood do carry the marker. Rh sensitization can occur during pregnancy if an Rh-negative woman is pregnant with a baby who has Rh-positive blood. If this occurs, the immune system reacts to the Rh factor by producing antibodies to destroy it (Rh sensitization). During the first pregnancy, Rh sensitization usually does not pose a problem for the mother or baby. This is because the first exposure of fetal blood to maternal blood normally does not occur until delivery, which then becomes the sensitizing event. Maternal antibodies take some time to develop. However, if the mother was sensitized before the pregnancy (e.g., as a result of a previous abortion, ectopic pregnancy, or amniocentesis that caused bleeding into the uterus) or if there is a subsequent pregnancy with an Rh-positive fetus, maternal antibodies can destroy fetal red blood cells.

LOOK AGAIN

See Chapter 11: General Principles of Pathophysiology, pp. 245-246.

NOTE

If the mother is Rh-negative and the father is Rh-positive, the baby has a 50% chance of being Rh-positive, and blood Rh sensitization can occur.

If both parents have Rh-negative blood, the baby will have Rh-negative blood. Sensitization will not occur.

Women are tested early in pregnancy for their Rh factor and to determine if they have been sensitized. Women who have Rh-negative blood and who are not sensitized will require antibody tests until delivery; the newborn will have blood tested at birth. Injections of Rh immune globulin (e.g., RhoGAM) are usually given to prevent Rh sensitization. (This will need to be repeated with each pregnancy.) Women who are sensitized will need careful monitoring and serial blood testing to measure antibody levels during their pregnancy. Doppler studies and amniocentesis may be performed to monitor the fetus. If fetal anemia is severe, the baby may need blood transfusions before birth (intrauterine transfusion) and immediately after birth. Early cesarean delivery is common in these cases.

Rh DISEASE

An infant born with Rh disease may have no symptoms of the illness. Other newborns can have a serious and life-threatening blood disorder known as erythroblastosis fetalis. (The most common form of erythroblastosis fetalis is ABO incompatibility. The less common form is Rh incompatibility.) Symptoms of the disease include anemia, jaundice, edema, an enlarged liver or spleen, and hydrops fetalis (the accumulation of fluid throughout body tissues, including the lungs, heart, and abdominal organs). Rh disease is treated with blood transfusion.

Pregnancy-Induced Hypertensive Disorders

Pregnancy-induced hypertensive (PIH) disorders occur in about 6% to 8% of pregnancies in the United States; they increase the risk to the mother and the fetus. PIH disorders are generally divided into three categories: gestational hypertension, preeclampsia, and eclampsia.[5]

GESTATIONAL HYPERTENSION

Gestational hypertension (GH) occurs during pregnancy and resolves during the postpartum period. It is recognized by a new blood pressure reading of 140/90 mm Hg or higher. This condition is thought to result from rejection of the pregnancy by the immune system and can be an early sign of preeclampsia.

PREECLAMPSIA AND ECLAMPSIA

Preeclampsia is gestational hypertension with proteinuria. The hypertension can be *mild* or *severe* (a diastolic blood pressure that exceeds 110 mm Hg). The progression of preeclampsia to eclampsia is unpredictable and can occur rapidly.[10] The pathophysiology of preeclampsia, which does not reverse until after delivery, is characterized by vasospasm, endothelial cell injury, increased capillary permeability, and activation of the clotting cascade. The signs and symptoms of preeclampsia result from hypoperfusion to the tissue or organs involved (Box 46-4). Generalized edema is a possible sign of preeclampsia although it may occur both in a normal pregnancy and in a pregnancy

BOX 46-4 Signs and Symptoms of Preeclampsia

Cerebrum
Headache
Hyperreflexia

Retina
Blurred vision
Diplopia

Gastrointestinal System
Right upper quadrant or epigastric pain and tenderness

Renal System
Proteinuria
Azotemia
Oliguria
Anuria

Vasculature or Endothelium
Hypertension
Edema
Activation of the clotting cascade

Placenta
Abruptio placentae
Fetal distress

complicated by another disorder (Figure 46-9, *A* and *B*). In addition to a first-time pregnancy, factors associated with preeclampsia include advanced maternal age, chronic hypertension, chronic renal disease, vascular diseases such as diabetes and systemic lupus, and multiple gestation. Preeclampsia is a clinical diagnosis that can be confirmed by postpartum renal biopsy. When preeclampsia is suspected, most patients are hospitalized.

DID YOU KNOW?

HELLP Syndrome

The most severe form of preeclampsia is **HELLP syndrome** (*H*, hemolysis; *EL,* elevated liver enzymes; *LP,* low platelet count). HELLP syndrome is a true obstetrical emergency that affects about 10% of pregnant women who have preeclampsia or eclampsia.[11] Signs and symptoms of HELLP syndrome include headache, worsening nausea and vomiting, upper abdominal pain, and vision disturbances. When the disease is not treated early, up to 25% of women develop serious complications. Without treatment, a small number of women die. The death rate among babies born to mothers with HELLP syndrome varies and depends on birth weight and the development of the baby's organs, especially the lungs. Definitive treatment is to deliver the newborn as soon as possible. The disease affects blood clotting abilities and liver function with consequences that can be harmful to both mother and child.

HELLP syndrome often is asymptomatic with vague complaints made by the patient of "feeling unwell," related to severe preeclampsia. (It often presents without elevated blood pressure or proteinuria.) The prominent symptom of HELLP syndrome is pain in the right upper quadrant, the lower chest, or epigastric area. There also may be tenderness because of liver distention. It is important to avoid traumatizing the liver by abdominal palpation and to use care in transporting the patient. A sudden increase in intraabdominal pressure, including a seizure, could lead to rupture of a subcapsular hematoma, resulting in internal bleeding and hypovolemic shock.[12]

Eclampsia is the occurrence of seizures in a patient with other signs of preeclampsia. It is most common in patients with severe preeclampsia. It is a disease of unknown origin that primarily affects previously healthy, normotensive

FIGURE 46-9 Generalized edema is a possible sign identified with preeclampsia although it may occur both in a normal pregnancy and in a pregnancy complicated by another disorder. **A,** Facial edema may be subtle. **B,** Pitting edema of the lower leg. (From McKinney ES, et al: *Maternal-child nursing,* ed 3, St Louis, 2009, Saunders.)

women in their first pregnancy. The disease occurs after 20 weeks' gestation, often near term, but may occasionally be seen postpartum. Preeclampsia is dangerous for the expectant mother and fetus for two reasons[2]: (1) it can develop and progress rapidly; and (2) the early symptoms are often unnoticed by the woman or may be attributed to other causes.

MANAGEMENT

Not all hypertensive patients have preeclampsia. Also, not all preeclamptic patients have hypertension. The illness has many serious complications. Thus the paramedic should always suspect preeclampsia or eclampsia when hypertension or headache, visual changes, or epigastric pain present in late pregnancy or within 2 weeks' postpartum. If preeclampsia or eclampsia is suspected, prehospital care is directed at preventing or controlling seizures and treating hypertension (under the guidance of medical direction).

Seizure activity in eclampsia most often is characterized by tonic-clonic activity (described in Chapter 25). The seizure often begins around the mouth in the form of twitching. Eclampsia may be associated with apnea during the seizure. Labor can begin suddenly and progress rapidly. The regimen for managing severe preeclampsia is as follows:

1. Place the patient in a left lateral recumbent position to help maintain or improve uteroplacental blood flow. It also will help to lessen the risk of insult to the fetus.
2. Handle the patient gently and minimize sensory stimulation. (For example, darken the ambulance.) This will help to avoid seizures.
3. Administer high-concentration oxygen and monitor O_2 saturation. Assist respirations as needed.
4. Initiate IV therapy per protocol.
5. Anticipate seizures at any moment. Be prepared to provide airway, ventilatory, and circulatory support.
6. Be ready to administer the following medications per medical direction and local protocol:
   a. ***Magnesium sulfate*** 10%. The loading dose is normally 4 grams over 20 minutes. It is rare for this to make a patient hypermagnesemic. The antidote **(*calcium gluconate*)** should be close at hand if necessary to treat respiratory depression.
   b. ***Diazepam*** or ***lorazepam***
      (1) May precipitate a fall in blood pressure.
      (2) May jeopardize fetal circulation.
      (3) Closely monitor vital signs.
7. Gently transport the patient to a proper medical facility.

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) is diabetes caused by pregnancy. The condition occurs in about 4% of all pregnancies, affecting 135,000 women in the United States each year.[13] GDM is thought to be related to an inability of the mother to metabolize carbohydrates. This may be caused by a deficiency of the mother's insulin or from placental hormones that block the action of the mother's insulin (*insulin resistance*). As a result, the mother's body is not able to produce or use all of the insulin it needs during the pregnancy. Excessive amounts of her glucose are transmitted to the fetus where it is stored as fat. Treatment for GDM includes regular glucose monitoring, dietary modification, and exercise. In some cases, pregnant women will need insulin injections to manage the condition. Gestational diabetes mellitus usually subsides after pregnancy. However, it may return in later years or with future pregnancies.

Most women with GDM are aware of their condition through prenatal care and have healthy pregnancies and healthy babies. Without treatment, however, mothers with GDM often have very large babies. This results in a more difficult labor and delivery (with increased risk for fetal and maternal injury) and a longer recovery. In addition, children whose mothers had GDM are at higher risk for certain health problems. Examples of such are respiratory distress syndrome, obesity, and related health issues as children or adults. These children also have an increased risk for developing type 2 diabetes during their lifetime.[13]

MANAGEMENT

Prehospital care for patients with insulin-dependent GDM may include airway, ventilatory, and circulatory support; glucose testing; management of hypoglycemia with IV fluids and ***dextrose;*** or management of hyperglycemia with the administration of IV fluids and ***insulin*** (per medical direction) (see Chapter 26).

Infection

Numerous infections can pose problems for the pregnant mother and some can be spread to the developing fetus and newborn. One example is the HIV infection (described in Chapter 28). Another is TORCH infection, described below. Infectious diseases that may affect a woman's pregnancy, fetus, or newborn are listed in Box 46-5.

TORCH INFECTION

TORCH is an acronym for a special group of infections (**TORCH infections**) that may be acquired by a woman during pregnancy. "TORCH" stands for the following infections:

BOX 46-5 Pregnancy and Infection

Urinary tract infection
Vaginal infection
Sexually transmitted infections
Bacterial vaginosis
Candidiasis
Chlamydial infection
Gonorrhea
Human papillomavirus
Syphilis
Trichomoniasis

T: Toxoplasmosis
O: Other infections: namely, hepatitis B, syphilis, and herpes zoster (the virus that causes chickenpox)
R: Rubella (formerly known as German measles)
C: Cytomegalovirus (CMV)
H: Herpes simplex virus (the cause of genital herpes)

TORCH infections can be passed to the fetus in the womb, resulting in fetal death or serious complications for the newborn. These complications include[14]:

- Miscarriage
- Congenital heart disease or heart defects (rare)
- Hearing impairment, including deafness
- Mental retardation or other learning, behavioral, or emotional problems
- Anemia
- Liver or spleen enlargement
- Pneumonia
- Microcephaly (small head and brain size)
- Jaundice
- Low birth weight or poor growth inside the womb
- Blindness or other vision problems, such as cataracts (a clouding of the lens of the eye)
- Skin rash or scarring

Most TORCH infections can be prevented through immunization, good personal hygiene, and safe sex practices. In the case of toxoplasmosis, prevention includes avoidance of raw meat and exposure to cats, which can sometimes carry the disease.

BLEEDING COMPLICATIONS RELATED TO PREGNANCY

Although most pregnancies are successful events, complications can and do occur. Vaginal bleeding during pregnancy can result from spontaneous abortion (miscarriage), ectopic pregnancy, abruptio placentae, placenta previa, uterine rupture, or postpartum hemorrhage. Patients with vaginal bleeding have varying degrees of blood loss. Some require aggressive resuscitation.

CRITICAL THINKING
When a mother loses blood from vaginal hemorrhage, what effect does that have on her fetus?

Spontaneous Abortion

Spontaneous abortion is the nontherapeutic termination of pregnancy from any cause before 20 weeks' gestation. (Between 21 and 36 weeks' gestation, it is known as a *preterm birth*.) Abortion is the most frequent cause of vaginal bleeding in pregnant women. It occurs in about 1 in 10 pregnancies. Box 46-6 lists common classifications of abortion.[3]

Most spontaneous abortions occur in the first trimester, usually before the tenth week. The patient often is anxious and apprehensive and complains of vaginal bleeding with pain. Bleeding may be slight (dime- or quarter-sized spotting) or profuse. The pain may be referred to the lower back and is often described as cramp-like and similar to the pain of labor or menstruation. In addition, the patient may have suprapubic pain. When obtaining a history, the paramedic should ascertain the time of onset of pain and bleeding, the amount of blood loss (a soaked sanitary pad suggests 20 to 30 mL of blood loss), and whether the patient passed any tissue with the blood. If the patient passed tissue during bleeding episodes, the tissue should be collected and transported with the patient for analysis.

MANAGEMENT

The assessment of all first-trimester bleeding should include close observation for signs of significant blood loss and hypovolemia. The paramedic should measure vital signs often during transport. Depending on the patient's hemodynamic status, IV fluid therapy may be indicated. All patients with suspected abortion should receive oxygen, emotional support, and transportation for physician evaluation.

Ectopic Pregnancy

An **ectopic pregnancy** occurs when a fertilized ovum implants anywhere other than the uterus. Ectopic gestation occurs in about 2% of all pregnancies; it is the leading cause

BOX 46-6 Classifications of Abortion

Complete abortion: An abortion in which the patient has passed all of the products of conception
Criminal abortion: An intentional ending of any pregnancy under any condition not allowed by law
Elective abortion: The elective termination of a pregnancy for nonmedical reasons
Habitual abortion: Three or more consecutive pregnancies that end in abortion
Incomplete abortion: An abortion in which the patient has passed some but not all of the products of conception
Induced abortion: An abortion in which the pregnancy is terminated intentionally
Missed abortion: The retention of the fetus in utero for 4 or more weeks after fetal death
Septic abortion: An abortion complicated by fever, endometritis, parametritis, pelvic disease, often leading to sepsis
Spontaneous abortion: An abortion that usually occurs before the twelfth week of gestation (the lay term is *miscarriage*). (Predisposing factors include acute or chronic illness in the mother, abnormalities in the fetus, and abnormal attachment of the placenta. Often the cause is unknown)
Therapeutic abortion: A pregnancy legally terminated for reasons of maternal well-being
Threatened abortion: An abortion in which a patient has some uterine bleeding with an intrauterine pregnancy in which the internal cervical os is closed. A threatened abortion may stabilize and end in normal delivery or progress to an incomplete or complete abortion

of first-trimester death and accounts for more than 6% of all maternal deaths in the United States.[5] Death from ectopic pregnancy usually results from hemorrhage.

Ectopic pregnancy has many causes. Most involve factors that delay or prevent the passage of the fertilized ovum to its normal site of implantation. Predisposing factors include pelvic inflammatory disease, adhesions from previous surgery, tubal ligation, previous ectopic pregnancy, and possibly the presence of intrauterine contraceptive devices. Thus obtaining a full gynecological history is important in risk assessment. Although the time from fertilization to rupture varies, most ruptures occur by 2 to 12 weeks' gestation.

The signs and symptoms of ectopic pregnancy often are difficult to distinguish from those of a ruptured ovarian cyst, pelvic inflammatory disease, appendicitis, or abortion (thus the name the *great imitator*). The classic triad of symptoms includes abdominal pain, vaginal bleeding, and amenorrhea (absence of menstruation); however, vaginal bleeding may be absent, spotty, or minimal, and amenorrhea may be replaced by oligomenorrhea (scanty flow). The variable presentation of this type of pregnancy is one reason for its high-risk profile. Other symptoms of ectopic pregnancy include signs of early pregnancy. These include referred pain to the shoulder, nausea, vomiting, syncope, and the classic signs of shock.

MANAGEMENT

A ruptured ectopic pregnancy is a true emergency. It calls for initial resuscitation measures and rapid transport for surgical intervention. The patient may become unstable quickly. If the paramedic suspects an ectopic pregnancy, the patient should be managed like any victim of hemorrhagic shock—with airway, ventilatory, and circulatory support and IV fluid resuscitation.

Third-Trimester Bleeding

Third-trimester bleeding occurs in 4% of all pregnancies and is never normal.[5] About half of bleeding episodes are a result of abruptio placentae, placenta previa, or uterine rupture. Table 46-1 differentiates among abruptio placentae, placenta previa, and uterine rupture.

ABRUPTIO PLACENTAE

Abruptio placentae is partial or full detachment of a normally implanted placenta at more than 20 weeks' gestation. It occurs in about 1% of all pregnancies and is severe enough to result in fetal death in about 15% of cases of abruption.[15] Predisposing factors to abruptio placentae include maternal hypertension, preeclampsia, multiple pregnancies, trauma, and previous abruption.

NOTE

Maternal use of cocaine, which causes vasoconstriction in the endometrial arteries, is a leading cause of abruptio placentae.[2]

CRITICAL THINKING

Why is abruptio placentae associated with such a high fetal death rate?

TABLE 46-1 Differentiation of Abruptio Placentae, Placenta Previa, and Uterine Rupture

History	Bleeding	Abnormal Pain	Abdominal Examination
Abruptio Placentae Association with severe hypertension, toxemia of pregnancy, and methamphetamine or cocaine use	Often absent or scant episode of dark vaginal bleeding	Present	Localized uterine tenderness Fetal heart rate slows after contractions Absent fetal heart tones
Placenta Previa Previous cesarean section Grand multiparity	Bleeding after intercourse Classic bleeding pattern: 1 bleed in early second trimester 1 bleed in late second or early third trimester 1 severe bleed after onset of labor	Usually absent	Lack of uterine tenderness Labor Fetal heart tones
Uterine Rupture Previous cesarean section Tetanic contraction	Possible vaginal bleeding	Severe pain usually present and associated with sudden onset of nausea and vomiting	Diffuse abdominal tenderness Sudden cessation of labor Bradycardia

The common presentation of abruptio placentae is sudden third-trimester vaginal bleeding and pain. The vaginal bleeding may be minimal. The degree of shock is often out of proportion to the visible blood loss because much of the hemorrhage is concealed behind the placenta. The more extensive the separation, the greater the uterine irritability, resulting in a tender abdomen and rigid uterus. Contractions may be present. The absence of fetal heart tones or a bradycardic fetal heart rate suggests severe abruptio placentae, and fetal death is likely.

PLACENTA PREVIA

Placenta previa is placental implantation in the lower uterine segment partially or completely covering the cervical opening. It occurs in about 5 in 1000 deliveries.[16] The incidence is higher in preterm births. The condition is characterized by painless, bright red bleeding with or without uterine contraction. The bleeding may occur in episodes and may be slight to moderate. In addition, bleeding may become more profuse if active labor begins. Fetal heart rate slows because of hypoxia.

Placenta previa is associated with increasing maternal age, multiple pregnancies, previous cesarean section, and previous placenta previa episodes. Recent sexual intercourse can lead to bleeding.

UTERINE RUPTURE

Uterine rupture is a spontaneous or traumatic rupture of the uterine wall. It most frequently results from reopening of a previous uterine scar (e.g., a previous cesarean section). It also may result from a prolonged or obstructed labor, or direct trauma. Uterine rupture occurs in about 1 in 1500 pregnancies. It carries a 0% to 1% maternal mortality rate and a 2% fetal mortality rate in developed countries. The fetal mortality rate, which had been about 65% in the 1960's and 1970's, has steadily declined in the last 2 decades to less than 5%.[17]

Uterine rupture is characterized by sudden abdominal pain described as steady and "tearing," active labor, early signs of shock (complaints of weakness, dizziness, anxiety), and bleeding, which may not be visible. On examination, the abdomen usually is rigid. The patient complains of diffuse abdominal pain. Fetal parts may be felt easily through the abdominal wall.

MANAGEMENT

The prehospital management of a patient with third-trimester bleeding is aimed at preventing shock. The paramedic should not try to examine the patient vaginally; doing so may increase hemorrhage and precipitate labor. Emergency care measures should include the following:

1. Provide adequate airway, ventilatory, and circulatory support as needed (with spinal precautions if indicated).
2. Place the patient in a left lateral recumbent position.
3. Begin transport immediately.
4. Initiate IV therapy with volume-expanding fluid.
5. Apply a fresh perineal pad. Note the time of application to assess bleeding during transport.
6. Check fundal height. Document it for baseline measurement.
7. Closely monitor the patient's vital signs en route to the medical facility.
8. Closely monitor fetal heart rate.

LABOR AND DELIVERY

Parturition is the process by which the infant is born. Near the end of pregnancy the uterus becomes increasingly irritable and exhibits occasional contractions. These contractions become stronger and more frequent until parturition begins. During and as a result of these contractions, the cervix begins to dilate. As uterine contractions increase, complete cervical dilation occurs to about 10 cm; the amniotic sac usually ruptures; and the fetus, and shortly thereafter the placenta, is expelled from the uterus through the vaginal canal (Figure 46-10).

Stages of Labor

Labor follows several distinct stages.[3] The lengths of these stages vary depending on whether the mother is nullipara or multipara (Box 46-7). Thus the paramedic should use the stages of labor only as a guideline in assessing labor progression in the average pregnancy.

FIRST STAGE OF LABOR

The **first stage of labor** begins with contractions and ends when the cervix is fully dilated at 10 cm. This stage of labor is divided into early labor, active labor, and transition.

NOTE

About 2 to 3 weeks before the onset of *active labor,* the cervix undergoes the process of softening, effacement (thinning), and dilation. During this timeframe, the fetus may move into the mother's pelvis. This is commonly called *lightening.* Lightening is characterized by relief of pressure in the mother's upper abdomen and a simultaneous increase in pressure in her pelvis. **Braxton-Hicks contractions** refer to irregular tightening of the pregnant uterus. These begin in the first trimester (before 30 weeks' gestation). They are usually benign and painless. They often subside with walking or other exercise. Many patients are not aware of Braxton-Hicks contractions. They may perceive them as a slight uterine hardening. As the pregnancy continues, the Braxton-Hicks contractions increase in frequency and duration.

Early labor is defined by cervical dilation of 0 to 3 cm and contractions occurring every 5 to 20 minutes and lasting 30 to 45 seconds. In this stage of labor, the mother typically notices backache and mild discomfort. The contractions progress over time, becoming longer, stronger, and closer together. Between contractions, the mother feels relatively normal and pain free.

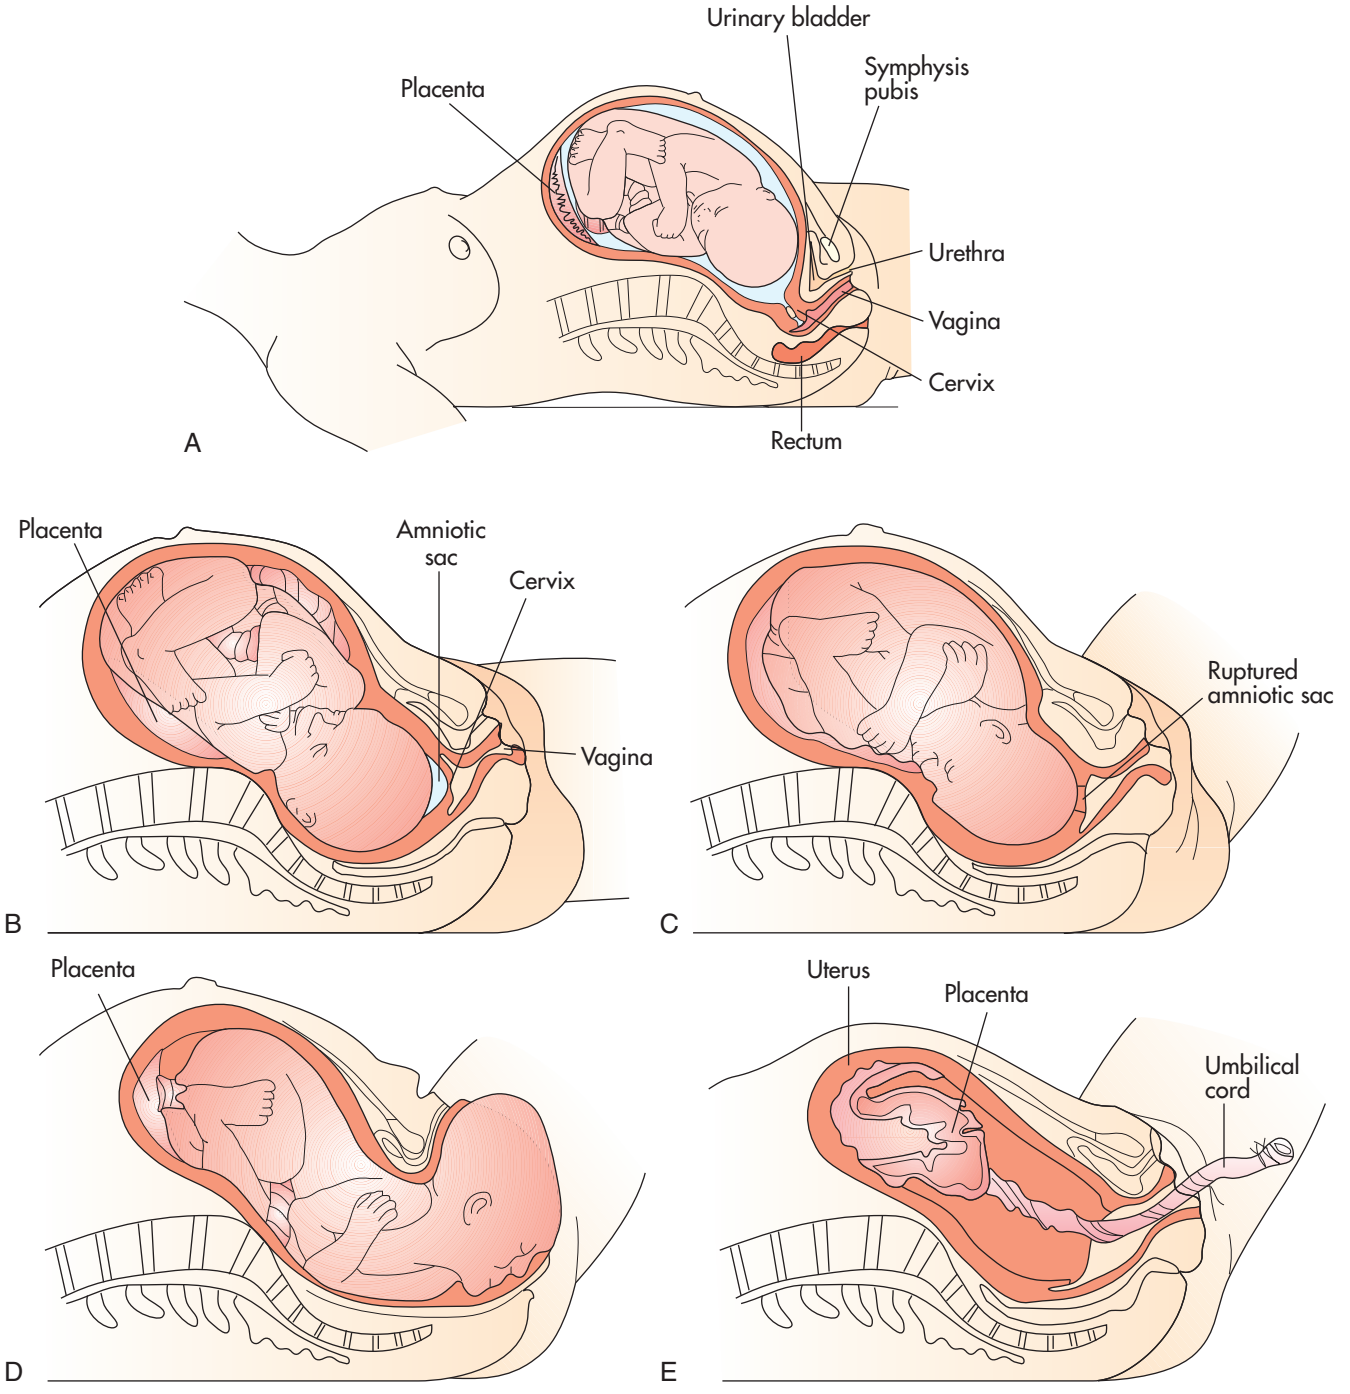

FIGURE 46-10 Parturition. **A,** The relation of the fetus to the mother. **B,** The fetus moves into the birth canal. **C,** Dilation of the cervix is complete. **D,** The fetus is expelled from the uterus. **E,** The placenta is expelled.

For first-time mothers, this stage of labor may last 8 to 20 hours. With subsequent births, the stage lasts 6 to 8 hours or less.

Active labor is defined by cervical dilation of 4 to 8 cm, and contractions 4 to 5 minutes apart, lasting about 60 seconds. This stage marks the beginning of intense contractions. Between contractions, the mother may experience trembling, nausea, and vomiting. Coached relaxation and slowed breathing between contractions often is comforting to the mother. This stage of labor usually lasts 1 to 2 hours.

Transition is defined by cervical dilation of 8 to 10 cm. During transition, contractions are about 2 to 3 minutes apart and last for about 60 to 90 seconds. The contractions are intense and may occur with little rest for the mother. They may be accompanied by rectal pressure if the baby's head is positioned low. In many pregnancies, the amniotic sac ruptures (*rupture of membranes*) toward the end of the

BOX 46-7 Stages of Labor

Stage I
- Onset of regular contractions to complete cervical dilation
- Average time: Early labor 8-20 hours in primipara, 6-8 hours or less in multipara
- Active labor 1-2 hours
- Transition 15-30 minutes on average

Stage II
- Full dilation of cervix to delivery of the newborn
- Average time: 1-2 hours in primipara, 30 minutes or less in multipara

Stage III
- Immediately after delivery of the infant until expulsion of the placenta
- Average time: 5 to 60 minutes regardless of parity

BOX 46-8 Premonitory Signs of Labor

Lightening
Braxton-Hicks contractions
Cervical changes
Bloody show
Rupture of membranes

first stage of labor. The period of transition lasts only 15 to 30 minutes on average (Box 46-8).

CRITICAL THINKING
What comfort measures can you use during transportation for the patient who is in the first stage of labor?

SECOND STAGE OF LABOR

The **second stage of labor** is measured from full dilation of the cervix to delivery of the infant. During this stage, the fetal head enters the birth canal. The mother's contractions become more intense and frequent (usually 2 to 3 minutes apart). Often the mother becomes diaphoretic and tachycardic during this stage. She experiences an urge to bear down with each contraction. In addition, she may express the need to have a bowel movement. This is a normal sensation caused by pressure of the fetal head against the mother's rectum. During this stage a **mucous plug** (sometimes mixed with blood, thus the name *bloody show*) is expelled from the dilating cervix and discharged from the vagina. (The mother may not notice passage of the plug.) The presenting part of the fetus (usually the head) emerges from the vaginal opening. This process, known as **crowning,** indicates that delivery is imminent. The second stage of labor usually lasts 1 to 2 hours in the nullipara mother. It usually lasts 30 minutes or less in the multipara mother (Box 46-9).

BOX 46-9 Cardinal Movements: Positional Changes During Birth

Infants must make several positional changes (*cardinal movements*) during the birth process. These movements are deliberate and precise changes made by the infant so that passage through the bony pelvis can occur. These positional changes are descent, flexion, internal rotation, extension, external rotation, and expulsion.

Descent is the movement of the baby's head into the pelvic cavity. Babies enter the birth canal with their head in the transverse position, with the occiput either to the right or to the left. *Flexion* occurs during descent as the head encounters resistance. This causes the baby's head to flex so that the chin meets the chest. As the head reaches the pelvic floor, it rotates to an anterior-posterior position *(internal rotation)* to accommodate for the smallest diameter of the birth canal between the ischial spines. *Extension* occurs as the fetus stops flexion of the head when the baby's head, face, and chin are born. Following extension, the baby must rotate *(external rotation)* from an anterior-posterior position to a transverse position (facing one of the mother's thighs). This movement (also known as *restitution*) allows for the shoulders to pass under the mother's pubic arch. After external rotation, the shoulders are born. This is followed by full delivery of the newborn *(expulsion)*.

THIRD STAGE OF LABOR

The **third stage of labor** begins with delivery of the infant and ends when the placenta is expelled and the uterus has contracted (described later in this chapter). The length of this stage varies from 5 to 60 minutes, regardless of parity.

Signs and Symptoms of Imminent Delivery

The following signs and symptoms indicate that delivery is imminent. With these, the paramedic should prepare for childbirth at the scene:

- Regular contractions lasting 45 to 60 seconds at 1- to 2-minute intervals. Intervals are measured from the beginning of one contraction to the beginning of the next. If contractions are more than 5 minutes apart, there generally is time to transport the mother to a receiving hospital.
- The mother has an urge to bear down or has a sensation of a bowel movement.
- There is a large amount of bloody show.
- Crowning occurs.
- The mother believes that delivery is imminent.

If any of these signs and symptoms are present, the EMS crew should prepare for delivery. With the exception of cord presentation (described later in this chapter), the paramedic should not try to delay delivery. If complications are anticipated or an abnormal delivery occurs, medical direction may recommend expedited transport of the patient to a medical facility.

Preparation for Delivery

When preparing for delivery, the paramedic should try to provide an area of privacy. The mother should be positioned on a bed, stretcher, or table. The surface should be long enough to project beyond the mother's vagina. The delivery area should be as clean as possible. It should be covered with absorbent material to guard against staining and contamination by blood and fecal material.

The mother should be placed on her back. Her knees should be flexed and widely separated (or in another position preferred by the mother). The vaginal area should be draped appropriately. If delivery occurs in a car, the mother should be instructed to lie on her back across the seat with one leg flexed on the seat and the other leg resting on the floorboard. A pillow or blanket, if available, should be placed beneath the mother's buttocks. This will aid in the delivery of the infant's head. The paramedic should evaluate the mother's vital signs for baseline measurements. The fetal heart rate may be monitored for signs of fetal distress. Per protocol and medical direction, the paramedic should consider maternal oxygen administration and IV access for fluid administration or postdelivery administration of ***oxytocin*** if needed.

The mother should be coached to bear down and push during contractions and to rest between contractions to conserve strength. If the mother finds it difficult to refrain from pushing, she should be encouraged to breathe deeply or "pant" through her mouth between contractions. Deep breathing and panting help decrease the force of bearing down and promote rest.

DELIVERY EQUIPMENT

Prehospital delivery equipment ("OB kit") generally includes the following components (Figure 46-11):

- Surgical scissors
- Cord clamps or umbilical tape
- Towels
- Surgical masks
- 4 × 4 inch gauze sponges
- Sanitary napkins
- Bulb syringe and DeLee suction kit
- Baby blanket and baby stocking cap
- Plastic bag for placental transportation
- Neonatal resuscitation equipment
- IV fluid supplies

Personal protective measures should be used when assisting in a delivery. Sterile technique should be used when handling equipment.

FIGURE 46-11 Prehospital delivery equipment.

Assistance With Delivery

In most cases the paramedic only assists in the natural events of childbirth. The chief duties of the EMS crew are to prevent an uncontrolled delivery and protect the infant from cold and stress after the birth. The following are steps to be taken in assisting the mother with a normal delivery (Figure 46-12):

1. Observe standard precautions.
2. When crowning occurs, apply gentle palm counterpressure to the infant's head to prevent an explosive delivery and tearing of the mother's perineum. If membranes are still intact, tear the sac with finger pressure to allow escape of amniotic fluid.
3. After delivery of the head, examine the infant's neck for a looped (*nuchal*) umbilical cord. If the cord is looped around the neck, gently slip it over the infant's head.
4. Suction the infant's mouth and nose with a bulb syringe to clear the airway. Perform suction after the head appears but before the next contraction. The next contractions deliver the shoulders and chest. The risk of aspiration is minimal.
5. Support the infant's head as it rotates for shoulder presentation. Most infants present face down. The infant usually rotates to the left or right so that the shoulders present in an anterior-posterior position.
6. If the shoulders do not spontaneously deliver with the next contraction, using gentle pressure, guide the infant's head downward to deliver the anterior shoulder and then upward to release the posterior shoulder. The rest of the infant is delivered quickly by smooth uterine contraction.
7. Be careful to grasp and support the infant as he or she emerges, using a dry towel or clean piece of clothing. Hold the infant with his or her head dependent to aid drainage of secretions. Place the infant on the mother's abdomen if she is able to hold her infant.
8. Clear the infant's airway of any secretions with sterile gauze. Suction the infant's nose and mouth if there is coarse gurgling.
9. Dry the infant with sterile towels, and cover the infant (especially the head) to reduce heat loss.
10. Record the infant's gender and time of birth.

FIGURE 46-12 Normal delivery. **A,** When crowning occurs, apply gentle palm pressure to the infant's head. **B,** Examine the neck for the presence of a looped umbilical cord. **C,** Support the infant's head as it rotates for shoulder presentation. **D,** Guide the infant's head downward to deliver the anterior shoulder. **E,** Guide the infant's head upward to release the posterior shoulder. (From Al-Azzawi F: *Color atlas of childbirth and obstetric techniques,* London, 1990, Wolfe.)

CRITICAL THINKING
How do you think you will feel after attending a birth of a healthy infant?

Evaluation of the Infant

After delivery, the infant should be positioned on the side or with padding under the back if needed. The paramedic should clear the airway and provide tactile stimulation to initiate respirations. If there is no need for resuscitation, the paramedic should assign an **Apgar score** at 1 minute and 5 minutes to evaluate the infant (Table 46-2). Criteria for computing the Apgar score include *appearance* (color), *pulse* (heart rate), *grimace* (reflex irritability to stimulation), *activity* (muscle tone), and *respiratory effort*. Each criterion is rated from 0 to 2. The numbers are added for a total Apgar score.

NOTE
Newly born infants who do not require resuscitation can generally be defined by a rapid assessment of the following four characteristics:

- Was the baby born after a full-term gestation?
- Is the amniotic fluid clear of meconium and evidence of infection?
- Is the baby breathing or crying?
- Does the baby have good muscle tone?

If the answer to all four of these questions is "yes," the baby does not need resuscitation and should not be separated from the mother. If the answer to any of these questions is "no," the infant should be resuscitated (see Chapter 47).

An Apgar score of 10 indicates that the infant is in the best possible condition, 7 to 9 indicates that the infant is slightly depressed (near normal), 4 to 6 indicates that the infant is moderately depressed, and 0 to 3 indicates that the infant is severely depressed. Most newborns have an Apgar score of 8 to 10 at 1 minute after birth. Newborns with an Apgar score of less than 6 generally require resuscitation; however, *the paramedic should not solely use the Apgar score to determine the need for resuscitation.*[18] (Neonatal resuscitation is presented in Chapter 47.)

TABLE 46-2 The Apgar Scoring System

SIGN	0	1	2
*A*ppearance (skin color)	Blue, pale	Body pink, blue extremities	Completely pink
*P*ulse rate (heart rate)	Absent	<100 beats/min	>100 beats/min
Grimace (irritability)	No response	Grimace	Cough, sneeze, cry
*A*ctivity (muscle tone)	Limp	Some flexion	Active motion

CUTTING THE UMBILICAL CORD

After the paramedic delivers and evaluates the infant and the cord has stopped pulsing, the umbilical cord should be clamped (or tied with umbilical tape) and cut (Figure 46-13). Clamping or cutting the cord may be delayed for at least 1 minute in term and preterm infants not requiring resuscitatioin.[18] The paramedic should take the following steps to manage the umbilical cord:

1. Clamp the cord about 4 to 6 inches away from the infant in two places.
2. Cut between the two clamps with sterile scissors or a scalpel.
3. Examine the cut ends of the cord to ensure that there is no bleeding. If the cut end attached to the infant is bleeding, clamp the cord proximal to the previous clamp and reassess for bleeding. Do not remove the first clamp.
4. Handle the cord carefully at all times because it can tear easily.

Delivery of the Placenta

If the baby and mother are in good condition and if the mother is agreeable, place the baby at her breasts to encourage suckling. This will stimulate the release of oxytocin that will lead to decreased blood loss. The placenta normally is delivered within 20 minutes of the infant. Thus transport should not be delayed for placental delivery. Placental delivery is characterized by episodes of contractions, a palpable rise of the uterus within the abdomen, lengthening of the umbilical cord protruding from the vagina, and a sudden gush of vaginal blood.

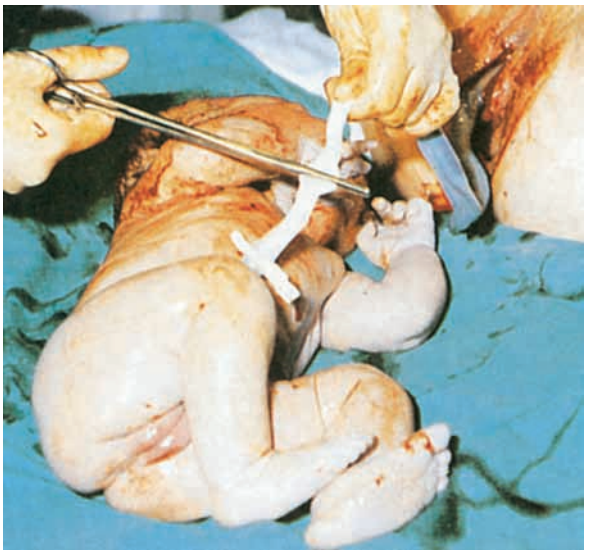

FIGURE 46-13 After delivery and evaluation of the infant, the paramedic clamps and cuts the cord. (From Al-Azzawi F: *Color atlas of childbirth and obstetric techniques,* London, 1990, Wolfe.)

After birth of the infant and clamping of the cord, the mother should be told to bear down with contractions. The paramedic should place one hand lightly on the mother's abdomen and the other hand should apply steady traction to the cord. This is not a pulling motion. Traction is used to keep the cord taut until there is a gush of vaginal blood or lengthening of the cord.

NOTE

The hand that is placed on the mother's abdomen *may* feel the rise of the uterus with cord lengthening or the gush of vaginal blood. This can indicate that the placenta is ready to deliver or only partly separated from the uterine wall. At this time, the paramedic should gently increase traction on the cord and ask the mother to bear down with the next contraction. As she pushes, gently pull down and out on the cord. If there is no immediate progress (further lengthening of the cord), stop pulling and reinstate steady cord traction and wait for spontaneous cord lengthening to occur. Again, placental delivery should not delay patient transport.

When the placenta is expelled, it should be placed in a plastic bag or other container and transported with the mother and infant to the receiving hospital. At the hospital the placenta will be examined for abnormality and completeness. Pieces of placenta retained in the uterus can cause persistent hemorrhage and infection. After the delivery of the placenta, the paramedic should assess the mother's perineum for tears. If tears are present, the bleeding should be managed by applying sanitary napkins to the area and maintaining direct pressure. The paramedic should initiate fundal massage (described later) to promote uterine contraction, and monitor the mother during transport for signs of hemorrhage or shock. Medical direction also may prescribe oxytocin to manage postpartum bleeding, if needed.

SHOW ME THE EVIDENCE

These authors attempted to distinguish characteristics of planned versus unplanned home births. They reviewed data from 11,787 home births from 19 states that occurred in 2006. Of these home births, 9810 (83.2%) were planned. Of the unplanned birth group, 26% reported no prenatal care. Women who had an unplanned delivery at home were more likely to be non-white, to smoke, to have no prenatal care, and to be younger than those who planned home delivery. Prematurity was present in 3% of planned versus 26% of unplanned home births. A significant limitation of the study was that the authors could not identify cases that were planned for home delivery but were instead taken to the hospital. They conclude that although there are only about 4000 unplanned home births in the United States each year, this group is high-risk and effort should be made to identify their characteristics during prenatal care.

From Declercq E, MacDorman MF, Menacker F, et al: Characteristics of planned and unplanned home births in 19 states, *Obstet Gynecol* 116(1):93-99, 2010.

Postpartum Hemorrhage

Postpartum hemorrhage is characterized by more than 500 mL of blood loss after the delivery of the newborn. (The actual volume of blood loss is difficult to estimate with accuracy.) Hemorrhage often occurs within the first few hours after delivery. Yet it can be delayed up to 24 hours. Postpartum hemorrhage occurs in about 5% of all deliveries and accounts for up to 25% of obstetrical deaths.[5] Hemorrhage often results from ineffective or incomplete contraction of the interlacing uterine muscle fibers. Other causes of postpartum hemorrhage include retained pieces of placenta or membranes in the uterus. Hemorrhage can also be caused by vaginal or cervical tears during delivery. Risk factors associated with postpartum hemorrhage include **uterine atony** (lack of uterine tone) from prolonged or tumultuous labor, grand multiparity, twin pregnancy, placenta previa, and a full bladder.

NOTE

Lochia is postpartum vaginal discharge that contains blood, mucus, and placental tissue from the lining of the uterus. This discharge is normal, and typically continues for about 2 to 4 weeks after childbirth. Lochia is similar to menstrual bleeding, but initially heavier, and then diminishes. The discharge usually begins as bright red, and will later become pink or yellow-white in color.

MANAGEMENT

Postpartum hemorrhage can occur in the prehospital setting after a field delivery, home delivery, or delivery at an independent birthing center. The assessment and management are similar to those described for third-trimester bleeding. In addition, the paramedic should take the following measures to encourage uterine contraction:

1. *Massage the uterus.* Palpate the uterus for firmness or loss of tone. If the uterus does not feel firm, apply fundal pressure by supporting the lower uterine segment with the edge of one hand just above the symphysis and massaging the fundus with the other hand. Continue massaging until the uterus feels firm. Reevaluate the patient every 10 minutes; note the location of the fundus in relation to the level of the umbilicus, the degree of firmness, and vaginal flow.
2. *Encourage the infant to breastfeed.* If the mother and infant are stable and the mother is agreeable, place the newborn to her breast to encourage breastfeeding. Stimulation of the breasts may promote uterine contraction.
3. *Administer oxytocin.* Per medical direction and after ensuring that a second fetus is not present in the uterus, add 10 units of ***oxytocin*** to 1000 mL of lactated Ringer's solution. Infuse at 20 to 30 drops/min via microdrip tubing (titrated to the severity of hemorrhage and uterine response or as ordered by medical direction). Continue

with fluid resuscitation as indicated by the patient's vital signs.

NOTE
The paramedic should manage external bleeding from a perineal tear with direct pressure. There should be no attempts at vaginal examination or vaginal packing to control hemorrhage. These patients should be rapidly transported for physician evaluation.

DELIVERY COMPLICATIONS

As stated previously, most women have uncomplicated pregnancies. Prehospital deliveries seldom present any significant problems for the mother, newborn, or paramedic crew. The delivery complications discussed in this chapter include cephalopelvic disproportion, abnormal presentation, premature birth, multiple gestation, precipitous delivery, uterine inversion, pulmonary embolism, and fetal membrane disorders. Box 46-10 lists factors that should alert the paramedic to anticipate an abnormal delivery.

BOX 46-10 Factors Associated With High-Risk Delivery

Maternal Factors

- Maternal age: very young or very old
- Absence of prenatal care
- Maternal lifestyle: alcohol, tobacco, or drug usage
- Preexisting maternal illness, including diabetes, chronic hypertension, or Rh sensitization
- Previous obstetrical history of the following:
  - Premature delivery
  - Previous malformed neonate
  - Previous multiple births
  - Previous cesarean delivery
- Intrapartum disorders
  - Preeclampsia
  - Prolonged rupture of membranes
  - Prolonged labor
  - Abnormal presentation
  - Abruptio placentae
  - Placenta previa

Fetal Factors

- Lack of fetal well-being
  - History of decreased fetal movement
  - Hydramnios (excess amniotic fluid)
  - History of heart rate abnormalities
  - Evidence of fetal distress
- Fetal immaturity: prematurity as established by dates, ultrasound, uterine size, amniocentesis
- Fetal growth: history of poor intrauterine growth or postdate delivery; fetal macrosomia (birth weight more than 4000 g [8 lb])
- Specific fetal malformation detected by ultrasound: diaphragmatic hernia or omphalocele

Cephalopelvic Disproportion

Cephalopelvic disproportion is a condition in which the newborn's head is too large or the mother's birth canal is too small to allow normal labor or birth. The mother often is primigravida and having strong, frequent contractions for a prolonged period. Prehospital care is limited to maternal oxygen administration, IV access for fluid resuscitation if needed, and rapid transport to the receiving hospital.

Abnormal Presentation

Most infants are born head first (cephalic or vertex presentation). But sometimes a presentation is abnormal. These include a breech presentation, shoulder dystocia, shoulder presentation, and a cord presentation **(prolapsed umbilical cord).**

BREECH PRESENTATION

In a **breech presentation** the largest part of the fetus (the head) is delivered last. Breech presentation occurs in 3% to 4% of deliveries at term.[5] Breech presentation is more frequent with multiple births and when labor occurs before 32 weeks' gestation. Categories of breech presentation include the following (Figure 46-14)[5]:

- *Frank breech.* The fetal hips are flexed and the legs extend in front of the fetus. The buttocks are the presenting part. Frank breech accounts for about 60% to 65% of breech presentations.
- *Complete breech.* The fetus has both knees and hips flexed. The buttocks are the presenting part. Complete breech accounts for about 5% of breech presentations.
- *Incomplete breech.* The fetus has one or both hips incompletely flexed. This results in presentation of one or both lower extremities (often a foot). Incomplete breech accounts for about 25% to 30% of breech presentations.

CRITICAL THINKING
What resources can you use to assist in a delivery with an abnormal presentation?

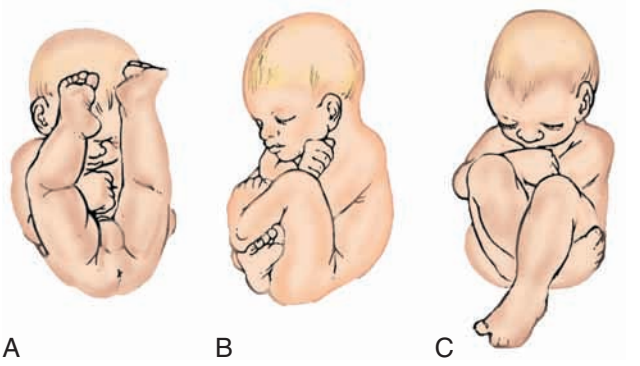

FIGURE 46-14 Types of breech presentation. **A,** Front or back. **B,** Complete. **C,** Incomplete.

Management. An infant in a breech presentation is best delivered in a hospital where emergency cesarean section is an alternative to vaginal delivery. Sometimes, however, the paramedic must assist in a breech delivery. If delivery is imminent, the EMS crew should proceed as follows:

1. Prepare the mother for delivery as described earlier in this chapter.
2. Provide supplemental oxygen and IV access; continuously monitor the fetal heart rate.
3. Allow the fetus to deliver spontaneously up to the level of the umbilicus. If the fetus is in a frank breach presentation, gently extract the legs downward after the buttocks are delivered.
4. After the infant's legs are clear, support his or her body with the palm of the hand and volar surface of the arm.
5. After the umbilicus is visible, gently extract a 4- to 6-inch loop of umbilical cord to allow delivery without excessive traction on the cord. Gently rotate the fetus to align the shoulders in an anterior-posterior position. Continue with gentle traction until the axilla is visible.
6. Gently guide the infant upward to deliver the posterior shoulder.
7. Gently guide the infant downward to deliver the anterior shoulder.
8. Be aware that the head often is delivered without difficulty after shoulder delivery. Be careful to avoid excessive head and spine manipulation or traction.

If the head does not deliver immediately, action must be taken to prevent suffocation of the infant. The paramedic should maintain the fetal head in a flexed position by placing the index and middle fingers on either side of the infant's nose (the *Mauriceau maneuver*).[19] The fetal body should be supported in a neutral position, using care not to overextend the baby's neck. During this maneuver a second rescuer should apply suprapubic pressure. If the head does not deliver quickly, poor fetal outcome is likely.[5] The mother should be transported rapidly to the hospital.

SHOULDER DYSTOCIA

Shoulder dystocia occurs when the fetal shoulders are wedged against the maternal symphysis pubis. This blocks shoulder delivery. In this presentation the head delivers normally but then pulls back tightly against the maternal perineum (the *turtle sign*). Shoulder dystocia is a common condition in pregnancy, occurring in 1 in 300 deliveries.[5] Complications include brachial plexus damage, fractured clavicle, and fetal anoxia from cord compression. Fifty percent of shoulder dystocia cases occur in women without risk factors.

Management. Shoulder dystocia delivery requires dislodging one shoulder and then rotating the fetal shoulder girdle at an angle into the wider part of the pelvic opening. Because the shoulder is pressing against the pelvis, there is a potential for cord compression. Thus the paramedic should deliver the anterior shoulder immediately after the head. Several maneuvers can help the paramedic successfully deliver an infant when shoulder dystocia arises. The following steps represent one approach to shoulder dystocia:

1. Position the mother on her left side in a dorsal-knee-chest position. This increases the diameter of the pelvis.
2. Try to guide the infant's head downward to allow the anterior shoulder to slip under the symphysis pubis. Avoid excessive force or manipulation.
3. Gently rotate the fetal shoulder girdle at an angle to the wider pelvic opening. The posterior shoulder usually delivers without resistance. Medical direction may recommend that the paramedic try to deliver the posterior shoulder first by rotating the posterior shoulder downward and into the left posterior quadrant. The anterior shoulder usually follows.
4. After delivery, continue with resuscitative measures as needed.

SHOULDER PRESENTATION

Shoulder presentation *(transverse presentation)* results when the long axis of the fetus lies perpendicular to that of the mother. This position usually results in the fetal shoulder lying over the pelvic opening. The fetal arm or hand may be the presenting part. This abnormal presentation occurs in only 0.3% of deliveries but occurs in 10% of second twins.[5]

Management. Normal delivery of a shoulder presentation is not possible. The paramedic should provide the mother with adequate oxygen, ventilatory, and circulatory support and then provide rapid transport to the hospital. A cesarean delivery is required regardless of the condition of the fetus.

CORD PRESENTATION

Cord presentation (prolapsed cord) occurs when the cord slips down into or out of the vagina after the amniotic membranes have ruptured. The umbilical cord is compressed against the presenting part of the fetus. This diminishes fetal oxygenation from the placenta. A prolapsed cord occurs in about 0.3% to 0.6% of all deliveries.[5] When fetal distress is present, the paramedic should suspect a prolapsed cord. Predisposing factors include breech presentation, premature rupture of membranes (described later), multiple gestation, a long cord, and preterm labor.

Management. Fetal asphyxia can ensue rapidly if circulation through the cord is not reestablished and maintained until delivery. If the paramedic can see or feel the umbilical cord in the vagina, the following steps should be taken:

1. With a gloved hand, gently push the infant back into the vagina. Elevate the presenting part to relieve pressure on the cord. The cord may retract spontaneously. However, the paramedic should not try to reposition the cord.
2. Maintain this hand position during rapid transport to the hospital. The definitive treatment is a cesarean delivery.
3. Position the mother with hips elevated as much as possible. The Trendelenburg or knee-chest position may relieve pressure on the cord.
4. Administer oxygen to the mother.

5. If help is available, apply moist sterile dressings to the exposed cord. This will minimize temperature changes that may cause umbilical artery spasm.
6. Instruct the mother to pant with each contraction to prevent bearing down.

OTHER ABNORMAL PRESENTATIONS

Other abnormal presentations include *face* or *brow (military) presentation* and *occiput posterior presentation*. In these presentations the infant's head is delivered face up instead of face down. Face-up presentations result in increased risks to the fetus because of difficult labor and delivery. Sometimes the fetus has other associated abnormalities. These presentations may require cesarean delivery. Thus early recognition of potential complications, maternal support and reassurance, and rapid transport for definitive care are the goals of prehospital management.

Premature Birth

A **premature infant** is an infant born before 37 weeks' gestation (Figure 46-15). Low birth weight (less than 2.5 kg [5.5 lb]) also determines prematurity, although the conditions are not synonymous. Premature deliveries occur in 8% to 10% of all pregnancies.[20] After a preterm labor the newborn is at increased risk for hypothermia because of a large body surface/body mass ratio and at increased risk for cardiorespiratory distress because of the prematurely developed cardiovascular system. Therefore these infants require special care and observation. After delivery, prehospital management for a premature infant includes the following:

- Keep the infant warm. Dry the infant, wrap the infant in a warm blanket, place the infant on the mother's abdomen, and cover the mother and infant. If transport time is delayed, very small (<1500 g) infants should be wrapped in food-grade heat-resistant plastic wrap and placed under radiant heat in addition to other warming methods.[21]
- Frequently suction secretions from the infant's mouth and nares.
- Carefully monitor the cut end of the umbilical cord for oozing. If bleeding is present, manage as described before.
- Administer humidified free-flow oxygen through a makeshift oxygen tent. Aim oxygen flow toward the top of the tent; do not allow it to flow directly into the infant's face.
- Protect the infant from contamination. Don a mask and gown and minimize family member and bystander contact with the infant.
- Gently transport the mother and infant to the receiving hospital.

One should note that *tocolytic agents* (drugs used to inhibit labor) are used widely today by some mothers who are at risk for a premature birth. These drugs may be administered in the home setting. They include magnesium sulfate, nicardipine, nifedipine, ritodrine, terbutaline, indomethacin, and others.[2] The paramedic should ask the patient about any recent medication use, including the use of tocolytic agents.

Multiple Gestation

A **multiple gestation** is a pregnancy with more than one fetus. Historically, twin births usually occurred in only 1% of all deliveries. Because of the increasing use of fertility treatments, about 30% of every 1000 live births are now multiple births[5] (Box 46-11). Multiple gestation places more stress on the maternal system and also is accompanied by an increased complication rate. Associated complications include premature labor and delivery (30% to 50% of twin deliveries are premature), premature rupture of membranes, abruptio placentae, postpartum hemorrhage, and abnormal presentation. A mother who has not received prenatal care may be unaware of her multiple pregnancy.

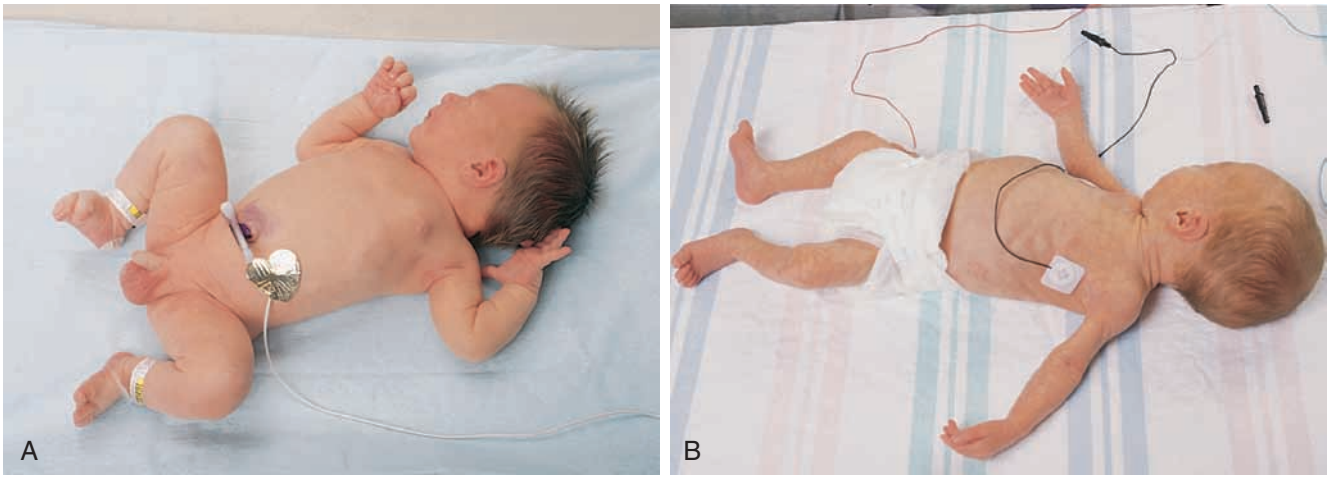

FIGURE 46-15 Posture in newborns. **A,** The healthy full-term infant remains in a strongly flexed position. **B,** The preterm infant's extremities are extended. (From Murray SS, McKinney ES: *Foundations of maternal newborn nursing,* ed 5, Philadelphia, 2010, Saunders.)

BOX 46-11 Twin Terminology

Fraternal twins result from the fertilization of two ova by two spermatozoa. Each fraternal twin has a separate placenta. Each also is separated by individual amniotic membranes. Fraternal twins are not identical in appearance. They are often of different gender.

Identical twins result from the fertilization of a single ovum. They may share a common placenta and amniotic sac or have separate placental structures. Identical twins are less common than fraternal twins. (They occur in one out of three twin conceptions.) Unlike fraternal twins, identical twins look alike, are of the same gender, and are genetically identical.

CRITICAL THINKING

Do you have enough supplies on your ambulance to manage more than one delivery?

DELIVERY PROCEDURE

First-twin delivery is identical to single delivery with the same presentation. However, up to 50% of second-twin deliveries are not in a normal presentation position. Fetuses are smaller in multiple births.

After the delivery of the first twin, the paramedic should cut and clamp (or tie) the umbilical cord as described earlier. Within 5 to 10 minutes after delivery of the first twin, labor begins again. The delivery of the second twin usually occurs within 30 to 45 minutes. Medical direction may recommend transport before the delivery of the second twin. Usually both twins are born before the delivery of the placenta.

Infants in multiple births often are smaller than infants in single term births. The paramedic should give special attention to keeping these infants warm, well oxygenated, and free from unnecessary contamination as described for premature infants. Postpartum hemorrhage may be more severe after multiple births. Hemorrhage may require fluid resuscitation, uterine massage, and ***oxytocin*** infusion to control bleeding.

Precipitous Delivery

A **precipitous delivery** is a rapid spontaneous delivery with less than 3 hours from onset of labor to birth. Precipitous delivery results from overactive uterine contractions and insignificant maternal soft tissue or bony resistance. A precipitous delivery most often occurs in a mother who is grand multipara. It can be associated with soft tissue injury and uterine rupture (rare). Precipitous delivery has an increased perinatal mortality rate because of trauma and hypoxia. The main danger to the fetus during this kind of delivery is from cerebral trauma or tearing of the umbilical cord.

If the paramedic expects a precipitous delivery, attempts should be made to prevent an explosive one. This can be done by providing gentle counterpressure to the infant's head; however, the paramedic should not attempt to detain fetal head descent. After delivery, the infant should be kept dry and warm to prevent heat loss. The mother should be examined for perineal tears that often accompany a rapid birth.

Uterine Inversion

Uterine inversion is an infrequent complication of childbirth where the uterus turns "inside out." The condition is thought to occur in about 1 in 2000 deliveries.[5] Uterine inversion is a serious condition. The resultant postpartum hemorrhage is associated with a maternal mortality rate of around 15%.

Uterine inversion may occur suddenly after a contraction or with increased abdominal pressure caused by coughing or sneezing. However, uterine inversion more often is caused by medical personnel or a medical procedure (**iatrogenic)** secondary to excessive pulling on the umbilical cord and fundal massage. The risk is elevated when the placenta has implanted high in the uterus. Uterine inversion is *incomplete* if the uterine fundus does not extend beyond the cervix; it is *complete* if the fundus does protrude through the cervix; and it is *prolapsed* if the entire uterus protrudes through the vaginal ring. Signs and symptoms of uterine inversion include postpartum hemorrhage and sudden and severe lower abdominal pain. The hemorrhage may be profuse. Hypovolemic shock may develop quickly.

MANAGEMENT

Prehospital care for a patient with uterine inversion includes airway, ventilatory, and circulatory support and rapid transportation for physician evaluation. Medical direction may recommend that the paramedic attempt manual replacement of the uterus only if the cervix has not yet constricted. The technique for manual replacement is as follows:

1. Place the patient in a supine position.
2. Do not attempt to remove the placenta, if it has not already been delivered. Doing so is likely to increase hemorrhage.
3. Apply pressure with the fingertips and palm of a gloved hand and push the fundus upward and through the cervical canal. If this is ineffective, cover all protruding tissues with moist sterile dressings and rapidly transport the patient.

Manual replacement of the uterus may be painful to the patient. Medical direction may indicate the use of analgesics. The paramedic should explain the need for the procedure to the patient.

Pulmonary Embolism

The development of pulmonary embolism during pregnancy, labor, or the postpartum period is a significant cause of maternal death.[22] The embolus often results from a blood clot in the pelvic circulation (venous thromboembolism). There is a slight increased risk of pulmonary embolus with cesarean versus vaginal delivery. The patient often has classic signs and symptoms. These include sudden dyspnea;

sharp, focal chest pains; tachycardia; tachypnea; and sometimes hypotension. If the embolism occurs in the prehospital setting, emergency care should be focused on airway, ventilatory, and circulatory support; electrocardiogram monitoring; and rapid transportation for physician evaluation (see Chapter 24).

NOTE

Thromboembolism is 2 times as likely to occur in pregnancy and 5.5 times as likely to occur during the postpartum period. Pregnancy causes changes in the coagulation and fibrinolytic systems that persist into the postpartum period. During pregnancy, the levels of many coagulation factors are elevated. In addition, the fibrinolytic system is suppressed. Together, this hinders clot disintegration (lysis). The result is that factors that promote clot formation are increased to prevent maternal hemorrhage and factors that prevent clot formation are decreased. This results in a higher risk for thrombus formation during pregnancy and the postpartum period.[2]

Fetal Membrane Disorders

The fetal membrane disorders discussed in this chapter include premature rupture of membranes and amniotic fluid embolism. Another fetal membrane disorder, meconium staining, is described in Chapter 47).

PREMATURE RUPTURE OF MEMBRANES

Premature rupture of the membranes is a rupture of the amniotic sac before the onset of labor. The condition is termed *premature* regardless of fetal age. Premature rupture occurs in about 3% of pregnancies. In 10% to 15% of all cases, the fetus is at or near term.[5] Signs and symptoms include a history of a trickle or sudden gush of fluid from the vagina. The paramedic should transport patients for physician evaluation. The medical facility will prepare for delivery if the patient begins labor. Delivery is required if an infection of fetal membranes is diagnosed **(chorioamnionitis).**

Chorioamnionitis is linked to premature rupture of membranes occurring 24 hours before labor begins. It also can occur with a prolonged labor, in part as a result of multiple vaginal exams. The infection generally is accompanied by maternal fever, chills, and uterine pain. Infection is treated with antibiotics. The definitive treatment for this infection is the delivery of the fetus.

AMNIOTIC FLUID EMBOLISM

When amniotic fluid enters the maternal circulation during labor or delivery or immediately after delivery, an **amniotic fluid embolism** can occur. Probable routes of entry include lacerations of the endocervical veins during cervical dilation, the lower uterine segment or placental site, and uterine veins at sites of uterine trauma. Particulate matter in the amniotic fluid (e.g., meconium, lanugo hairs, and fetal squamous cells) forms an embolus and obstructs the pulmonary vasculature. Amniotic fluid embolism is rare, occurring in 6 to 14.8 per 100,000 primigravid and multiparous deliveries, respectively.[5] The condition most often is seen in multiparous women late in the first stage of labor. Other conditions that can increase the incidence of this severe complication are placenta previa, abruptio placentae, and intrauterine fetal death. The maternal mortality rate is high.

The signs and symptoms of amniotic fluid embolism are the same as those described for pulmonary embolism. They may include cardiopulmonary arrest. These patients are managed with airway, ventilatory, and circulatory support; fluid resuscitation; and rapid transportation.

SUMMARY

- Cultural differences may influence a woman's response to pregnancy and childbirth. The paramedic should be sensitive to these cultural beliefs.
- Fertilization of an ovum by a sperm forms a zygote that divides as it passes through the fallopian tube to become a morula. The trophoblast cells of the morula implant within 7 days after fertilization and transform into the life support systems of the embryo. The blastocyst cells develop into the embryo.
- The placenta is a disklike organ. It is composed of interlocking fetal and maternal tissues. It is the organ of exchange between the mother and fetus. Blood flows from the fetus to the placenta through two umbilical arteries. These arteries carry deoxygenated blood. Oxygenated blood returns to the fetus through the umbilical vein. The amniotic sac is a fluid-filled bag. It completely surrounds and protects the embryo.
- The developing ovum is known as an embryo during the first 8 weeks of pregnancy. After that time and until birth it is called a fetus. Gestation (fetal development) usually averages 40 weeks from the time of fertilization to the delivery of the newborn.
- At birth, in the normal newborn the arteriovenous shunts present in the fetus close.
- Gravida is the total number of current and past pregnancies. Para refers to past pregnancies that resulted in a live birth.
- The pregnant woman undergoes many physiological changes that affect the genital tract, breasts, gastrointestinal system, cardiovascular system, respiratory system, and metabolism.
- The patient history should include obstetrical history; presence of pain; presence, quantity, and character of vaginal bleeding; presence of abnormal vaginal

discharge; presence of "bloody show"; current general health and prenatal care; allergies and medicines taken; and maternal urge to bear down.

- The goal in examining an obstetrical patient is to rapidly identify acute life-threatening conditions. A part of this involves recognizing imminent delivery. Then the paramedic must take the proper management steps. In addition to the routine physical examination, the paramedic should assess the abdomen, uterine size, and fetal heart sounds.
- If birth is not imminent, the paramedic should limit prehospital care for the healthy patient. It should be limited to basic treatment modalities. It should include transport for physician evaluation as well.
- Causes of fetal death from maternal trauma include death of the mother, separation of the placenta, maternal shock, uterine rupture, and fetal head injury.
- To treat a critically ill pregnant patient, administer high-concentration oxygen. Tilt the patient left lateral. Administer IV fluid if there are signs of shock. Aggressively resuscitate the mother in an attempt to save the baby. Cardiac arrest can occur from a number of causes. Rapid transport is indicated.
- Hyperemesis gravidarum presents with severe nausea, vomiting, weight loss, and electrolyte disturbance. Fluid therapy is indicated if there are signs of dehydration.
- Rh sensitization occurs if the mother has Rh-negative blood and the baby Rh-positive blood. It can cause anemia, jaundice, edema, enlarged liver or spleen, and hydrops fetalis.
- Gestational hypertension is onset of blood pressure greater than 140/90 mm Hg during pregnancy. It can indicate preeclampsia.
- Preeclampsia occurs after 20 weeks' gestation. The criteria for diagnosis include hypertension, protein in the urine, and excessive weight gain with edema. Eclampsia is characterized by the same signs and symptoms with the addition of seizures or coma.
- Gestational diabetes mellitus is diabetes caused by pregnancy.
- Infection during pregnancy can place the mother and fetus at risk. TORCH is an acronym for infections the mother can pass to the fetus that cause fetal death or complications.
- Vaginal bleeding during pregnancy can result from abortion (miscarriage), ectopic pregnancy, abruptio placentae, placenta previa, uterine rupture, or postpartum hemorrhage. Abortion is the termination of pregnancy from any cause before 20 weeks' gestation. Ectopic pregnancy occurs when a fertilized ovum implants anywhere other than the uterus. Abruptio placentae is partial or complete detachment of the placenta at more than 20 weeks' gestation. Placenta previa is placental implantation in the lower uterine segment partially or completely covering the cervical opening. Uterine rupture is a spontaneous or traumatic rupture of the uterine wall.
- The first stage of labor begins with the onset of regular contractions. It ends with complete dilation of the cervix. The second stage of labor is measured from full dilation of the cervix to delivery of the infant. The third stage of labor begins with delivery of the infant and ends when the placenta is expelled and the uterus has contracted.
- One of the primary responsibilities of the EMS crew is to prevent an uncontrolled delivery. The other is to protect the infant from cold and stress after birth.
- Criteria for computing the Apgar score include appearance (color), pulse (heart rate), grimace (reflex irritability), activity (muscle tone), and respiratory effort.
- More than 500 mL of blood loss after the delivery of the newborn is called a postpartum hemorrhage. It often results from ineffective or incomplete contraction of the uterus.
- Paramedics should be alert to factors that point to a possible abnormal delivery.
- Cephalopelvic disproportion produces a difficult labor because of the presence of a small pelvis, an oversized uterus, or fetal abnormalities. Most infants are born head first (cephalic or vertex presentation). However, sometimes a presentation is abnormal. In breech presentation, the largest part of the fetus (the head) is delivered last. Shoulder dystocia occurs when the fetal shoulders impact against the maternal symphysis pubis. This blocks shoulder delivery. Shoulder presentation (transverse presentation) results when the long axis of the fetus lies perpendicular to that of the mother. The fetal arm or hand may be the presenting part. Cord presentation occurs when the cord slips down into the vagina or presents externally.
- A premature infant is born before 37 weeks' gestation.
- A multiple gestation is a pregnancy with more than one fetus. It is accompanied by an increased complication rate.
- A precipitous delivery is a rapid spontaneous delivery with less than 3 hours from onset of labor to birth. The main danger to the fetus is from cerebral trauma or tearing of the umbilical cord.
- Uterine inversion is a rare complication of childbirth. It is a serious complication. With this condition, the uterus turns "inside out."
- The development of pulmonary embolism during pregnancy, labor, or the postpartum period is a significant cause of maternal death.
- Premature rupture of the membranes is a rupture of the amniotic sac before the onset of labor, regardless of gestational age.
- An amniotic fluid embolism may occur when amniotic fluid enters the maternal circulation during labor or delivery or immediately after delivery.

CHAPTER

47 Neonatal Care

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Identify risk factors associated with the need for neonatal resuscitation.
2. Describe physiological adaptations at birth.
3. Describe the pathophysiology and implications of selected genetic anomalies present in some neonates.
4. Outline the prehospital assessment and management of the neonate.
5. Describe resuscitation of the distressed neonate.
6. Discuss postresuscitative management and transport.
7. Describe signs and symptoms and prehospital management of specific neonatal resuscitation situations.
8. Identify injuries associated with birth.
9. Describe appropriate interventions to manage the emotional needs of the neonate's family.

KEY TERMS

antepartum The period before labor and delivery.

apnea An absence of spontaneous respirations.

atrial septal defect A congenital anomaly in which an opening exists between the heart's two upper chambers.

central cyanosis Cyanosis of the tongue and mucous membranes; usually reflects decreased saturation of the hemoglobin in arterial blood.

choanal atresia A bony or membranous occlusion that blocks the passageway between the nose and pharynx; it can result in serious ventilation problems in the neonate.

cleft lip An incomplete closure of the infant's lip that occurs when one or more fissures fail to fuse in the embryo.

cleft palate An incomplete closure in the hard palate of the roof of the mouth that runs along its midline; occurs when one or more fissures fail to fuse in the embryo.

coarctation of the aorta A congenital defect in which there is narrowing or constriction of the aorta.

cold stress A condition that occurs when the body is unable to warm itself.

congenital anomalies Defects that occur during fetal development.

diaphragmatic hernia A herniation in the diaphragm caused by the improper fusion of structures during fetal development.

Dubowitz score A scoring method of clinical assessment in the newborn from birth until 5 days old. The score includes 10 neurological signs for the infant's maturity and 12 physical signs (external signs of development) to determine apparent gestational age.

esophageal atresia The incomplete formation of the esophagus.

hypoplastic left heart syndrome A condition in which the heart's left side, including the aorta, aortic valve, left ventricle, and mitral valve, is underdeveloped.

intestinal malrotation A congenital defect caused by abnormal rotation of the intestine around the superior mesenteric artery during embryological development.

intrapartum The period during labor and delivery.

meconium staining The inhalation of meconium by the fetus or newborn; this can block air passages and result in failure of the lungs to expand or cause other pulmonary dysfunction.

neonate An infant in the first 28 days of life.

newborn An infant in the first few hours of life.

omphalocele A type of hernia in which the infant's intestines or other abdominal organs protrude through the umbilicus; results during fetal development when the muscles in the abdominal wall do not close properly.

peripheral cyanosis Cyanosis that is confined to the extremities (common in the first few minutes of life); also known as *acrocyanosis*.

Pierre Robin syndrome A complex of congenital anomalies including a small mandible, a tongue that falls back into the airway, and a cleft palate.

preterm infant An infant born before 37 weeks' gestation.

pulmonary atresia A congenital anomaly in which no pulmonary valve exists; blood cannot flow from the right ventricle into the pulmonary artery and on to the lungs.

pulmonary hypoplasia A congenital malformation characterized by incomplete development of lung tissue.

pyloric stenosis A congenital defect in which there is narrowing of the pylorus (the opening from the stomach

into the small intestine). It is the most common cause of intestinal obstruction in infancy.

single-ventricle defects Complex defects that occur in the embryonic stage and result when one of the ventricles is underdeveloped.

tetralogy of Fallot A congenital cardiac anomaly that consists of four defects: pulmonic stenosis, ventricular septal defect, malposition of the aorta so that it rises from the septal defect or the right ventricle, and right ventricular hypertrophy.

total anomalous pulmonary venous return A congenital heart defect in which the four pulmonary veins that transport oxygen-rich blood back to the heart from the lungs are not properly attached to the left atrium.

tracheoesophageal fistula An abnormal connection between the esophagus and trachea that results from a failed fusion of the tracheoesophageal ridges during fetal development.

transposition of the great arteries A congenital defect in which the positions of the great arteries are reversed; the aorta arises from the right ventricle and the pulmonary artery from the left ventricle.

tricuspid atresia A congenital defect in which there is absence or abnormal development of a tricuspid valve.

truncus arteriosus A rare type of congenital heart disease characterized by a large ventricular septal defect over which a large, single great vessel (truncus) arises.

ventricular septal defect A congenital anomaly in which an opening exists between the heart's two lower chambers.

About 10% of newborns require some assistance to begin breathing at birth, and about 1% require extensive resuscitation.[1] This chapter addresses risk factors that may lead to the need for resuscitation in newborns. It also describes initial care that may be required for the newborn and neonate.

RISK FACTORS ASSOCIATED WITH THE NEED FOR RESUSCITATION

The vast majority of term newborns require no resuscitation beyond maintenance of temperature, and mild stimulation.[2] The incidence of complications, however, increases as birth weight decreases. In fact, resuscitation is required for about 80% of the 30,000 babies who weigh less than 1500 g (3½ lb) at birth.[3]

NOTE
The term **newborn** refers to a recently born infant in the first few hours of life. The term **neonate** refers to a newly born infant in the first 28 days of life.

The average term newborn weighs about 3600 g (7.5 lb). The baby's birth weight depends on a number of factors, including the size and racial origin of the parents. For example, small parents tend to have small babies. Also, Asian babies tend to be smaller than Caucasian babies. Newborn boys usually weigh about 8 oz more than do baby girls. Causes of low birth weight include premature birth, undernourishment in the uterus, and certain maternal factors. These factors include, for example, preeclampsia and cigarette smoking during pregnancy.

In addition to low birth weight, various **antepartum** (before labor and delivery) and **intrapartum** (during labor and delivery) risk factors may affect the need for resuscitation. (See Chapter 46 for review of the obstetrical history.) These include the following[4]:

- Antepartum
  - Multiple gestation
  - Inadequate prenatal care
  - Mother's age (less than age 16 or older than age 35)
  - History of perinatal morbidity or mortality
  - Postterm gestation
  - Drugs/medications
  - Toxemia, hypertension, diabetes
  - Perinatal infections
  - Known fetal malformations
- Intrapartum
  - Premature labor
  - Meconium-stained amniotic fluid
  - Rupture of membranes greater than 18 hours before delivery
  - Use of narcotics within 4 hours of delivery
  - Abnormal presentation
  - Prolonged labor or precipitous delivery
  - Prolapsed cord
  - Bleeding (abruptio placentae)

BOX 47-1 Neonatal Resuscitation Equipment and Drugs

In addition to a standard obstetrics kit, neonatal resuscitation equipment should include the following:

- Endotracheal tube stylets for full-term infants
- Endotracheal tubes (2.5, 3.0, 3.5, 4.0)
- Meconium aspirator attachment
- Laryngoscope blades (straight, 0, and 1)
- Laryngoscope handles
- Face masks (premature, newborn, and infant sizes)
- Orogastric/nasogastric tubes
- Multiple blankets
- Medications and fluids
  - Dextrose 10%
  - Epinephrine 1:10,000
  - Naloxone
  - Sodium bicarbonate (0.5 mEq/mL; 4.2% solution)
  - Volume expanders (normal saline, lactated Ringer's solution)
- Self-inflating bag (450 to 750 mL)
- Umbilical vessel catheterization equipment
- Suction catheters (5, 8, and 10 French)
- Syringes (1, 3, 10, and 20 mL)
- Three-way stopcocks

When any of the foregoing risk factors are present during delivery, the paramedic should prepare equipment and drugs that may be needed for neonatal resuscitation (Box 47-1). Medical direction also should be advised of the situation so the appropriate destination hospital can be determined.

CRITICAL THINKING
Does your ambulance have the right size equipment for resuscitation of the newborn?

CONGENITAL ANOMALIES

Congenital anomalies are defects that occur during fetal development. (They develop usually within the first trimester.) They are present in about 2% of all births. These defects are responsible for 20% of all infant deaths.[5] Thus the presence of congenital anomalies may be a factor in the need for neonatal resuscitation. Congenital anomalies may be heritable, caused by maternal infection, alcohol or other drug use during pregnancy (*teratogens*), and other factors.[4] Congenital defects presented in this chapter include anomalies of the airway, heart, and the abdomen and lower back. Spina bifida was described in Chapter 25.

NOTE
Prehospital care for infants born with congenital anomalies requires early assessment to control and protect the airway, positioning to improve respirations, suction to clear the airway, oxygen administration, and careful monitoring with pulse oximetry to ensure adequate ventilation. Advanced airway equipment should be kept close at hand.

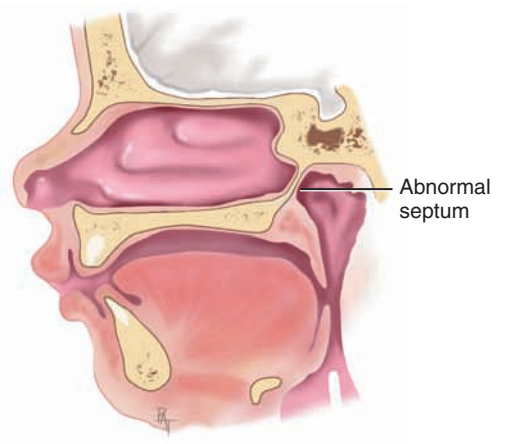

FIGURE 47-1 Choanal atresia. (From Jarvis C: *Physical examination and health assessment,* ed 6, Philadelphia, 2012, Saunders.)

Anomalies of the Airway

CHOANAL ATRESIA

Choanal atresia is a bony or membranous occlusion that blocks the passageway between the nose and pharynx (Figure 47-1). The defect is thought to occur during fetal development when the thin tissue that separates the nose and mouth remains after birth. Choanal atresia is the most common nose abnormality in newborn infants, affecting about 1 in 7000 live births.[5] It commonly is associated with other congenital anomalies.

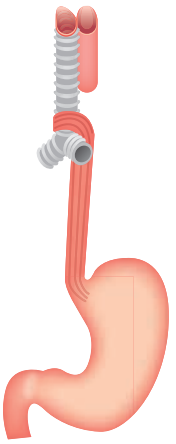
NOTE
Newborns generally breathe through their nose unless they are crying. Therefore, babies born with choanal atresia have difficulty breathing unless they are crying. Resuscitation, including tracheal intubation, may be required.

Choanal atresia may affect one or both sides of the nasal cavity and may require surgical repair. Bilateral obstruction can result in serious ventilation problems. Depending on the degree of obstruction, symptoms may include:

- Chest wall retraction (unless the infant is breathing through the mouth or crying)
- Dyspnea, which may result in cyanosis (unless infant is crying)
- Inability to nurse and breathe at same time
- Persistent one-sided nasal blockage or discharge

TRACHEOESOPHAGEAL FISTULA

Tracheoesophageal fistula is a congenital disorder that occurs in about 1 in every 4000 live births.[5] It is an abnormal connection between the esophagus and trachea that results from a failed fusion of the tracheoesophageal ridges during fetal development. It commonly occurs along with **esophageal atresia** (the incomplete formation of the esophagus) (Figure 47-2). If not surgically corrected, both conditions can allow for food and fluid in the esophagus



Esophageal Atresia with Distal TEF

Incidence: 85%–88%
Clinical Manifestations: Feeding causes regurgitation and coughing. Constant flow of saliva. Gastric distention.
Diagnostic Findings: Contrast reveals blind pouch. Air on abdominal x ray.
Surgical Treatment: One-stage surgical repair to ligate fistula and anastomose esophagus.

FIGURE 47-2 Esophageal atresia. (Modified from McKinney ES et al: *Maternal-child nursing,* ed 3, St Louis, 2009, Saunders.)

to enter the trachea and lungs. The defect can also allow for air in the trachea to enter the esophagus. Signs and symptoms of both disorders in the newborn include:

- Copious salivation
- Choking
- Coughing
- Regurgitation during feeding
- Cyanosis

Many infants born with tracheoesophageal fistula or esophageal atresia have other congenital anomalies, including heart, kidney, and limb deformities (often occurring together). These infants are unable to feed properly. Once diagnosed, early surgery is required.

CLEFT LIP AND CLEFT PALATE

A **cleft lip** is incomplete closure of the infant's lip. It occurs when one or more fissures fail to fuse in the embryo. It is visible at birth as a vertical, usually off-center split in the upper lip that may extend to the nose (Figure 47-3). A **cleft palate** is a fissure in the hard palate of the roof of the mouth that runs along its midline. Both conditions can occur with other congenital anomalies. A cleft palate may involve one or both sides of the roof of the mouth and can extend through the hard and soft palates into the nasal cavity. A cleft lip or cleft palate can cause nasal deformity and difficulty in feeding and speech, and is associated with frequent ear infections. The condition affects 1 in every 2500 live births.[5] A cleft lip or cleft palate can lead to failure to thrive, misaligned teeth, and difficulties with speech. The defect is corrected with one or more surgeries, usually beginning in the first year of life.

FIGURE 47-3 Cleft lip. (From Lissauer T, Clayden G: *Illustrated textbook of paediatrics,* ed 2, St Louis, 2001, Mosby.)

FIGURE 47-4 Pierre Robin syndrome. (From Lissauer T, Clayden G: *Illustrated textbook of paediatrics,* ed 2, St Louis, 2001, Mosby.)

PIERRE ROBIN SYNDROME

Pierre Robin syndrome is a complex of congenital anomalies including a small mandible, a tongue that falls back into the airway, and a cleft palate. Additional craniofacial abnormalities and defects of the eyes and ears may be present with this syndrome (Figure 47-4). Symptoms of the disorder include a high-arched palate, a receding chin, a tongue that appears large for the jaw, and teeth that are present at birth (*natal teeth*). Pierre Robin syndrome occurs in 1 in every 2000 live births.[5]

Complications associated with Pierre Robin syndrome include breathing difficulties, poor feeding early in life, cerebral hypoperfusion, pulmonary hypertension, and congestive heart failure. Death can result from respiratory failure, secondary to airway obstruction. The condition is managed with surgical repair of the cleft palate and other methods to prevent breathing difficulties and episodes of

choking. Most children have some relief from the effects of the syndrome as the jaw grows and allows more space for the tongue.

NOTE
As a rule, oral airways are rarely indicated for airway control in neonates. However, in infants born with birth defects that affect the airway, an oral airway should be inserted. Examples include newborns with bilateral choanal atresia, Pierre Robin syndrome, and unusual enlargement of the tongue (*macroglossia*). Infants born with these and other craniofacial defects are prone to airway obstruction and choking. They should not be placed supine.

Anomalies of the Heart

Congenital heart abnormalities refer to defects in the heart's structure. These defects occur during embryonic development and are present at birth (Box 47-2). Congenital heart defects are the most common type of birth defect. They affect 8 of every 1000 newborns, 50% of which produce hemodynamic effects from altered cardiac function. Each year, more than 35,000 babies in the United States are born with congenital heart defects. About 1 million American adults live with a congenital heart abnormality.[6]

Causes of congenital heart defects are often unknown. Heredity may play a role in some heart defects. For example, a parent who has a congenital heart defect may be more likely than other people to have a child with the condition. In rare cases, more than one child in a family is born with a heart defect. Children who have genetic disorders, such as Down syndrome, often have congenital heart defects. (Half of all babies who have Down syndrome have congenital heart defects.) Smoking during pregnancy also has been linked to several congenital heart defects, including septal defects.[6] Other possible causes of congenital heart defects include[4]:

BOX 47-2 Congenital Heart Diseases

Congenital heart disease can be an underlying cause of congestive heart failure. These include:

Cyanotic Disease
Hypoplastic left heart syndrome (HLHS)
Tricuspid atresia
Transposition of the great arteries (TGA)
Tetralogy of Fallot (ToF)
Total anomalous pulmonary venous return (TAPVR)
Truncus arteriosus

Noncyanotic Disease
Coarctation of the aorta (CoA)
Atrial septal defect (ASD)
Ventricular septal defect (VSD)
Patent ductus arteriosus (PDA)

- Maternal rubella
- Maternal ingestion of alcohol
- Maternal ingestion of drugs or certain medications

Congenital heart defects can involve the interior walls of the heart, the heart valves, or the arteries and veins that carry blood to the heart and other body tissues. These defects can range from "simple defects" with no signs or symptoms to "complex defects" that are life threatening. There are many types of congenital heart defects. Specific diseases discussed in this section include left-to-right shunt abnormalities, valvular defects, single-ventricle defects, transposition, and congenital dysrhythmias. Prehospital care for these patients may be limited to providing only comfort measures and transport to an appropriate medical facility. In some cases, complete support of vital functions will be needed. Infants who are born with congenital heart defects often require surgery within the first week of life. Additional surgeries may also be needed through adulthood. Medication therapy and long-term physician care are required.

NOTE
Signs and symptoms of congenital heart defects depend on the number, type, and severity of the defects. In infants, signs and symptoms may include tachypnea, cyanosis, poor circulation, and fatigue (e.g., tiring easily when feeding). Older children who have congenital heart defects may tire easily or be short of breath during physical activity. In severe cases (and in adults) signs and symptoms of heart failure may develop. Congenital heart defects do not cause chest pain. A heart murmur may or may not be present and is not diagnostic. (Many healthy children have heart murmurs.)

LEFT-TO-RIGHT SHUNT

The most common physiology seen in patients with congenital heart disease involves a **left-to-right shunt.** The physiological effect of a left-to-right shunt is that oxygenated blood is shunted from the left (systemic) side to the right (pulmonary) side to be oxygenated again, creating a redundant circulation. This leads to an increased venous return from the lungs, via the pulmonary veins, to the left atrium and the left ventricle. The associated volume overload on the left ventricle and the pulmonary circulation decreases cardiac output. Left-to-right shunts are classified according to their hemodynamic effects.

Coarctation of the Aorta. Coarctation of the aorta (CoA) is a narrowing or constriction of the aorta. The defect usually occurs in a short segment of the aorta known as the *juxtaductal part*. The location of this segment is just beyond where the arteries branch to the head and arms, close to where the ductus arteriosus attaches. (The ductus arteriosus is a blood vessel that is normally present in a fetus and that normally closes or contracts in the first hours of life [Figure 47-5].) Coarctation may be caused by the presence of extra ductal tissue that extends into the adjacent aorta, which results in aortic narrowing as the ductal tissue

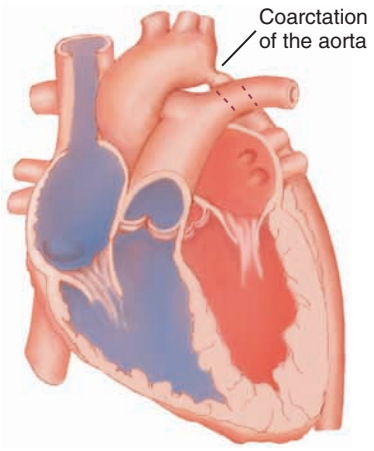


FIGURE 47-5 Coarctation of the aorta. (From McKinney ES, et al: *Maternal-child nursing,* ed 3, St Louis, 2009, Saunders.)

contracts. Coarctation may also occur along with other cardiac defects, typically involving the left side of the heart (e.g., left septal defect). In the presence of a coarctation, the left ventricle has to work harder, because it must generate a higher pressure than normal to force blood through the narrow segment of the aorta to the lower part of the body.

CoA is common in children with some chromosomal abnormalities, such as Turner's syndrome. Coarctation usually presents in the first month of life. It is suspected when the physician is unable to feel (or feels weak) pulses in the groin or the legs of an infant or when the lower body is cyanotic. (A murmur may also be present.) Patients with CoA are at increased risk for hypertension, ruptured aorta, aortic aneurysm, and stroke. Care is aimed at improving ventricular function and improving circulation to the lower extremities with various drugs. Surgical repair is sometimes needed.

Septal Defects. Septal defects (a "hole in the heart") may involve the atrium or ventricle. With **atrial septal defect** (ASD) an opening exists between the heart's two upper chambers. This lets some blood from the left atrium return via the hole to the right atrium instead of flowing through the left ventricle, out the aorta and to the body. Many children with ASD have few, if any, symptoms. Closing the atrial defect by open-heart surgery in childhood can prevent serious problems later in life.

With **ventricular septal defect** (VSD), an opening exists between the heart's two lower chambers. Some blood that has returned from the lungs and been pumped into the left ventricle flows to the right ventricle through the hole instead of being pumped into the aorta. Because the heart has to pump extra blood and is overworked, the heart may become enlarged. Pulmonary hypertension also can develop. If a septal defect is large, surgery may be needed to close the hole. The hallmark of a septal defect is a loud heart murmur.

Patent Ductus Arteriosus. Patent ductus arteriosus (PDA) allows blood to mix between the pulmonary artery and the aorta. As described previously, before birth an open passageway (the ductus arteriosus) exists between these two blood vessels. Normally this closes within a few hours of birth. When closure does not occur, some blood that should flow through the aorta and on to nourish the body returns to the lungs. (This is quite common in premature infants but rather rare in full-term **babies.**[7]) If the ductus arteriosus is large, a child may become fatigued quickly, grow slowly, and be prone to pulmonary infection, especially pneumonia. If the ductus arteriosus is small, the child often seems healthy. Surgery is sometimes needed to close the ductus arteriosus and restore normal circulation.

Truncus Arteriosus. Truncus arteriosus is a rare type of congenital heart disease. It is characterized by a large ventricular septal defect over which a large, single great vessel (truncus) arises. It occurs when a single blood vessel (the truncus) arises from the right and left ventricles, instead of the normal two vessels (the pulmonary artery and the aorta). This single great vessel carries blood both to the body and to the lungs. The truncus sits over a large opening or hole in the wall between the two pumping chambers (ventricular septal defect). A decrease in peripheral vascular resistance at birth causes a left-to-right shunt with evidence of congestive heart failure early in life. These children have a very high incidence of pulmonary hypertension and vascular disease. Children with this defect may experience shortness of breath, decreased exercise endurance, and sometimes headaches and dizziness. Surgical repair is needed to close the ventricular septal defect and separate blood flow to the body from blood flow to the lungs. Long-term follow-up care is required.

VALVULAR DEFECTS

Some children are born with defective heart valves that occurred during embryonic development. These defects may present at birth or during childhood, or not become apparent until adulthood. Common valvular defects include stenosis of the tricuspid and mitral valves (on the left side of the heart) and stenosis of the aortic and pulmonic valves (on the right side of the heart). The narrowing (caused by valvular lesions) of one or more of these valves leads to a pressure gradient across the valve during the time blood is flowing through the valve opening.[8]

Mitral valve stenosis results from a narrowing of the mitral valve orifice when the valve is open. The high resistance across the stenotic mitral valve causes blood to back up into the left atrium, thereby increasing left atrial pressure. This results in the left atrial pressure being much greater than the left ventricular pressure during diastolic filling. Mitral valve stenosis is associated with a diastolic murmur because of turbulence that occurs as blood flows across the stenotic valve.

Tricuspid valve stenosis is similar to mitral valve stenosis except that the pressure and volume changes occur on the right side of the heart.

Aortic valve stenosis is characterized by the left ventricular pressure being much greater than the aortic pressure during left ventricular ejection. Left ventricular pressure is greatly

elevated and the aortic pressure is slightly reduced. The pressure gradient across the stenotic lesion results from both increased resistance (related to narrowing of the valve opening) and turbulence distal to the valve (associated with a systolic murmur).

Pulmonic valve stenosis is similar to aortic valve stenosis except that the changes in pressure are on the right side of the heart. This leads to an increased resistance to outflow. In turn, this elevates right ventricular pressure and limits pulmonary blood flow. Pulmonary valve stenosis accounts for about 8% to 12% of all congenital defects in children.[9] A stenotic pulmonary valve may occur without associated congenital abnormalities, although it is most often associated with other structural abnormalities of the heart.

SINGLE-VENTRICLE DEFECTS

Single-ventricle defects are complex and rare. They occur in the embryonic stage and result when one of the ventricles is underdeveloped. The most common types of single-ventricle defects are tricuspid atresia, pulmonary atresia, and hypoplastic left heart syndrome.[10] In the prehospital setting, standard resuscitation procedures should be followed in infants and children with single-ventricle anatomy. It should be noted, however, that end-tidal CO_2 measurements in these children may not be a reliable indicator of cardiopulmonary resuscitation (CPR) quality. This is because in children with single-ventricle anatomy, pulmonary blood flow changes rapidly and will not always reflect cardiac output during CPR.[1a] Modifications in the care of these patients will be provided in the in-hospital setting.

Tricuspid Atresia. Tricuspid atresia is the absence or abnormal development of a tricuspid valve. This prevents the normal flow of blood from the right atrium to the right ventricle and results in a right ventricle that is small and not fully developed. Ultimately, the blood cannot enter the lungs for oxygenation. The survival of these patients depends on the presence of an atrial septal defect and usually a ventricular septal defect. Because there is no atrioventricular pathway, an atrial septal defect must be present to maintain blood flow. Likewise, because there is an underdeveloped right ventricle, there must be a way to pump blood into the pulmonary arteries through a ventricular septal defect. (A patent ductus arteriosus is also usually formed to increase pulmonary flow.) Cyanosis and shortness of breath are usually present in these infants until surgical repair is made. Surgery is required to repair the connection between the arteries to the body and the arteries to the lungs.

Pulmonary Atresia. In **pulmonary atresia,** no pulmonary valve exists. Blood cannot flow from the right ventricle into the pulmonary artery and on to the lungs. (The right ventricle and tricuspid valve also are often poorly developed.) In these patients, an opening in the atrial septum lets blood exit the right atrium, so low-oxygen blood mixes with the oxygen-rich blood in the left atrium. The left ventricle pumps this mixture of oxygen-poor blood into the aorta and out to the body. As a result, the infant appears cyanotic. Often, the only source of blood flow to the lung is the patent ductus arteriosus. Surgical repair is required.

Hypoplastic Left Heart Syndrome. Hypoplastic left heart syndrome (HLHS) is a condition in which the heart's left side, including the aorta, aortic valve, left ventricle, and mitral valve, is underdeveloped. Blood returning from the lungs must flow through an opening in the wall between the atria (atrial septal defect). The right ventricle pumps the blood into the pulmonary artery, and blood reaches the aorta through a patent ductus arteriosus. Surgical repair is required.

TETRALOGY OF FALLOT

Tetralogy of Fallot (ToF) is a rare congenital heart defect that affects about 5 out of every 10,000 babies.[11] Tetralogy of Fallot involves four heart defects:

1. A large ventricular septal defect (VSD)
2. Pulmonary stenosis
3. Right ventricular hypertrophy
4. An overriding aorta

The VSD allows oxygen-rich blood from the left ventricle to mix with oxygen-poor blood from the right ventricle. Pulmonary stenosis causes the heart to work harder than normal to pump blood through the narrowed pulmonary valve, causing right ventricular hypertrophy. In tetralogy of Fallot, the aorta is between the left and right ventricles (*an overriding aorta*), directly over the VSD. (In healthy hearts, the aorta is directly attached to the left ventricle.) As a result, oxygen-poor blood from the right ventricle flows directly into the aorta instead of into the pulmonary artery to the lungs. Together, these four defects prevent blood from reaching the lungs for oxygenation. As a result, oxygen-poor blood flows out to the body, resulting in cyanosis. (Other signs and symptoms of ToF include a heart murmur, delayed growth and development, and clubbing of the fingers.) Although the cause of the defect is often unknown, contributing factors that may occur during pregnancy include:

- German measles (rubella) and some other viral illnesses
- Poor nutrition
- Overuse of alcohol
- Age (mother older than 40 years)
- Diabetes

Heredity may also play a role in causing tetralogy of Fallot. An adult who has tetralogy of Fallot is at an increased risk of having a baby with the condition. Children who have certain genetic disorders, such as Down syndrome and DiGeorge syndrome, often have congenital heart defects, including tetralogy of Fallot. Surgical repair of the four defects is required early in life. Babies who have unrepaired tetralogy of Fallot sometimes have "tet spells" when blood oxygen level suddenly drops. This is often in response to an activity such as crying or having a bowel movement (Figure 47-6). The drop in oxygen level causes severe cyanosis. The baby also may:

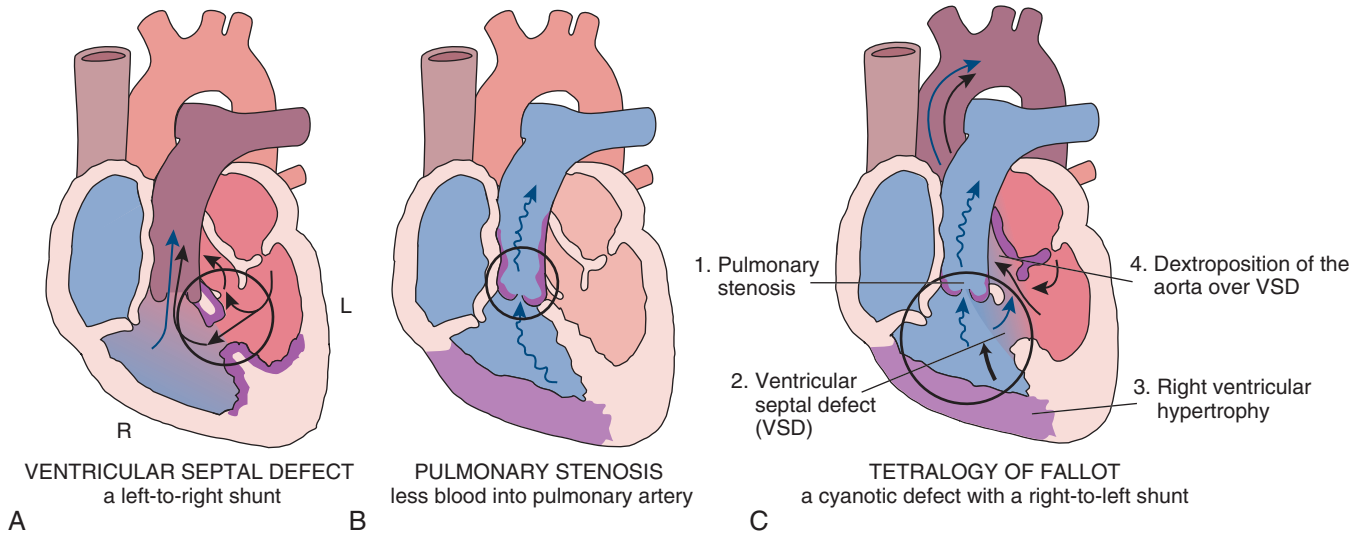

FIGURE 47-6 Congenital heart defects. (From Gould BE, Dyer R: *Pathophysiology for the health professional,* ed 4, St Louis, 2011, Saunders.)

- Have difficulty breathing
- Become very tired and limp
- Not respond to a parent's voice or touch
- Become irritable and fussy
- Lose consciousness

TRANSPOSITION OF THE GREAT ARTERIES

In a healthy heart, the aorta and pulmonary artery are properly positioned and aligned with the appropriate ventricle. If this is reversed (transposed), the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. This congenital heart defect is known as **transposition of the great arteries** (TGA). TGA results in the systemic and pulmonary circulations being in parallel rather than in series. As a result, oxygen-poor blood returning from the body to the right atrium and right ventricle is pumped out to the aorta and to the body. Oxygen-rich blood returning from the lungs to the left atrium and ventricle is sent back to the lungs via the pulmonary artery. Like other heart defects, survival of these patients before surgical repair depends on the presence of an ASD, a VSD, or PDA. Untreated, more than 50% of infants with transposition will die in the first month of life, 90% in the first year.[12]

TOTAL ANOMALOUS PULMONARY VENOUS RETURN

Total anomalous pulmonary venous return (TAPVR) is a congenital heart defect in which the four pulmonary veins that carry oxygen-rich blood back to the heart from the lungs are not properly attached to the left atrium. Instead, they are improperly attached to another area (usually the superior vena cava). With this defect, oxygen-rich blood that should return to the left atrium—and then the left ventricle, the aorta, and the body—instead mixes with the oxygen-poor blood flowing into the right side of the heart. In other words, blood simply circles to and from the lungs, and never to the body.

To survive before corrective surgery, a large ASD or patent foramen ovale (a passage between the left and right atria) must exist to allow oxygenated blood to flow to the left side of the heart and the rest of the body. Infants with TAPVR may appear critically ill with the following symptoms[13]:

- Lethargy
- Poor feeding
- Rapid breathing
- Poor growth
- Frequent respiratory tract infections
- Cyanosis

CONGENITAL DYSRHYTHMIAS

Many children born with congenital heart disease (CHD) now live well into adulthood. It has been estimated that there are more than 800,000 adults with CHD living in the United States.[14] Of these, approximately 45% are considered to have mild forms of CHD (e.g., atrial septal defect, valvular pulmonary stenosis), 40% are classified as having moderate disease (e.g., tetralogy of Fallot), and 15% are considered to have complex disease (e.g., single ventricle, transposition of the great arteries). Although dysrhythmias can develop within any of these groups, the incidence is highest for patients in the moderate and severe categories.

Malfunctions in embryonic development that are responsible for congenital heart defects can directly impact the development of the heart's conduction system (especially displacement of the atrioventricular [AV] node and bundle of His). This makes these patients more vulnerable to many dysrhythmias, including atrial fibrillation, atrial flutter, reentry tachycardias, and heart blocks. Standards of care for patients with dysrhythmias that result from CHD

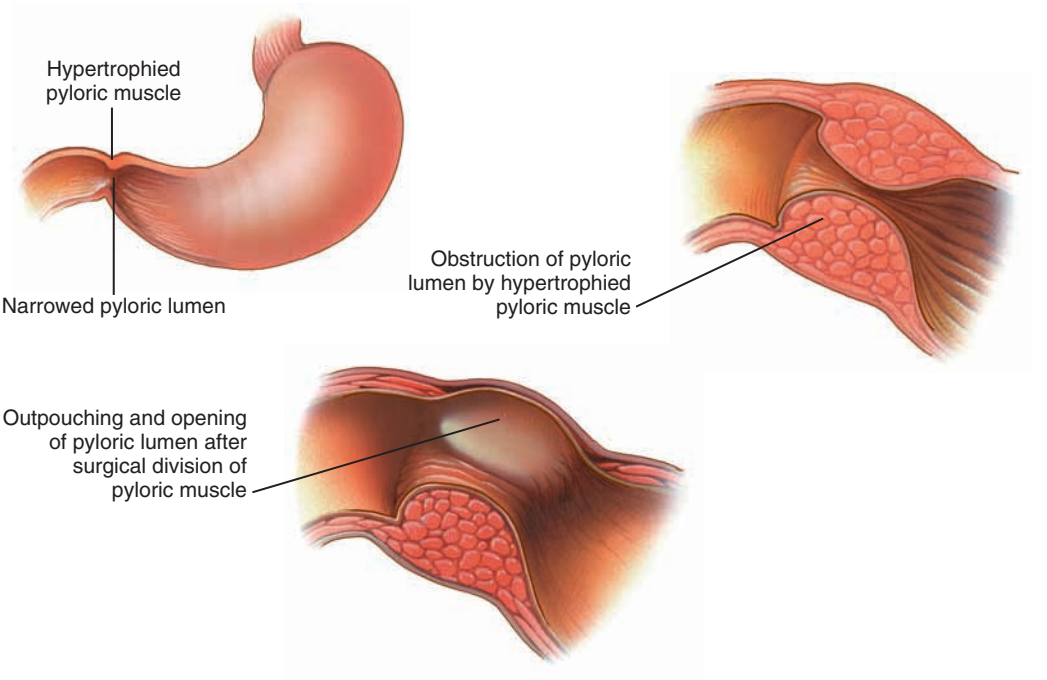

FIGURE 47-7 In pyloric stenosis, the pyloric muscle hypertrophies and obstructs the passage of stomach contents into the intestines. (From Price DL, Gwin JF: *Pediatric nursing: an introductory text,* ed 10, St Louis, 2008, Saunders.)

follow the same treatments guidelines as for other patients (see Chapter 48).

Anomalies of the Abdomen and Lower Back

INTESTINAL MALROTATION

Intestinal malrotation is caused by abnormal rotation of the intestine around the superior mesenteric artery during embryological development. It is a congenital defect that can cause a serious bowel obstruction. The condition occurs in about 1 in every 500 live births.[15] Malrotation is commonly seen with other birth defects such as omphalocele, diaphragmatic hernia, and Hirschsprung's disease. The condition usually becomes evident within the first week of life; 75% of cases are diagnosed within the first 12 months. The illness may be acute or chronic. The primary presenting sign in acute malrotation is emesis that contains bile. Features of chronic malrotation include recurrent bouts of abdominal pain and diarrhea (alternating with constipation), intolerance of solid food, jaundice, lower gastrointestinal (GI) tract bleeding, and gastroesophageal reflux. If symptoms persist, the child may develop shock, including poor perfusion, decreased urine output, and hypotension. Malrotation requires surgical repair.

PYLORIC STENOSIS

Pyloric stenosis is narrowing of the pylorus (the opening from the stomach into the small intestine). It is the most common cause of intestinal obstruction in infancy.[16] The narrowing occurs from muscles around the pylorus that have grown too large (Figure 47-7). The diagnosis is usually made when an infant presents with a history of progressive, forceful vomiting. This usually begins within the second or third week of life. Parents may complain that the baby is "spitting up." They often have tried a different formula in formula-fed babies without any change being noted. Signs and symptoms are related to dehydration and may include dry mucous membranes, slow capillary refill, sunken fontanelles, and decreased urine output (dry diapers for several hours). After diagnosis, surgery will be required to dilate the muscles around the pyloric valve of the stomach.

DIAPHRAGMATIC HERNIA

Diaphragmatic hernia is caused by the malformation of the diaphragm during fetal development. The condition affects 1 in every 2500 to 5000 live births.[5] Diaphragmatic hernia may occur on the right, left, or both sides, but the left side is most common. It results from a defect (hole) in the diaphragm muscle. The opening allows abdominal organs, such as the stomach, bowel, liver, and spleen, to enter the chest cavity (Figure 47-8). As a result, the lung on the affected side does not develop normally **(pulmonary hypoplasia),** and this reduces lung capacity. Other organs can be damaged as well, including the heart. A significant prenatal shift in the mediastinum may indicate some degree of pulmonary hypoplasia on the contralateral side.[4] The infant's head and thorax should be elevated to assist with downward displacement of the abdominal organs and to help improve ventilation.

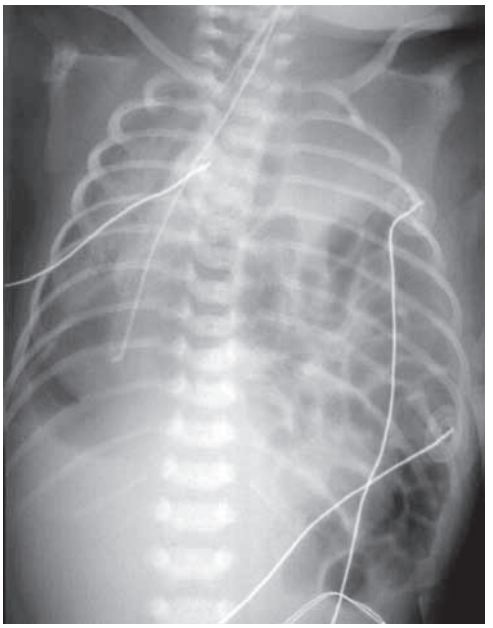

FIGURE 47-8 Left-sided congenital diaphragmatic hernia. Note the loops of bowel present in the thoracic cavity. (From Kacmarek RM, Dimas S: *The essentials of respiratory care,* ed 4, St Louis, 2005, Mosby.)

NOTE
Diaphragmatic hernia is a true emergency that requires surgical repair. Newborns who do not survive usually die within the first days or weeks of life. Survival for the infant who requires mechanical ventilation in the first 18 to 24 hours of life is about 50%. If there is no respiratory distress within the first 24 hours of life, survival approaches 100%.[4]

Respiratory distress usually develops shortly after birth. Other symptoms include cyanosis that is unresponsive to ventilations, tachypnea, and tachycardia. On examination, the infant born with this disorder may have irregular chest wall movement, displaced heart sounds, absent breath sounds on the affected side, and bowel sounds in the chest cavity. In addition, the abdomen may be scaphoid (flat) and feel "full" on palpation. Medical direction may recommend placement of an orogastric tube, with low periodic suction to improve ventilations. In some cases, tracheal intubation may be needed. The use of a bag device or aggressive positive-pressure ventilation may cause gastric distention and worsen the condition. (The use of a bag device is contraindicated.) Surgery is required to repair the hernia and to place the abdominal organs in their normal location. If the condition is diagnosed during pregnancy, fetal surgery may be indicated.

OMPHALOCELE

An **omphalocele** is a type of hernia in which the infant's intestines or other abdominal organs protrude through the umbilicus. It results during fetal development when the muscles in the abdominal wall (umbilical ring) do not close properly. As a result, the intestines remain outside the umbilical cord (Figure 47-9). The defect affects 1 in every 5000 to 6000 live births. Up to 25% to 40% of infants with an omphalocele will have another (often more serious) congenital anomaly.[5] The omphalocele usually is first seen on ultrasound during prenatal care.

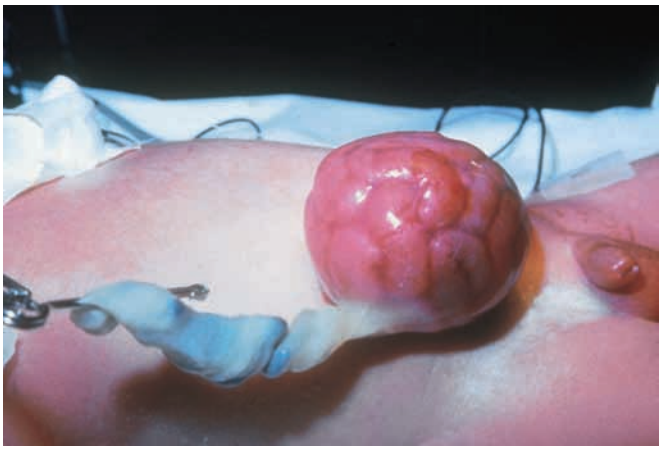

FIGURE 47-9 Omphalocele in membranous sac. (From Hockenberry MJ: *Wong's nursing care of infants and children,* ed 9, St Louis, 2011, Mosby.)

Most omphaloceles will be quite visible at birth. The omphalocele may be small (containing only a small section of intestines) or large (containing the liver and spleen). The protruding organs will usually be covered by a thin sac of peritoneum (*intact omphalocele*). The umbilical vessels are usually present within the sac. Exposed tissue should be protected and covered with moist, sterile gauze pads to prevent injury and infection. Rupture of an omphalocele (*nonintact omphalocele*) may occur immediately before or during delivery.

NOTE
An umbilical cord that appears unusually large in diameter should be examined for the presence of a small omphalocele before it is clamped and cut as part of the delivery process. If suspected, the cord should not be clamped or cut. The paramedic should consult with medical direction.

An omphalocele usually is successfully repaired with surgery. As part of the surgery, the exposed tissues of a small omphalocele will be covered and held in place with a special plastic pouch (*silo*) that over time squeezes the exposed tissue back into the infant's abdomen. Surgical repair of the infant's abdominal muscles may be needed as well. Surgery for a larger omphalocele with an intact sac is often delayed. The tissue will eventually be covered by the growth of surrounding skin, after which surgery can be performed to improve cosmetic outcome.

PHYSIOLOGICAL ADAPTATIONS AT BIRTH

Newborns make three major physiological adaptations at birth that are necessary for survival: (1) emptying fluids from their lungs and beginning ventilation, (2) changing their circulatory pattern, and (3) maintaining body temperature.[17]

During vaginal delivery, the newborn's chest usually is compressed. This forces fluid from the lungs into the mouth and nose. As the chest wall recoils, air is drawn into the lungs. The newborn takes the first breath in response to chemical changes and changes in temperature.

When the cord is cut and placental circulation ceases, the circulatory system must function on its own. This involves the immediate and permanent closure of the pathways that allowed the fetus to receive oxygen without the use of lungs (described in Chapter 46). As the lungs expand with initial breaths, the resistance to blood flow in the lungs decreases, and the newborn's blood begins to be oxygenated.

LOOK AGAIN
See Chapter 46: Obstetrics, pp. 1279-1280.

Newborns are sensitive to hypoxia. Permanent brain damage will occur from prolonged hypoxemia. Causes of hypoxia include compression of the cord, difficult labor and delivery, maternal hemorrhage, airway obstruction, hypothermia, newborn blood loss, and immature lungs in the premature newborn. Cardiovascular anomalies also may result in hypoxia.

Newborns are at risk for rapidly developing hypothermia. Thus they should be delivered in a warm, draft-free area when possible. This risk factor is due to their larger body surface area (BSA), decreased tissue insulation, and immature temperature regulatory mechanisms. The cool, wet environment of birth also increases heat loss for the newborn. Newborns try to conserve body heat through vasoconstriction and an increase in their metabolism. This places them at risk for hypoxemia, acidosis, bradycardia, and hypoglycemia.

ASSESSMENT AND MANAGEMENT OF THE NEONATE

The initial steps of assessment and management of any newborn should be accomplished within about 60 seconds (the "Golden Minute").[1] Following these steps enables the paramedic to immediately recognize an infant in need of resuscitation. It also leads to efficient and effective emergency care delivery. The initial steps in assessment and management of the neonate are (Figure 47-10)[1]:

1. Provide warmth by drying the baby to prevent heat loss and avoid hypothermia.
2. Position the head in a sniffing position to open the airway.
3. Clear the airway if necessary with a bulb syringe or suction catheter.
4. Provide tactile stimulation to initiate breathing if necessary.
5. Further evaluate the infant.

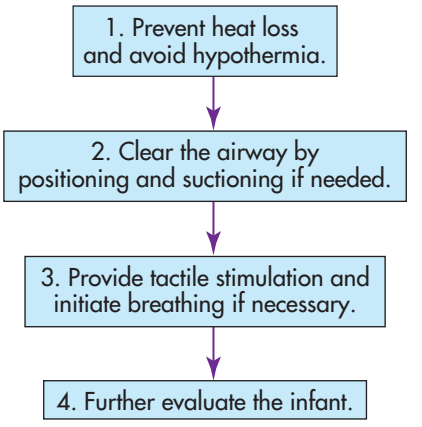

FIGURE 47-10 Steps in neonatal assessment and management.

NOTE
Body substance isolation (BSI) precautions are recommended during delivery of a newborn. Gloves and other appropriate protective barriers (including gowns and goggles) should be worn when handling the newborn or contaminated equipment.

SHOW ME THE EVIDENCE
In a case-control retrospective study conducted from 1995 to 1999, Scottish researchers investigated unplanned out-of-hospital deliveries in an attempt to identify risk factors associated with them. During that period 117 women delivered 121 babies accidentally in the prehospital setting. Each study birth was compared to the next woman who delivered in the hospital after spontaneous labor. Compared to hospital deliveries, the study group women were likely to be of greater parity and to have less prenatal care. Babies in the study group were more likely to be younger gestational age and lower birth weight, to deliver after a shorter labor, and to be admitted to the neonatal intensive care unit than the control group. The infant mortality rate in the accidental delivery group was six times higher than the controls.

From Rodie VA, Thomson A, Norman J: Accidental out-of-hospital deliveries: an obstetric and neonatal case control study, *Acta Obstet Gynecol Scand* 81(1):50-54, 2002.

Prevent Heat Loss and Avoid Hypothermia

Even healthy term newborns are limited in their ability to conserve heat when exposed to a cold environment and are at risk for developing hypothermia. Therefore, immediately after delivery, the infant's body and head should be dried

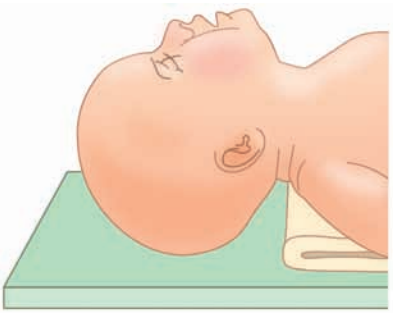

FIGURE 47-11 Positioning the neonate to open the airway.

to prevent evaporative heat loss and metabolic derangements that may be instigated by **cold stress** (when the body is unable to warm itself). The act of drying also provides gentle stimulation, which may initiate respirations. Care should be taken to remove any wet coverings from the infant and cover the infant with dry wrappings. The majority of heat loss can be prevented by covering the newborn's head (which accounts for 20% of the newborn's BSA). Covering the baby in plastic wrapping such as food wrap can prevent hypothermia.[1]

CRITICAL THINKING
What other measures can you take to warm the infant?

Clear the Airway by Positioning and Suctioning (If Needed)

After the newborn has been dried and covered, the next step is to establish an open airway. This is achieved by placing the infant supine, with the head in a sniffing position. Care should be taken to prevent hyperextension or underextension, which may compromise the airway. Placing a blanket or towel under the infant's shoulders (thereby elevating the torso ¾ to 1 inch) can help maintain the correct position (Figure 47-11).

CRITICAL THINKING
Do infants breathe through their noses or mouths?

Once the infant has been properly positioned, most newborns will breathe without difficulty. If the airway is obstructed by secretions, a bulb syringe or catheter can be used to suction the nose and mouth. It is preferable to suction the mouth first to prevent aspiration in case the infant gasps when the nose is cleared. Each application of suction should last no more than 5 seconds to prevent hypoxia. The newborn's heart rate should be monitored during suctioning, and time should be provided during suction attempts for spontaneous ventilation.

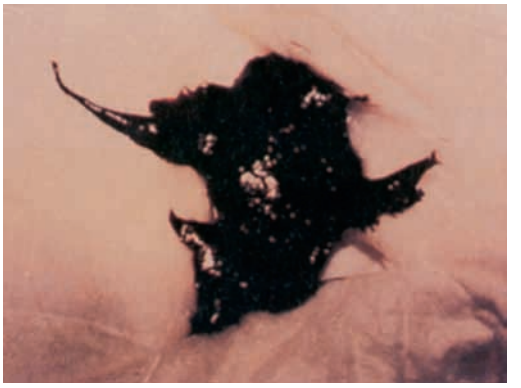

FIGURE 47-12 Meconium-stained birth.

NOTE
Suctioning the airway at birth can stimulate the posterior pharynx and can produce a vagal response with resulting bradycardia, apnea, or both. Therefore, suctioning should be reserved for babies who have obvious obstruction to spontaneous breathing or who require positive-pressure ventilation. Supplemental oxygen delivery (described elsewhere) should be guided by pulse oximetry results.[1]

MECONIUM STAINING

Meconium staining is the presence of fetal stool in the amniotic fluid. It occurs in utero or intrapartum and in about 12% of all deliveries.[4] Meconium staining becomes more common in postterm and small-for-gestational-age newborns. It is also common in those infants who develop fetal distress during labor and delivery. Meconium staining is associated with increased perinatal mortality, hypoxemia, aspiration pneumonia, pneumothorax, and pulmonary hypertension.

The appearance of meconium depends on the amount of meconium particles and amniotic fluid. Meconium staining may appear as only a slight yellow or light green staining that is thin and watery. Or it may have a thick, pea-soup appearance that is dark green or black (Figure 47-12). When thick meconium is present in amniotic fluid, a chance exists that the particles will be aspirated into the infant's mouth, and potentially into the trachea and lungs. This can lead to partial or complete obstruction of the airways. Death can result from hypoxia, hypercapnia, and acidosis.

NOTE
Meconium can be used to test for maternal drug use. It has a greater sensitivity than urine and positive findings that persist longer. If time permits, a specimen should be collected and delivered to the emergency department.

If meconium (or evidence of infection) is observed and the newborn is vigorous (strong respiratory efforts, good

muscle tone, and a heart rate greater than 100 beats per minute), no special care of the airway is required. If the newborn is not vigorous (absent or depressed respirations, decreased muscle tone, heart rate less than 100 beats per minute), endotracheal (ET) intubation and endotracheal suctioning are recommended immediately after birth.[1] Because the presence of meconium can be determined only after the membranes have ruptured, it is critical that the paramedic crew have airway equipment available. Emergency care for these newborns includes the following steps (Figure 47-13):

1. Prepare the necessary equipment (e.g., intubation equipment, bulb syringe, and DeLee suction, 12 F [French] or 14 F suction catheter, portable suction and irrigation solution, gauze pads, infant bag device). Intubation equipment should include padding for patient positioning, stethoscope, number 0 and number 1 laryngoscope blades, ET tubes (2.5, 3.0, 3.5, 4.0), stylet, meconium aspirator, and oxygen tubing. The procedure for endotracheal intubation of an infant is described in Chapter 15.

LOOK AGAIN

See Chapter 15: Airway Management, Respiration, and Artificial Ventilation, pp. 439-445.

2. After delivery, clear the infant's airway and thoroughly suction the nose, mouth, and pharynx. Remove residual meconium in the hypopharynx by suction under direct visualization.
3. Quickly intubate the trachea. Apply suction to the proximal end of the ET tube using the DeLee device while withdrawing the tube. During intubation and suctioning, aim 100% oxygen toward the infant's face and monitor the fetal heart rate for bradycardia. If bradycardia develops, ventilate the infant's lungs using a bag device after suctioning to prevent persistent bradycardia and hypoxia.
4. Repeat the intubation-suction-extubation cycle until no further meconium is obtained. Do not ventilate between intubations.
5. After tracheal suction is complete, continue resuscitative measures as needed. If respirations are adequate, manage the infant's airway in the normal fashion. Medical direction may recommend that an 8 F orogastric tube that is aspirated with a syringe and left open to air be placed to prevent aspiration of gastric contents after resuscitation is complete.

If tracheal suctioning cannot be achieved promptly and the infant is bradycardic, consider bag-mask ventilation.[1]

Provide Tactile Stimulation to Initiate Breathing

If drying does not induce respirations in the infant, additional tactile stimulation should be provided. The two safe and appropriate methods of tactile stimulation are slapping or flicking the soles of the infant's feet and rubbing the infant's back.

Further Evaluate the Infant

Drying and positioning are necessary in every infant at birth. These maneuvers are used to open the airway and initiate breathing. To further evaluate the infant the paramedic should follow these steps:

1. Observe and evaluate the infant's respirations. If they are normal (e.g., crying), continue the evaluation. If available, place a neonatal pulse oximetry probe on the right upper extremity (usually the infant's wrist or medial surface of the palm) to monitor oxygen saturation. Target SpO_2 readings after birth are provided in Box 47-3.
2. Evaluate the infant's heart rate by stethoscope or palpation of the pulse in the base of the umbilical cord. If it is greater than 100 beats/min, continue the evaluation.
3. Evaluate the infant's color. Peripheral cyanosis (*acrocyanosis*) is common in the first few minutes of life and does not indicate hypoxemia. If the infant's color is normal ("pinking up") and the SpO_2 readings are increasing, continue the evaluation by obtaining the Apgar score.

NOTE

Cyanosis can be divided into two types: central and peripheral. **Central cyanosis** (identified by cyanosis of the tongue and mucous membranes) usually reflects *decreased saturation* of the hemoglobin in arterial blood. The cause is most often from heart or lung disease. Less commonly, it results from an increased amount of abnormal hemoglobin. **Peripheral cyanosis** is confined to the extremities. This type of cyanosis reflects a *difference in the saturation* of hemoglobin between arterial and venous blood at a time when arterial hemoglobin saturation is normal. Peripheral cyanosis occurs when blood vessels in the hands and feet constrict and slow the flow of blood. As a result, more oxygen than usual is permitted to be extracted from hemoglobin by the surrounding tissues, thus desaturating it. Peripheral cyanosis is expected and considered normal in newborn infants.

APGAR SCORE

The Apgar score (described in Chapter 46) enables rapid evaluation of a newborn's condition at specific intervals after birth. It routinely is assessed at 1 and 5 minutes of age.

BOX 47-3 Target SpO_2 Readings After Birth[1]

1 minute	60% to 65%
2 minutes	65% to 70%
3 minutes	70% to 75%
4 minutes	75% to 80%
5 minutes	80% to 85%
10 minutes	85% to 95%

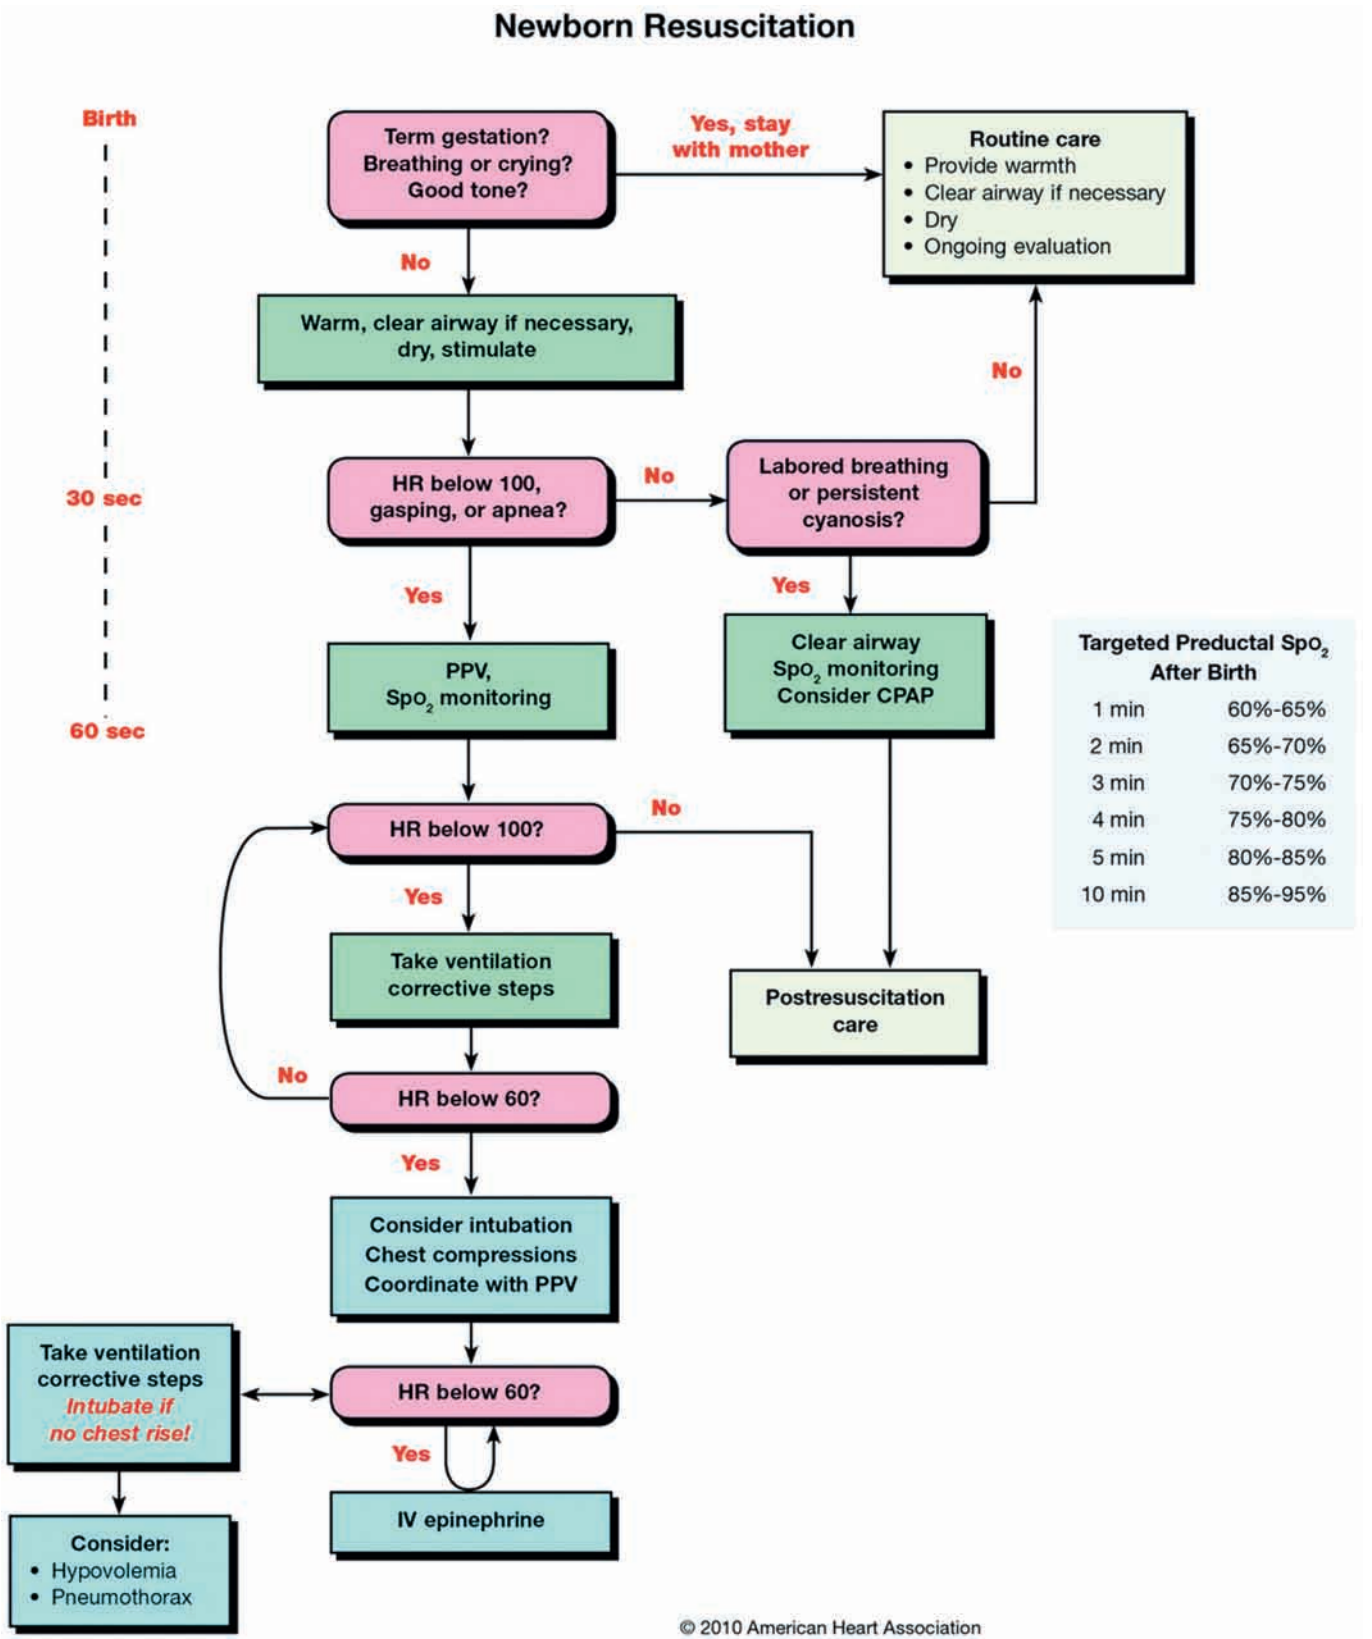

FIGURE 47-13 Neonatal flow algorithm. (Reprint with permission: American Heart Association Guidelines For CPR and ECC, *Circulation* 122 [suppl 3]: S685-S919, American Heart Association, Inc, 2010.)

Although the Apgar score is a useful tool to evaluate the newborn, it should not be used alone in determining the need for resuscitation. To review, an Apgar evaluates **a**ppearance, **p**ulse rate, **g**rimace, **a**ctivity, and **r**espirations. A score of 7 to 10 is considered normal; a score of 4 to 6 identifies a moderately distressed infant who requires oxygen and stimulation; and a score less than 4 identifies a severely distressed infant who requires resuscitation (Table 47-1).

RESUSCITATION OF THE DISTRESSED NEONATE

Newborns who are full term, who have an airway that is clear of meconium or have no evidence of infection, who are breathing and crying, and who have good muscle tone do not usually require resuscitation. As described earlier, this assessment should be completed within 60 seconds. If resuscitation is required because of inadequate respirations or heart rate, the infant will need one or more of the following interventions in sequence[1] (Figure 47-14):

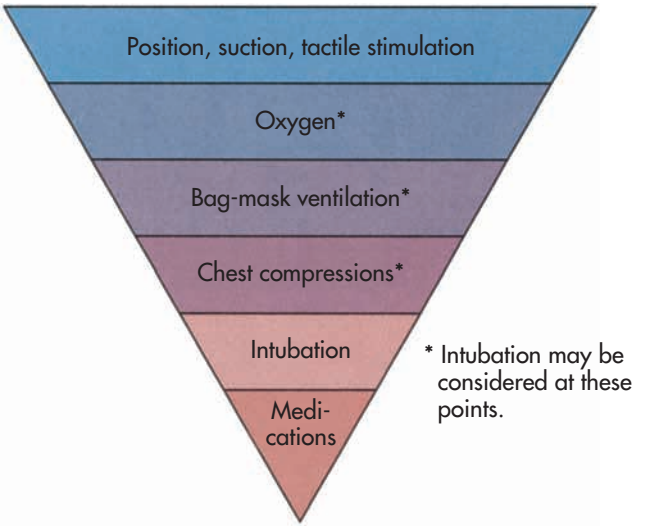

FIGURE 47-14 Inverted pyramid reflecting the approximate relative frequency of neonatal resuscitative efforts. Note that a majority of infants respond to simple measures.

> **NOTE**
> The newborn should have regular respirations that are sufficient to improve color, achieve target SpO_2 ranges, and maintain a heart rate of greater than 100 beats per minute.

1. Reevaluate initial steps in stabilization (provide warmth, position, clear airway if necessary, dry, and stimulate).
2. Provide ventilations.
3. Provide chest compressions at 120/min.
4. Administer ***epinephrine*** and/or volume expanders.

TABLE 47-1 APGAR Score*

	POINTS		
Assessment	**0**	**1**	**2**
Heart rate	Absent	Below 100 beats/min	100 beats/min or higher
Respiratory effort	No spontaneous respirations	Slow respirations or weak cry	Spontaneous respirations with strong, lusty cry
Muscle tone	Limp	Minimal flexion of extremities; sluggish movement	Flexed body posture; spontaneous and vigorous movement
Reflex	No response to suction	Minimal response (grimace) to suction or gentle slap on soles	Responds promptly to suction or gentle slap to sole with cry or active movement
Color	Pallor or cyanosis	Bluish hands and feet only	Pink (light skinned) or absence of cyanosis (dark skinned); pink mucous membranes

0 1 2 3 4	**5 6 7**	**8 9 10**
Infant needs resuscitation.	Gently stimulate by rubbing infant's back while administering oxygen. Determine whether mother received narcotics, which may have depressed infant's respirations. Have naloxone (Narcan) available for administration.	Provide no action other than support of infant's spontaneous efforts and continued observation.

From Murray SS, McKinney ES: *Foundations of maternal newborn nursing,* ed 5, St Louis, 2010, Saunders
*The Apgar score is a method for rapid evaluation of the infant's cardiorespiratory adaptation after birth. The nurse scores the infant at 1 minute and 5 minutes in each of five areas. The assessments are arranged from most important (heart rate) to least important (color). The infant is assigned a score of 0 to 2 in each of the five areas, and the scores are totaled. Resuscitation should not be delayed until the 1-minute score is obtained. However, general guidelines for the infant's care are based on three ranges of 1-minute scores. *Note:* Neonatal resuscitation measures, if needed, do not await 1-minute Apgar scoring but are instituted at once.

The need to progress in sequence from one intervention to the next is based on the simultaneous assessment of the infant's respirations, heart rate, and oximetry readings. About 30 seconds should be allotted to complete each step, to reevaluate, and to decide whether to progress to the next sequenced step in resuscitation.[1]

Reevaluate Initial Steps in Stabilization

The initial steps in stabilization should be reevaluated. The paramedic should ensure that the infant is dry and warm. (Cold stress can increase oxygen consumption and impede effective breathing.) Hypothermia can be associated with perinatal respiratory depression. Additional methods that can be used to warm a newborn include covering the baby in plastic wrap (food-grade, heat-resistant plastic) and placing the baby skin-to-skin with the mother and covering both with a blanket. Hyperthermia should be avoided. The goal is to achieve and maintain a normal body temperature for the newborn.

The head and neck of the newborn should be properly positioned (or repositioned) to ensure an open airway. In addition, the paramedic can make other attempts at stimulation to initiate breathing. If the infant is breathing, but color and SpO_2 do not improve within 90 seconds after birth or if there is central cyanosis, supplemental oxygen should be given. Free-flow oxygen mixed with air can be applied through a face mask and flow-inflating bag, an oxygen mask, or a hand cupped around the oxygen tubing (held 2 inches from the infant's nose). Oxygen therapy should be guided by pulse oximetry measurements and continued until the target SpO_2 range is achieved. Oxygen delivery should begin with bag-mask ventilation with room air and then be titrated to maintain SpO_2 in the target range. If the baby is bradycardic (heart rate less than 60 beats per minute) after 90 seconds of resuscitation, oxygen concentration should be increased to 100% until recovery of a normal heart rate.[1]

NOTE
Babies born at term should begin resuscitation with blended oxygen (oxygen mixed with air) guided by pulse oximetry, rather than giving 100% oxygen. Healthy babies born at term have an initial oxygen saturation of less than 60% and can require more than 10 minutes to reach saturations above 90%. Hyperoxia can be toxic to newborns, especially preterm infants.[1]

Provide Ventilations

As stated previously, the newborn should have regular respirations that are sufficient to maintain target SpO_2 and a heart rate greater than 100 beats per minute. Gasping and apnea indicate the need for assisted ventilations. Increasing or decreasing heart rate can also provide clues of improvement or deterioration in the newborn.

NOTE
Hypoxia is nearly always present in a newly born infant who requires resuscitation.

If respirations are inadequate (evidenced by low SpO_2 readings) or if the heart rate remains less than 100 beats per minute 30 seconds after completing the initial steps discussed earlier, positive-pressure ventilation should be initiated. Assisted ventilations should be provided at a rate of 40 to 60 breaths per minute to achieve or maintain a heart rate greater than 100 beats per minute.[1] Assisted ventilations can be delivered with a flow-inflating bag, with a self-inflating bag, or with a T-piece (a valved, mechanical device designed to control flow and limit pressure). Medical direction may recommend providing continuous positive airway pressure (CPAP) to infants who are breathing spontaneously, but with difficulty, following birth. Positive end-expiratory pressure (PEEP) may also be effective in supporting ventilations. The use of CPAP or PEEP should be guided by medical direction.

NOTE
The lungs of a preterm infant can be easily injured by large-volume inflations immediately after birth. Therefore, high pressures during assisted ventilations should be avoided with babies who are premature. High inflation pressures may be evident by excessive chest wall movement.

ENDOTRACHEAL INTUBATION

Endotracheal intubation may be indicated at several points during neonatal resuscitation. These include[1]:

- When tracheal suctioning of meconium is required
- If bag-mask ventilation is ineffective or prolonged
- When chest compressions are performed
- For special resuscitation circumstances, such as congenital diaphragmatic hernia or extremely low birth weight (less than 1000 g)

Before the paramedic considers intubation or pharmacological therapy, two components of the resuscitation process should be reevaluated:

1. Is chest movement adequate? Check for the adequacy of chest expansion and auscultate for bilateral breath sounds.
   a. Is the bag mask seal tight? A relatively large mask should be turned upside down for a better fit.
   b. Is the airway blocked from improper head position or secretions in the nose, mouth, or pharynx? Reassess head position and reexamine the airway for the presence of secretions.
   c. Is adequate ventilatory pressure being used? A bag mask pop-off valve may need to be disabled to allow for higher inspiratory pressures, especially for premature or meconium-aspiration delivery.[2]

d. Is air in the stomach interfering with chest expansion? Consider nasogastric or orogastric decompression per protocol.

2. Are target SpO_2 measurements within normal range?
   a. Is the oxygen tubing attached to the bag and flowmeter?
   b. If using a self-inflating bag, is the oxygen reservoir attached?

A prompt increase in heart rate and increased chest wall movement after endotracheal intubation and administration of intermittent positive-pressure ventilation are the best indicators of correct tube placement. However, the paramedic should verify tube placement visually during intubation and by using primary and secondary confirmation methods (described in Chapter 15). Exhaled carbon dioxide detection is effective and is the recommended method for confirmation of endotracheal tube placement in infants with adequate cardiac ouput.[1] (False-negative readings can occur, if the infant has poor or absent pulmonary flow.) The laryngeal mask airway (LMA) may be used to establish an airway in a newborn if bag-mask ventilation is ineffective or tracheal intubation has failed.

Provide Chest Compressions

Chest compressions are indicated if the newborn's heart rate is less than 60 beats per minute after 30 seconds of adequate ventilation with supplemental oxygen. (The paramedic should ensure that assisted ventilations are effective before initiating chest compressions.) As described in Chapter 22, chest compressions should be coordinated with ventilations to avoid simultaneous delivery. Compressions and ventilations should be delivered at a ratio of 3:1 at a rate of 120 per minute. This will achieve about 90 compressions and 30 breaths per minute.

To review, the two thumb–encircling hands' chest compression is the preferred technique for chest compressions for newly born infants and older infants who are full term. (Preterm infants and infants who are small for gestational age should have chest compressions performed using only two fingers.) Compressions should be performed on the lower third of the sternum. Depth of compression should be approximately one third of the anterior-posterior diameter of the chest and should be sufficiently deep to generate a palpable pulse.[1] Respirations, heart rate, and oxygenation should be reassessed frequently. Coordinated chest compressions and ventilations should continue until spontaneous heart rate is equal to or greater than 60 beats per minute.

CRITICAL THINKING

Why would compressions be initiated when the infant still has a pulse?

Administer Epinephrine and/or Volume Expanders

Drugs are rarely indicated in the resuscitation of the newly born infant. As a rule, drugs should be administered only if the heart rate remains below 60 beats per minute, despite adequate ventilation with 100% oxygen and effective chest compressions.[1] Drug therapy that may be indicated includes the administration of ***epinephrine*** and volume expanders. Buffers, a narcotic antagonist, or vasopressors are rarely useful (Table 47-2).

Important points for the paramedic to remember when administering drugs or volume expanders include:

1. The IV route is preferred for drug administration. All drugs should be given intravenously as soon as venous access is obtained. ***Epinephrine*** may be administered through the ET tube (at higher doses) while obtaining IV access, but safety and efficacy have not been established (Class IIb, LOE C). The concentration of ***epinephrine*** for either route is 1:10,000 (0.1 mg/mL).

NOTE

Bradycardia in the newborn infant is usually the result of inadequate lung inflation or hypoxemia. Therefore, establishing adequate ventilation is the most important step to correct it.

2. Volume expanders should be considered when blood loss is suspected. They should also be considered if the infant appears to be in shock (pale skin, poor perfusion, weak pulse) and has not responded to other resuscitative measures. (End-organ perfusion should be evaluated by comparing the strength of central versus peripheral pulses and through capillary refill tests.) Volume expanders should be given slowly and with caution when resuscitating premature infants. The recommended dose is 10 mL/kg, which may need to be repeated. Rapid infusions of large volumes of volume expanders have been associated with intraventricular hemorrhage.[1]

ROUTES OF DRUG ADMINISTRATION

Although the IV route is the preferred route for drug therapy in the newborn, other methods that may be considered include the endotracheal route and the intraosseous (IO) route (described in Chapter 14). During CPR or treatment of severe shock, IO access should be established when venous access cannot be rapidly achieved.[18]

NOTE

Venous access through the umbilical cord is usually not an option in the prehospital setting or beyond the first several days of birth.[19] The procedure also requires special training and authorization from medical direction. Accessing the umbilical vein is described in the Appendix, Advanced Practice Procedures in Critical Care.

TABLE 47-2 Medications for Neonatal Resuscitation

Medication	Dose/Route	Concentration	Weight (kg)	Total (mL)	Precautions
Epinephrine*†	0.01-0.03 mg/kg IV/IO	1:10,000	1	0.1-0.3	Give rapidly
			2	0.2-0.6	Repeat every 3-5 min
			3	0.3-0.9	
			4	0.4-1.2	
Volume expanders Normal saline or blood	10 mL/kg IV over 5-10 min		1	10	Reassess after each bolus
			2	20	
			3	30	
			4	40	
Naloxone	0.1 mg/kg IV, ET, or IM/subQ if perfusion is adequate	0.4 mg/mL	1	0.25	Repeat doses may be needed to prevent apnea
			2	0.50	
			3	0.75	
			4	1.00	
		1.0 mg/mL	1	0.1	Do not give if mother is suspected of abusing narcotics
			2	0.2	
			3	0.3	
			4	0.4	

*Epinephrine also may be given endotracheally 0.05-0.1 mg/kg.
†*Note:* The endotracheal tube dose may not result in effective plasma concentration of the drug, so vascular access should be established as soon as possible. Drugs administered by endotracheal tube should be diluted to a volume of 3 to 5 mL before instillation. Drugs given ET require higher dosing than when given IV/IO.

BOX 47-4 Dope Pneumonic

D: Dislodgement (ET tube is misplaced; right mainstem bronchus, esophagus)
O: Obstruction (secretions obstructing the tube)
P: Pneumothorax (decreased or absent breath sounds on the affected side)
E: Equipment failure (such as ventilator malfunction or disconnect)

LOOK AGAIN
See Chapter 14: Venous Access and Medication Administration, pp. 368-370.

POSTRESUSCITATION CARE

The three most common complications of the postresuscitation period are endotracheal tube migration (including dislodgment), tube occlusion by mucus or meconium, and pneumothorax (Box 47-4).[2] These complications should be suspected in the presence of the following:

- Decreased chest wall movement
- Diminished breath sounds
- Return of bradycardia
- Unilateral decrease in chest expansion
- Altered intensity to pitch of breath sounds
- Increased resistance to hand ventilation

Corrective management in the field for these postresuscitative complications may include adjustment of the endotracheal tube (exhaled carbon dioxide devices are recommended for monitoring tracheal tube placement), reintubation, and suction. Needle decompression to manage a suspected pneumothorax must be guided carefully by medical direction.

CRITICAL THINKING
How much movement would it take to dislodge an endotracheal tube from a neonate?

Induced Therapeutic Hypothermia

As described in Chapter 22, induced therapeutic hypothermia (33.5° to 34.5° C) can lower mortality and reduce neurological complications in some patients who have a return of spontaneous circulation (ROSC) following cardiac arrest. Protocols for this treatment in neonates ≥36 weeks' gestation generally include cooling within 6 hours following birth. The cooling is continued for 72 hours, after which the infant is slowly rewarmed over at least 4 hours.[1] Induced therapeutic hypothermia is not a prehospital consideration in neonatal resuscitation. The procedure is instituted in the hospital setting.

NEONATAL TRANSPORT

During transport of the neonate, it is important to maintain the infant's body temperature and prevent hypothermia. In addition, it is critical to maintain oxygen levels and

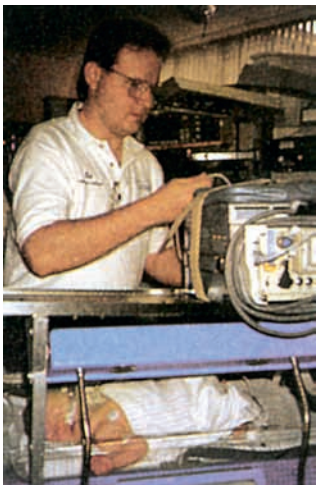

FIGURE 47-15 Neonatal transport. (Courtesy Nellcor Puritan Bennett, Minneapolis, Minn.)

to support the infant's ventilations. In the initial prehospital phase of care, transport strategies usually are limited to providing a warm ambulance, administering free-flow oxygen (warmed if available), covering the baby's head, and applying warm blankets to prevent hypothermic complications. Specialized transport equipment such as isolettes and radiant heating units often is used for interhospital transfers. These devices require special training. Highly trained neonatal transport teams consisting of paramedics, nurses, respiratory therapists, and physicians are part of well-organized regional referral systems throughout the United States (Figure 47-15).

SPECIFIC SITUATIONS

Specific situations may call for advanced life support for the neonate. These situations include apnea, bradycardia, prematurity, respiratory distress and cyanosis, hypovolemia, seizures, fever, hypothermia, hypoglycemia, vomiting and diarrhea, and common birth injuries. While providing advanced life support in these and other situations, the paramedic must consider the emotional needs of the mother and family. When possible, the paramedic should explain what is being done for the infant and why a procedure is necessary.

Apnea

Apnea is an absence of spontaneous respirations. *Primary apnea* is a self-limited condition controlled by P_{CO_2} levels. It is a common event immediately after birth. *Secondary apnea* is described as apnea that exceeds 20 seconds without spontaneous breathing occurring. This can lead to hypoxemia and bradycardia. Secondary apnea is common in the preterm infant. It often results from hypoxia or hypothermia. Secondary apnea also may be caused by conditions that include maternal use of narcotics or central nervous system depressants, prolonged or difficult labor and delivery, airway and respiratory muscle weakness, septicemia, metabolic disorders, and central nervous system disorders.

Emergency care for an infant with prolonged apnea begins with stimulating the infant to breathe. This is done by flicking the soles of the feet or rubbing the back. If needed, a bag device (with a disabled pop-off valve) should be used, while applying the least amount of pressure that produces adequate chest rise. The paramedic should suction secretions from the infant's airway as needed and maintain the infant's body temperature to prevent hypothermia. Endotracheal intubation and circulatory support may be required if central cyanosis persists despite adequate ventilations. Drug therapy that may be appropriate in managing some infants with prolonged apnea includes ***dextrose*** (10% dextrose in water), if hypoglycemia is confirmed. Another is ***naloxone*** for reversal of respiratory depression in a newborn whose mother received narcotics within 4 hours of delivery.[1] (As discussed earlier, narcotic antagonists should not be given to the infant if the mother is a drug abuser. Doing so may induce drug withdrawal in the neonate.) Apnea that is treated early and aggressively normally results in a good outcome.

Bradycardia

Bradycardia is described as a heart rate less than 100 beats/min. In the neonate, bradycardia most commonly is caused by hypoxia. It also may result from increased intracranial pressure, hypothyroidism, acidosis, and congenital AV nodal block in infants of mothers who have systemic lupus erythematosus. Other risk factors include prolonged suctioning and the use of airway or any invasive procedures during resuscitation that may cause vagal stimulation (e.g., inadequately secured ET tube movement). Bradycardia is a minimal risk to life in neonates if it is corrected quickly.

The initial management for a neonate with bradycardia is to assess for upper airway obstruction. Such obstruction may be caused by airway secretions, foreign body, or the position of the tongue or soft tissues of the neck. Prehospital care to improve ventilation may include airway positioning, suction, positive-pressure ventilation with supplemental oxygen, and tracheal intubation. The paramedic should monitor ventilatory and circulatory status of the infant closely. This will determine the need for more advanced life support measures. Such measures may include chest compressions and drug therapy (described later in this chapter and in Chapter 48: Pediatrics).

Prematurity

A **premature infant** (*preemie*) refers to a baby who is born before 37 weeks' gestation. (The weight of these newborns often is between 0.6 and 2.2 kg [from 1½ to 5 lb].) Healthy premature infants who weigh more than 1700 g have a survivability and outcome about equal to those of full-term infants. The mortality rate decreases weekly with gestation beyond the onset of fetal viability (currently around 23 to 24 weeks' gestation).[4] Premature infants have an increased

risk for respiratory depression, hypothermia, and brain injury from hypoxemia. They are also especially vulnerable to changes in blood pressure, intraventricular hemorrhage, and fluctuations in serum chemistry, such as changes in blood glucose and electrolyte levels. The degree of immaturity determines how the infant appears physically (based on maternal dates, expected date of confinement, size for gestational age). However, most premature infants will have a large trunk, short extremities, less subcutaneous fat than full-term infants, and skin that appears translucent. Premature infants have some telltale physical findings. These include lanugo (Fig. 47-16) and characteristic changes in the ears (Fig. 47-17) and in muscle tone (Fig. 47-18). Risk factors for prematurity are listed in Box 47-5.

The prehospital care for premature infants is the same as for any other newborn. It may include airway, ventilatory, and circulatory support. *The paramedic should attempt resuscitation if the infant has any signs of life.* Special care must be taken to maintain the infant's body temperature and to prevent hypothermia. Examples include wrapping the baby in food-grade resistant plastic and the application of radiant heat.[1] Transport to a facility with special services for low-birth-weight newborns may be indicated.

FIGURE 47-16 Infants at gestational age 20 to 28 weeks are covered with fine hair all over the body called lanugo. (From Gorrie T, McKinney E, Murray S: *Foundations of maternal newborn nursing,* Philadelphia, 1994, WB Saunders.)

DID YOU KNOW?

Dubowitz Score

The **Dubowitz score** or scale is a method of clinical assessment in the newborn from birth to 5 days old. The score includes 10 neurological signs for the infant's maturity and 12 physical signs (external signs of development) to determine apparent gestational age.[20] The two scores are added. The minimum score is 0. The maximum score is 72. Typically, the more neurologically mature, the higher the score.

NOTE

Concern for eye damage (retinopathy of prematurity) from long-term oxygen use in premature infants is not a consideration in the emergency setting. Hypoxemia causes irreversible brain damage in these newborns. High-concentration oxygen is indicated.

Respiratory Distress and Cyanosis

Prematurity is the most common cause of respiratory distress and cyanosis in the neonate. These conditions occur most often in infants less than 1200 g (2½ lb) and less than 30 weeks' gestation.[4] These problems may be related to the infant's immature central respiratory control center. The center is affected more easily by environmental and metabolic changes than that of the full-term infant. Other

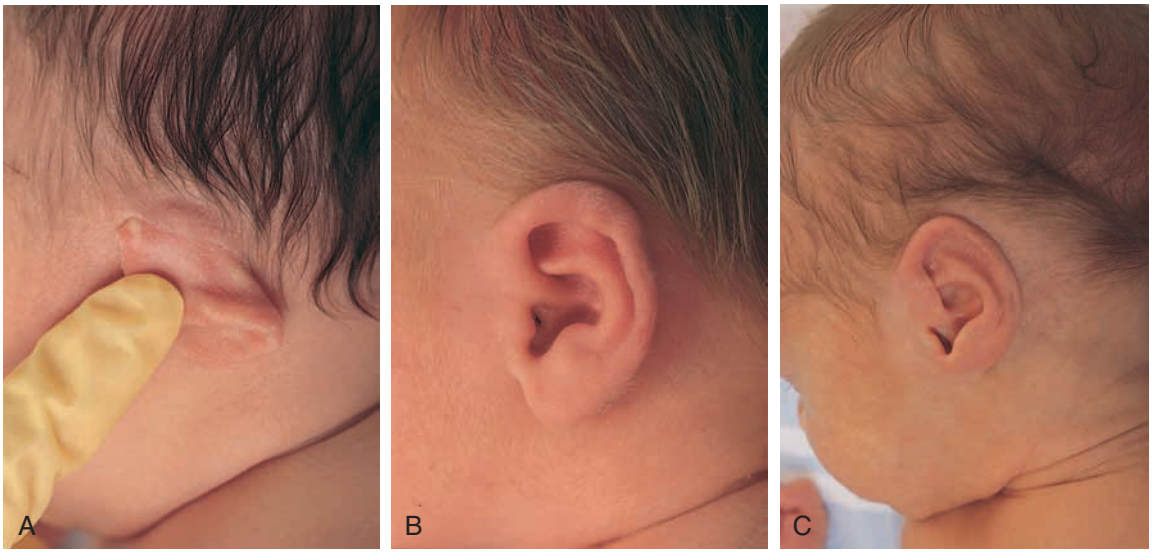

FIGURE 47-17 Ear maturation. **A** and **B,** Full-term infant. **C,** Preterm infant. (From Gorrie T, McKinney E, Murray S: *Foundations of maternal newborn nursing,* Philadelphia, 1994, WB Saunders.)

FIGURE 47-18 **A,** The term newborn shows flexion of the arms and legs. Note the acrocyanosis of the hands and feet. **B,** The preterm newborn holds extremities in extension, exposing more of the body surface area to the environment. This factor contributes to the development of cold stress and difficulty with thermoregulation. (From Leifer G: *Maternity nursing: an introductory text*, ed 10, St Louis, 2010, Saunders.)

BOX 47-5 Risk Factors for Prematurity

Factors Related to Comorbidity
Trauma
Neonatal sepsis
Maternal infection
Urinary tract infection
Chorioamnionitis (inflammation of fetal membranes)
Illness resulting in dehydration

Congenital Anomalies
Genetic disorders
Congenital malformations
Congenital heart defect
Spina bifida
Placental insufficiency
Oligohydramnios (deficiency of amniotic fluid)
Polyhydramnios (excess amniotic fluid)

Previous Premature Deliveries
Incompetent cervix
Relative large fetal size

Multiple Gestation
Eclampsia
Preeclampsia
Gestational hypertension

risk factors for respiratory distress and cyanosis in the neonate include multiple gestations, prenatal maternal complications, and infants born with the following conditions:

- Birth defects
- Central nervous system disorders
- Diaphragmatic hernia
- Esophageal atresia
- Lung immaturity
- Lung or heart disease
- Meconium or amniotic fluid aspiration
- Metabolic acidosis
- Mucous obstruction of nasal passages
- Pneumonia
- Primary pulmonary hypertension
- Shock and sepsis
- Tracheoesophageal fistula

Respiratory distress and cyanosis can lead to cardiac arrest in the neonate. The situation necessitates immediate actions to improve breathing and support respirations. Assessment findings may include tachypnea, paradoxical breathing, intercostal retractions, nasal flaring, expiratory grunting, and central cyanosis. As described earlier, respiratory insufficiency in the neonate generally is managed with stimulation, positioning of the airway, prevention of heat loss and hypothermia, oxygenation and ventilation, and suction and intubation with ventilatory support (if needed).

Hypovolemia

Hypovolemia in infants may result from dehydration, hemorrhage, trauma, or sepsis. It also may be associated with myocardial dysfunction. Signs and symptoms of hypovolemia include mottled or pale color, cool skin, tachycardia, diminished peripheral pulses, and delayed capillary refill despite normal ambient temperature. Shock may be present despite a normal blood pressure. Prompt and effective treatment of early signs of compensated shock may prevent the development of hypotension (decompensated shock) and associated high morbidity and mortality.[2] Prehospital

BOX 47-6 Causes of Neonatal Seizures

- Developmental abnormalities
- Drug withdrawal
- Hypoglycemia
- Hypoxic-ischemic encephalopathy
- Intracranial hemorrhage
- Meningitis or encephalopathy
- Metabolic disturbances

care is always directed at ensuring adequate airway, ventilatory, and circulatory support (including control of external hemorrhage) and providing rapid transport to an appropriate facility.

When signs of hypovolemia are present, the paramedic should give a fluid bolus (10 mL/kg over 5 to 10 minutes of isotonic crystalloid) immediately after obtaining IV access, and then reassess the infant. If signs of shock persist, the paramedic should give a second 10 mL/kg bolus. Further boluses should be given as needed and under the guidance of medical direction.

Seizures

Seizures occur in a small percentage of newborns. When present, they usually are a sign of an underlying abnormality (Box 47-6). Prolonged seizures or frequent seizures may result in metabolic changes and cardiopulmonary difficulties.

TYPES OF SEIZURES

Seizures in neonates usually are fragmented and not well sustained. They have been classified as subtle seizures, tonic seizures, multifocal seizures, focal clonic seizures, and myoclonic seizures.[4]

Subtle seizures involve eye deviation, blinking, sucking, swimming movements of the arms, and peddling movements of the legs. Apnea may be present during subtle seizures. *Tonic seizures* usually involve extension of the limbs. Less often, they involve flexion of the upper extremities and extension of the lower extremities. This type of seizure is more common in infants who are premature, especially in infants with intraventricular hemorrhage. *Multifocal seizures* usually involve clonic activity in one extremity that may migrate randomly to another area of the body. This type of seizure mainly occurs in full-term infants. *Focal clonic seizures* involve clonic, localized jerking. They have been known to occur in full-term and premature newborns. *Myoclonic seizures* involve flexion and jerking of the upper or lower extremities. These seizures may occur singly. They also may occur in a series of repetitive jerking cycles.

Emergency care for managing neonatal seizures includes providing airway, ventilatory, and circulatory support and maintaining the infant's body temperature. As described in Chapter 25, drug therapy that may be prescribed by medical direction includes ***dextrose*** to treat hypoglycemia, anticonvulsant agents, and perhaps benzodiazepines (for status epilepticus). Seizure activity is always considered pathological; rapid transport for physician evaluation is needed.

LOOK AGAIN
See Chapter 25: Neurology, pp. 785-788.

Fever

Fever in neonates is described as a rectal temperature greater than 100.4° F (38.0° C). Fever in neonates usually is a cause for concern and often is a response to an acute viral or bacterial infection. Fever also may result from a change in the infant's limited ability to control body temperature or be an effect of dehydration. The rise in core temperature increases oxygen demands and increases glucose metabolism. These increases may lead to metabolic acidosis. Assessment findings may include mental status changes (e.g., irritability and lethargy), a history of decreased intake, rashes and petechiae, and warm or hot skin.

NOTE
Term newborns produce beads of sweat on their brow but not over the rest of their bodies. Premature infants generally have no visible sweat.

The prehospital care for febrile infants mainly is supportive. As a rule, cooling procedures and the use of antipyretics will be delayed until the child has arrived at the hospital. Febrile seizures usually affect children between 6 months and 5 years of age. Generally they are not a concern in caring for the neonate (see Chapter 48). All febrile neonates require immediate transport for physician evaluation. These patients should be presumed to have systemic sepsis until it is proved otherwise.

Hypothermia

As described in Chapter 45, hypothermia is a core body temperature below 95° F (35° C). Hypothermia may result from a decrease in heat production, an increase in heat loss (through evaporation, conduction, convection, or radiation), or a combination of both. Neonates are sensitive to the effects of hypothermia because of their increased surface-to-volume ratio. This is especially the case when they are wet (e.g., after delivery). The associated increase in metabolic demand to maintain body temperature can cause metabolic acidosis, pulmonary hypertension, and hypoxemia. Hypothermia also may be a sign of sepsis in the neonate. Assessment findings may include the following:

- Pale color
- Cool skin (especially in the extremities)
- Respiratory distress
- Apnea
- Bradycardia
- Central cyanosis
- Acrocyanosis (cyanosis of the extremities)
- Irritability (initially)
- Lethargy (in the late stage)
- Absence of shivering (variable)

The prehospital care for these patients may include provision of basic and advanced cardiac life support. (This depends on the severity of hypothermia.) The care also

consists of rapid transport to an appropriate facility. Other therapeutic measures include ensuring that the infant is dry and warm, warming the hands before touching the newborn, and perhaps administering ***dextrose*** to treat hypoglycemia and IV therapy with warm fluids. The patient should be transported in a heated ambulance (76° to 80° F [24° to 26.5° C]).

Hypoglycemia

A blood glucose measurement less than 40 mg/dL in the infant indicates hypoglycemia (described in Chapter 26).[1] The condition should be determined by blood glucose screening on all sick infants. Hypoglycemia may be due to inadequate glucose intake or increased use of glucose. Risk factors associated with hypoglycemia include asphyxia, toxemia, being the smaller twin, central nervous system hemorrhage, and sepsis. Assessment findings may include the following:

- Twitching or seizure
- Limpness
- Lethargy
- Irritability
- Eye rolling
- High-pitched crying
- Apnea
- Irregular respirations
- Cyanosis (possibly)

NOTE

Small infants and chronically ill children have limited glycogen stores. These may be depleted rapidly during stress events. If allowed to persist, hypoglycemia can depress myocardial function. Hypoglycemia may have catastrophic effects on the brain as well.

The prehospital care is directed at ensuring adequate airway, ventilatory, and circulatory support; maintaining body temperature; providing rapid transport; and perhaps IV administration of ***dextrose 10%*** (per medical direction) (Box 47-7). The paramedic should check the glucose level again if the infant fails to respond to initial resuscitative measures. All infants who do not respond normally and those who are hypoglycemic and fail to respond to the ***dextrose*** should be transported immediately to a medical facility.

Vomiting and Diarrhea

Occasional vomiting or diarrhea is not unusual in the neonate. For example, vomiting mucus (that may be streaked with blood) is common in the first few hours of life. Also, five to six stools per day is considered normal, especially if the infant is breastfeeding. Persistent vomiting and/or diarrhea, however, should be considered warning signs of serious illness.

VOMITING

Persistent vomiting in the first 24 hours of life suggests an obstruction in the upper digestive tract or perhaps increased intracranial pressure. Vomit that contains non–bile-stained fluid is a sign of anatomical or functional obstruction. This obstruction is at or above the first portion of the duodenum. Vomiting also may indicate gastroesophageal reflux. Bile-stained vomit may result from obstruction below the opening of the bile duct. Vomit that contains dark blood usually is a sign of life-threatening illness. Assessment findings may include a distended stomach and signs of infection, dehydration, and increased intracranial pressure. The paramedic also should consider that the vomiting may be a result of drug withdrawal (from the mother's drug use).

The prehospital care usually requires maintaining an airway that is clear of vomit and ensuring adequate oxygenation. In severe cases, medical direction may advise that IV fluid therapy be started before transport. Fluid therapy treats dehydration and any bradycardia that may develop from vagal stimulation. If possible, infants should be transported on their sides. This will help prevent aspiration.

DIARRHEA

Persistent diarrhea can lead to serious dehydration and electrolyte imbalance in the neonate. The diarrhea often is associated with a bacterial or viral infection. Other possible causes include the following:

- Bacterial enteritis (*Clostridium difficile, Salmonella, Shigella*)
- Cystic fibrosis
- Lactose intolerance
- Neonatal abstinence syndrome (drug withdrawal)
- Phototherapy (a treatment for hyperbilirubinemia and jaundice in the newborn)
- Thyrotoxicosis
- Viral gastroenteritis (rotavirus)

Assessment findings often include the presence of loose stools, decreased urinary output, and signs of dehydration. Treatment consists of supporting the infant's vital functions, IV fluid therapy (per medical direction), and rapid transport to the receiving hospital.

Common Birth Injuries

Significant birth injury accounts for less than 2% of neonatal deaths and stillbirths in the United States. Of every 1000 live births, there is an average of 6 to 8 injuries. In general, larger infants are more susceptible to birth trauma. Higher rates are reported for infants who weigh more than 4500 g.[21]

BOX 47-7 Glucose Administration

Dose: 0.5 to 1.0 g/kg intravenously over 20 minutes

Preparation: Dilute dextrose 50% 1 : 1 with sterile water, resulting in 25% dextrose in water solution; administer 2 to 4 mL/kg.

or

Dilute dextrose 50% 1 : 4 with sterile water, resulting in 10% dextrose in water solution; administer 5 to 10 mL/kg.

Precautions: Hypertonic glucose is hyperosmolar and may sclerose peripheral veins.

Note: Some sterile water has preservatives containing alcohol. This solution should not be used. It can cause profound hypoglycemia and death when administered to infants.

An uncontrolled, explosive delivery (described in Chapter 46) is the greatest risk factor for birth injuries. Cranial injuries may include molding of the head and overriding of the parietal bones, soft tissue injuries from forceps delivery, subconjunctival and retinal hemorrhage, subperiosteal hemorrhage, and skull fracture. Intracranial hemorrhage can occur from trauma or asphyxia. Spine and spinal cord injury can result from strong traction or a lateral pull during delivery. Other birth injuries include peripheral nerve injury, liver or spleen injury, adrenal hemorrhage, clavicle or extremity fracture, and brain or soft tissue injury from hypoxia-ischemia. The assessment findings vary by the nature of the injury. They may include the following:

- Diffuse, sometimes ecchymotic, edematous swelling of the soft tissues of the scalp
- Paralysis below the level of spinal cord injury
- Paralysis of the upper arm with or without paralysis of the forearm
- Paralysis of the diaphragm
- Movement on only one side of the face when the newborn cries
- Inability to move the arm freely on the same side of a fractured clavicle
- Lack of spontaneous movement of an injured extremity
- Hypoxia
- Shock

The goal of prehospital care for an infant with a birth injury is to support the newborn's vital functions. This can be done by ensuring adequate oxygenation, ventilation, and circulatory support and administering fluid or drug therapy (if indicated). These infants are high-risk newborns. They require rapid transport to a proper medical facility.

Neonatal Resuscitation, Postresuscitation, and Stabilization

A neonate's heart generally is healthy and strong. However, disorders in the conduction system of the heart can and do occur. Most often the disorders occur as a result of hypoxemia and respiratory arrest. The outcome for these infants is poor if interventions are not initiated quickly. In addition, the likelihood for brain and organ damage is increased in infants who require resuscitation. The paramedic should continually assess and monitor neonates with respiratory distress for treatable causes of the distress.

Asystole and pulseless cardiac arrest are uncommon in the neonate. Like bradycardia, they usually are the result of hypoxia. Cardiac arrest also can be caused by primary and secondary apnea, unresolved bradycardia, and persistent fetal circulation (persistent pulmonary hypertension). Assessment findings may include peripheral cyanosis, inadequate respiratory effort, and ineffective or absent heart rate. Risk factors associated with cardiac arrest in the newborn include the following:

- Congenital malformations
- Congenital neuromuscular disease
- Drugs administered to or taken by the mother
- Intrapartum hypoxemia
- Intrauterine asphyxia

Emergency care for neonates with asystole or pulseless arrest was described earlier in this chapter and includes airway, ventilatory, and circulatory support; pharmacological therapy; and rapid transport to an appropriate medical facility.

NOTE

The decision to withhold resuscitation or to discontinue resuscitative efforts in the prehospital setting must be guided by medical direction. Infants without signs of life (no pulse or respiratory effort) after 10 minutes of resuscitation show either a high mortality or severe neurodevelopmental disability. Therefore, after 10 minutes of continuous and adequate resuscitative efforts, the discontinuation of resuscitation may be justified if there are no signs of life. Decisions to continue resuscitation beyond 10 minutes should be guided by medical direction. Factors that should be considered include presumed cause of the arrest, gestation of the baby, the presence or absence of complications, the potential role of therapeutic hypothermia, and the parents' wishes.[1]

CRITICAL THINKING

How will you feel if you deliver a critically ill or dead infant?

PSYCHOLOGICAL AND EMOTIONAL SUPPORT

The paramedic must be aware of the normal feelings and reactions of parents, siblings, other family members, and caregivers while providing emergency care to an ill or injured child. (These events also are often highly charged and emotional for the emergency crew.) The paramedic should keep those at the scene abreast of all procedures being performed and should inform family members of the necessity of the procedures.

NOTE

After delivery, the mother continues to be a patient herself. She still has certain physical and emotional needs.

As a rule, emergency responders should never discuss the infant's chances of survival with a parent or family member. They also should not give false hope about the infant's condition. The paramedic should assure the family that everything that can be done for the child is being done. The paramedic also should assure the family that their baby will receive the best possible care during transport and at the hospital. The hospital will have support personnel who can assist family members and loved ones.

SUMMARY

- Low birth weight and a variety of antepartum and intrapartum risk factors affect the need for resuscitation.
- Some of the more common congenital anomalies include choanal atresia, tracheobronchial fistula and atresia, Pierre Robin syndrome, cleft lip and cleft palate, congenital heart anomalies, pyloric stenosis, diaphragmatic hernia, omphalocele, and spina bifida.
- At birth, newborns make three major physiological adaptations necessary for survival: (1) emptying fluids from their lungs and beginning ventilation, (2) changing their circulatory pattern, and (3) maintaining body temperature.
- The initial steps of neonatal resuscitation (except for those born through meconium) are to prevent heat loss, clear the airway by positioning and suctioning, provide tactile stimulation and initiate breathing if necessary, and further evaluate the infant.
- If neonatal resuscitation is needed the paramedic should reevaluate the initial steps of stabilization (warm, position, clear airway, dry, stimulate, reposition). If there is no change, resuscitation proceeds in 30-second increments with ventilation, chest compressions, and, if needed, epinephrine administration.
- The three most common complications during the postresuscitation period are endotracheal tube position change (including dislodgment), tube occlusion by mucus or meconium, and pneumothorax. During transport of the neonate, it is important to maintain body temperature, oxygen administration, and ventilatory support.
- Specific situations that may require advanced life support for the neonate include meconium staining, apnea, diaphragmatic hernia, bradycardia, premature infants, respiratory distress and cyanosis, hypovolemia, seizures, fever, hypothermia, hypoglycemia, vomiting and diarrhea, and birth injuries.
- Primary apnea is common immediately after birth and is self-limiting. Secondary apnea is a pause in breathing that exceeds 20 seconds.
- Bradycardia is a heart rate less than 100 beats/min. It is most often caused by hypoxia.
- Premature infants have an increased risk of respiratory suppression, hypothermia, and head and brain injury. In addition to low birth weight, various antepartum and intrapartum risk factors may affect the need for resuscitation.
- Prematurity is the most common cause of respiratory distress in the neonate.
- Hypovolemia in infants may result from dehydration, hemorrhage, trauma, or sepsis.
- Seizures in the newborn signal an underlying abnormality.
- A temperature greater than 100.4° F (38.0° C) is a fever and often signals viral or bacterial infection.
- Hypothermia is a core body temperature below 95° F (35° C). It increases metabolic demand and can cause metabolic acidosis, pulmonary hypertension, and hypoxemia.
- Blood glucose level less than 40 mg/dL indicates hypothermia in the neonate.
- Injuries at birth may include cranial trauma, intracranial hemorrhage or brain injury, spine and spinal cord injury, peripheral nerve injury, spleen or liver injuries, fractures or soft tissue injury.
- The paramedic should be aware of the normal feelings and reactions of parents, siblings, other family members, and caregivers while providing emergency care to an ill or injured child.

CHAPTER

48 Pediatrics

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Identify the role of the Emergency Medical Services for Children program.
2. Identify age-related illnesses and injuries in pediatric patients.
3. Outline the general principles of assessment and management of the pediatric patient.
4. Identify modifications in patient assessment techniques that assist in the examination of patients at different developmental levels.
5. Describe the pathophysiology, signs and symptoms, and management of selected pediatric respiratory emergencies.
6. Describe the pathophysiology, signs and symptoms, and management of shock in the pediatric patient.
7. Describe the pathophysiology, signs and symptoms, and management of selected pediatric dysrhythmias.
8. Describe the pathophysiology, signs and symptoms, and management of pediatric seizures.
9. Describe the pathophysiology, signs and symptoms, and management of hypoglycemia and hyperglycemia in the pediatric patient.
10. Describe the pathophysiology, signs and symptoms, and management of infectious pediatric emergencies.
11. Identify common causes of poisoning and toxic exposure in the pediatric patient.
12. Describe special considerations for assessment and management of specific injuries in children.
13. Outline the pathophysiology and management of sudden infant death syndrome.
14. Describe the risk factors, key signs and symptoms, and management of injuries or illness resulting from child abuse and neglect.
15. Identify prehospital considerations for the care of infants and children with special needs.

KEY TERMS

apparent life-threatening events Clinical events in which young infants (usually less than 6 months of age) may experience abrupt changes in breathing, color, or muscle tone.

asthma A respiratory disorder characterized by recurring episodes of paroxysmal dyspnea, wheezing on expiration caused by constriction of the bronchi, coughing, and viscous mucoid bronchial secretions.

bacterial tracheitis A bacterial infection of the upper airway and subglottic trachea; it is characterized by expiratory wheezes, respiratory distress, inflammation, and obstruction at the level of the bronchioles.

bronchopulmonary dysplasia A chronic respiratory disorder characterized by scarring of lung tissue, thickened pulmonary arterial walls, and ventilation-perfusion mismatch; often occurs in infants who have dependence on long-term artificial ventilation.

child abuse The physical, sexual, or emotional maltreatment of a child.

croup An acute viral infection of the upper and lower respiratory tract that occurs primarily in infants and young children 3 months to 3 years of age; it is characterized by hoarseness, fever, a harsh and brassy cough, inspiratory stridor, and varying degrees of respiratory distress; also known as *laryngotracheobronchitis.*

emetic center An area located in the reticular formation of the brainstem; thought to be the control center for vomiting.

epiglottitis Inflammation of the epiglottis; a severe form of the condition that affects primarily children is characterized by fever, sore throat, stridor, croupy cough, and an erythematous epiglottis.

febrile seizure A seizure that results from fever.

hydrocephalus A pathological condition characterized by an abnormal accumulation of cerebrospinal fluid, usually under increased pressure, within the cranial vault, resulting in dilation of the ventricles.

jaundice A yellow discoloration of the skin, mucous membranes, and sclerae of the eyes caused by a greater than normal amount of bilirubin in the blood.

pathological jaundice A prolonged jaundice that results from illness in the newborn and a rapid rise in serum

bilirubin concentration; usually appears within 24 hours after birth.

pertussis An acute, highly contagious respiratory disease characterized by paroxysmal coughing that ends in a loud, whooping inspiration; also known as *whooping cough*.

physiological jaundice A common jaundice that occurs during the first week of life; caused by the breakdown of fetal red blood cells, which release bilirubin into the blood, and by the immaturity of the newborn's liver, which cannot effectively metabolize the bilirubin and prepare it for excretion into the urine.

pneumonia An acute inflammation of the lungs, usually caused by inhaled pneumococci of the species *Streptococcus pneumoniae*.

shunt A tube or device surgically implanted in the body to redirect body fluid from one cavity or vessel to another.

sudden infant death syndrome The unexpected and sudden death of an apparently normal and healthy infant that occurs during sleep.

Emergencies involving pediatric patients account for fewer than 10% of emergency medical services responses.[1] However, caring for these patients has unique challenges. The challenges are related to size, physical and intellectual maturation, and diseases specific to neonates, infants, and children. This chapter addresses the anatomical and physiological changes associated with normal growth and development, medical emergencies common to children, and initial assessment and management strategies that often are critical in the patient's survival.

(Courtesy Ray Kemp, St. Charles, Mo.)

THE PARAMEDIC'S ROLE IN CARING FOR PEDIATRIC PATIENTS

Paramedics play an important role in the care of infants and children. This role involves the prehospital care and interfacility transfer. Emergency medical services personnel can help to reduce mortality and morbidity for children as well. They can become active participants in school, community, and parent education programs and provide thorough documentation appropriate for prehospital trauma registries, epidemiological research, and surveillance (see Chapter 3). For paramedics, improvement of their knowledge and clinical skills is important. They can do this through continuing education programs that are specific to the pediatric age group. A sampling of continuing education programs includes the following:

- Neonatal Resuscitation Program
- Neonatal Advanced Life Support
- Pediatric International Trauma Life Support
- Pediatric Advanced Life Support
- Pediatric Education for Prehospital Professionals
- Prehospital Pediatric Care
- Teaching Resource for Instructors of Prehospital Pediatrics

Other ways to enhance continuing education and clinical skills include reading textbooks and journals, participating in Internet study programs, attending regional conferences and seminars, and working or volunteering at pediatric emergency departments, pediatric hospitals, or a pediatrician's office.

EMERGENCY MEDICAL SERVICES FOR CHILDREN

In 1985 the Emergency Medical Services for Children (EMSC) Demonstration Program was established through grants provided by the Maternal and Child Health Bureau of the U.S. Department of Health and Human Services and by the National Highway Traffic Safety Administration, a division of the U.S. Department of Transportation. This program, which was designed to enhance and expand emergency medical services for acutely ill and injured children, defined 12 basic components of an effective Emergency Medical Services for Children system[2]:

1. System approach
2. Education
3. Data collection
4. Quality improvement
5. Injury prevention
6. Access
7. Prehospital care
8. Emergency care
9. Definitive care
10. Rehabilitation
11. Finance
12. Continual health care from birth to young adulthood

CRITICAL THINKING

Are you familiar with any Emergency Medical Services for Children injury prevention programs that are in your area?

EMSC grants and the organizational efforts aimed at improving emergency care for children have resulted in specific programs targeted to prehospital care providers. These include continuing education programs, educational resources for instructors, equipment guidelines, protocols for prehospital management, quality improvement procedures for evaluating prehospital care for children, and designation of facilities with special capabilities for pediatric care.

As stated in *Emergency medical services for children: a report to the nation,* published in 1991 by the National Center for Education in Maternal and Child Health: "The lives of many infants, children, and young adults ... can be saved through implementation of emergency medical services for children. Outcomes for critically ill and injured children can be influenced by the provision of timely care by health care professionals who are well trained and equipped for pediatric emergency and critical care."[3] In 2005 the EMSC program celebrated its twentieth anniversary. As stated in the Institute of Medicine's 2006 report *Future of emergency care, emergency care of children: growing pains*: "The program's accomplishments are numerous ... The program has broadly advanced the state of pediatric emergency care nationwide. It has improved the availability of child-size equipment in ambulances and EDs; initiated hundreds of programs to prevent injuries; and provided thousands of hours of training to EMTs, paramedics, and other emergency medical care providers ... to help achieve the program's goals. ..."[4]

GROWTH AND DEVELOPMENT REVIEW

As described in Chapter 12, children have unique anatomical, physiological, and psychological characteristics that change during their development. The following is a review of growth and development by age group. Special considerations and approach strategies that must be considered when caring for pediatric patients are provided in Box 48-1 (see Chapter 20).

LOOK AGAIN
See Chapter 20: Secondary Assessment, pp. 555-557.

CRITICAL THINKING
How comfortable are you with the "normal" well child?

Newborn (First Few Hours of Life)

Assessment and care for the newborn are described in Chapter 47. The method most commonly used to evaluate the newborn is the Apgar score. Resuscitation of the newborn (if needed) should follow the recommendations established by the American Heart Association, including those found in the curriculum for the Neonatal Resuscitation Program. To review, the newborn's heart rate during the first 30 minutes of life is between 120 and 160 beats/min. Respirations at birth are usually between 40 and 60 breaths/min. They average 30 to 40 breaths/min within a few minutes after delivery (Table 48-1). The full-term newborn normally weighs 3 to 3.5 kg (about 6 to 8 lb) (Figure 48-1).

Neonate (First 28 Days of Life)

Total body weight in the neonate may decrease 5% to 10% during the first few days of life because of the excretion of extracellular fluid. This lost weight is regained by the second week of life and generally exceeds the newborn weight. Most infants gain an average of 5 to 6 oz per week.

Neonates respond to their environment with a range of stereotypical reflexes. These reflexes are protective and include those associated with breathing, eating, and stress

TABLE 48-1 Average Vital Signs by Age Group*

Age	Pulse (beats/min)	Respirations (breaths/min)	Blood Pressure (mm Hg)
Newborn	120-160	40-60	80/40
1 year	80-140	30-40	82/44
3 years	80-120	25-30	86/50
5 years	70-115	20-25	90/52
7 years	70-115	20-25	94/54
10 years	70-115	15-20	100/60
15 years	70-90	15-20	110/64

**Note:* Normal vital signs vary with age. Carry a reminder chart to ensure accuracy. Do not depend on your memory in an emergency. Blood pressure in a child older than 1 year may be estimated with the following formula: (age in years × 2) + 70 = minimum systolic blood pressure. Example for a 3-year-old child: (3 × 2 = 6) + 70 = 76 mm Hg.

BOX 48-1 Developmental Stages and Approach Strategies for Pediatric Patients

Infants

Major Fears
Separation and strangers

Approach Strategies
Provide consistent caretakers.
Reduce parents' anxiety, because it is transmitted to the infant.
Minimize separation from parents.

Toddlers

Major Fears
Separation and loss of control

Characteristics of Thinking
Primitive
Unable to recognize views of others
Little concept of body integrity

Approach Strategies
Keep explanations simple.
Choose words carefully.
Let toddler play with equipment (stethoscope).
Minimize separation from parents.

Preschoolers

Major Fears
Bodily injury and mutilation
Loss of control
The unknown and the dark
Being left alone

Characteristics of Thinking
Highly literal interpretation of words
Unable to abstract
Primitive ideas about the body (e.g., fear that all blood will "leak out" if a bandage is removed)

Approach Strategies
Keep explanations simple and concise.
Choose words carefully.
Emphasize that a procedure will help the child be healthier.
Be honest.

School-Age Children

Major Fears
Loss of control
Bodily injury and mutilation
Failure to live up to expectations of others
Death

Characteristics of Thinking
Vague or false ideas about physical illness and body structure and function
Able to listen attentively without always comprehending
Reluctant to ask questions about something they think they are expected to know
Increased awareness of significant illness, possible hazards of treatments, lifelong consequences of injury, and the meaning of death

Approach Strategies
Ask children to explain what they understand.
Provide as many choices as possible to increase the child's sense of control.
Reassure the child that he or she has done nothing wrong and that necessary procedures are not punishment.
Anticipate and answer questions about long-term consequences (e.g., what the scar will look like and how long activities may be curtailed).

Adolescents

Major Fears
Loss of control
Altered body image
Separation from peer group

Characteristics of Thinking
Able to think abstractly
Tendency toward hyperresponsiveness to pain (reactions not always in proportion to event)
Little understanding of the structure and workings of the body

Approach Strategies
When appropriate, allow adolescents to be a part of decision making about their care.
Give information sensitively.
Express how important their compliance and cooperation are to their treatment.
Be honest about consequences.
Use or teach coping mechanisms such as relaxation, deep breathing, and self-comforting talk.

or discomfort. Neonates sleep an average of 16 to 18 hours per day, with sleep and wakefulness evenly distributed over 24 hours. Infants are *obligate nose breathers* (breathing occurs mainly through the nose) during the first month of life. The horizontal position of the ribs produces the characteristic diaphragmatic breathing in this age group. Although crying is common in the neonate, the crying gradually decreases throughout infancy. Persistent crying may indicate physiological distress. Illnesses that may be encountered in this age group are those that cause respiratory problems, jaundice, vomiting, fever, sepsis, meningitis, and problems of prematurity (Figure 48-2).

Infant (2 to 12 Months)

During infancy, major advances in physical and mental skills occur as the brain and nervous system gradually mature. Their response to their environment evolves from reflexes of purposeful movements. During this period of

FIGURE 48-2 Neonate. (Courtesy the Sanders family, O'Fallon, Mo.)

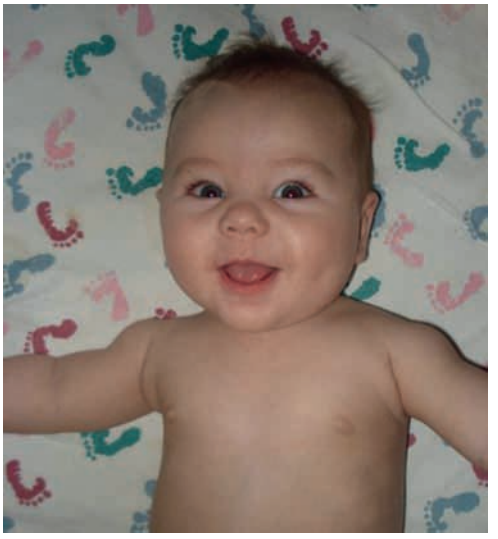

FIGURE 48-3 Infant. (Courtesy the Sanders family, O'Fallon, Mo.)

time, the musculature of the neck and back enables them to hold the head upright, sit, and babble (Figure 48-3). Between 4 and 6 months of age, most infants have doubled their birth weight, tripling it within 9 to 12 months. In the first year of life the heart also doubles in size, the heart rate gradually slows, and blood pressure begins to increase.

By 12 months of age the development of mature nerves is nearly complete and, along with muscle strength, enables many infants to stand and walk with little or no assistance. (Muscle weight in infants is about 25% of the entire musculoskeletal system.)

Common illnesses typically affect the respiratory, gastrointestinal, and central nervous systems. They manifest themselves as respiratory distress; nausea, vomiting, and diarrhea with dehydration; and seizures, respectively. Other illnesses that may be encountered in this age group include sepsis, meningitis, and sudden infant death syndrome (SIDS). (SIDS is also known as *sudden unexpected death in infancy*.) In addition, the older infant (6 to 12 months of age) may experience bronchiolitis, croup, foreign body airway obstruction, and physical injury from sexual abuse, neglect, falls, and motor vehicle crashes.

FIGURE 48-4 Toddlers.

Toddler (1 to 3 Years)

Muscle mass and bone density increase during the toddler years (Figure 48-4). Most children gain an average of 2 kg (about 4 lb) each year. By age 2 years, much of the nervous system is fully developed. By this time, basic motor skills (e.g., balance and walking) and fine motor skills (e.g., stacking building blocks) also become visible. In addition, most children are capable of controlling bladder and bowel function by 2 to 3 years of age. By 2 years of age, toddlers have developed unique personality traits, moods, and specific likes and dislikes. Basic language skills are mastered by age 3. However, these skills continue to be refined through childhood. By 3 years of age toddlers and preschoolers also begin to recognize the difference between the sexes and start to model themselves after persons of their own gender. Illnesses in this age group may cause respiratory distress (e.g., from asthma, bronchiolitis, foreign body aspiration, or croup), vomiting and diarrhea with dehydration, febrile seizures, sepsis, and meningitis. Toddlers who are learning to walk are prone to falls. They also may find themselves in dangerous environments without proper supervision or barriers (e.g., baby gates). Physical injuries also occur from poisonings from accidental ingestions, physical/sexual abuse, drowning, and motor vehicle crashes (Table 48-2).

Preschooler (3 to 5 Years)

During the preschool years, children experience advances in gross and fine motor skills (Figure 48-5). Peer relationships also begin to form with other children near the same age and level of maturity. These relationships often begin with play that involves acting out fantasies or using imagination for new situations, all of which can lead to problem-solving skills and cognitive development. Illnesses and injuries that may be encountered in this age group include

FIGURE 48-5 Preschooler. (Courtesy Norma Boozer, Florissant, Mo.)

those mentioned before for toddlers. As a result, preschoolers are more likely to experience injuries from thermal burns and pedestrian accidents, and be victims of submersion incidents or drowning. Preschoolers are curious and often have an urge to explore. Many have a minimal concept of danger.

School Age (6 to 12 Years)

The growth of school-age children is slower and steadier than during the infancy, toddler, and preschooler years (Figure 48-6). Most children gain about 3 kg (6.6 lb) per year. They average a yearly gain in height of about 2½ inches (6 cm). Most bodily functions reach adult levels in this age group. Two key areas of development during the school-age years include an increased ability to concentrate and learn quickly and the onset of puberty. Psychosocial development of school-age children varies by individual. As a rule, however, self-concept and moral traits and behavior begin to emerge during the school-age years. During these years, children spend more time with others outside their immediate family. Most illnesses in school-age children are caused by viral infection. Injuries become more common in this age group because of increased physical activity. These injuries include injuries from bicycle crashes, fractures from falls, and sport-related injuries.

NOTE

About 40,000 to 50,000 children are estimated to be injured permanently each year, and at least 1 million seek medical care because of unintentional injuries (the leading cause of death in children).[5]

Adolescent (13 to 18 Years)

During adolescence, the final phase of change in growth and development occurs (Figure 48-7). Organs rapidly increase in size, blood chemistry values become nearly equal to adult

FIGURE 48-6 School-age child. (Courtesy Stephanie Gates, Indianapolis, Indiana.)

FIGURE 48-7 Adolescent. (Courtesy the Sanders family, O'Fallon, Mo.)

levels, and growth of bone and muscle mass becomes nearly complete. Also in adolescence a person reaches reproductive maturity. With the development of secondary sex characteristics in both genders comes a final period of rapid growth. Most boys gain an average of 8 inches in height before age 21, when growth usually stops. Growth in girls is less dramatic and is usually complete by age 18.

Along with the physical changes associated with adolescence, most teenagers begin to experiment with different

identities. They begin to develop their personality into that of an adult. Many make dramatic moves away from parents and family members toward their peer groups. In their peer groups, they may experiment with alcohol and other drugs, sex, and extreme forms of behavior. In addition to those physical injuries mentioned for younger age groups, in this age group the paramedic may encounter behavioral emergencies associated with alcohol or other drug use, eating disorders, depression, suicide and suicide gestures, sexually transmitted diseases, pregnancy, and sexual assault.

ANATOMY AND PHYSIOLOGY REVIEW

As stressed throughout this text, physical differences in infants and children set them apart from the adult patient. The following is a review of anatomy and physiology by body region. Also included are special emergency care implications for the pediatric patient.

Head

Up until the age of 8 years, a child's head is proportionally large. It accounts for about 25% of the total body weight in newborns. Children also have a larger occipital region and a smaller face relative to adults. Because of these anatomical features, a high percentage of blunt trauma in children involves the head and face. The prominent occiput of the child predisposes the neck to slight flexion when the child is placed on a flat surface. To prevent this, a spine board with an occipital well or blankets placed under the child's torso should be used to maintain a neutral position of the neck.[1]

To accommodate for brain growth in the infant, the anterior fontanelle remains open for 9 to 18 months after birth. The anterior fontanelle is usually level or slightly below the surface of the skull. A tight or bulging fontanelle suggests increased intracranial pressure (ICP; as seen with meningitis or brain injury); a sunken fontanelle indicates possible dehydration. The paramedic should assess the anterior fontanelle in infants and young children who are ill or injured. The fontanelle is best assessed when the child is upright and not crying.

Airway

The airway structures of children are narrower and less stable at all levels than those of adults. This makes the airways of pediatric patients more easily blocked by secretions, obstructions, and injury or inflammation. In addition, the larynx is higher (at the level of cervical vertebrae C3 to C4) and more anterior, extending into the pharynx. The trachea is bifurcated at a higher level. The tracheal cartilage also is softer and smaller in length and diameter. The cricoid ring is the narrowest part of the airway in young children. The jaw is proportionally small, and the tongue is proportionally large. This increases the likelihood of airway obstruction by the tongue in the unconscious child. The epiglottis in infants is omega-shaped and extends into the airway at a 45-degree angle. The epiglottic folds also have softer cartilage and can become "floppy," causing airway obstruction. As described in Chapter 15 and later in this chapter, management considerations for these patients include the following:

- Placing padding under the shoulders of small children to maintain a neutral position of the airway
- Avoiding hyperflexion or hyperextension of the neck, which can obstruct the airway
- Using suction to clear the airway if secretions and particulate matter are present
- Modifying tracheal intubation techniques by ensuring a gentle touch to the soft tissue of the airway, which is easily injured and inflamed; using a straight blade that lifts the epiglottis; choosing an appropriately sized endotracheal tube; and constantly monitoring the airway for proper endotracheal tube placement with continuous capnography[6,7]

NOTE

Both cuffed and uncuffed endotracheal tubes are acceptable for intubating infants and children. Cuffed endotracheal tubes may decrease the risk of aspiration. If cuffed endotracheal tubes are used, cuff inflating pressure should be monitored and limited according to manufacturer's instructions (usually less than 20 to 25 cm H_2O).[6]

The paramedic also should remember that infants breathe mainly through the nose during the first month of life. Obstruction of the small nares by secretions can result easily in respiratory insufficiency. Thus assessment and suction of the nares as needed are important, and especially important in infants less than 6 months of age.

Chest and Lungs

In infants and young children the chief support for the chest wall comes from muscles rather than bones. These chest muscles are immature. They can fatigue easily. The use of these muscles for breathing also requires higher metabolic and oxygen consumption rates than in older children and adults. This increases the pediatric patient's susceptibility to the accumulation of lactic acid in the blood. The ribs of a child are more pliable and are positioned horizontally, and the mediastinum is more mobile. Therefore the chest wall offers less protection to internal organs. It allows for significant internal injury to occur without external signs of trauma. Rib fractures are less common in children. Yet they can occur with child abuse and other forms of trauma.

The lung tissue of a pediatric patient is fragile. Because of this and the limited protection provided by the chest wall, pulmonary contusions from trauma and pneumothorax from barotrauma are common in this age group. When evaluating a pediatric patient who has suffered major trauma, the paramedic should remember that infants and

children are diaphragmatic breathers and are prone to gastric distention; the mobile mediastinum may have a greater shift with a tension pneumothorax; and the thin chest wall easily transmits breath sounds, which may complicate the assessment of a pneumothorax or endotracheal tube placement. As a result, auscultation of breath sounds from the axillary regions in addition to the anterior and posterior thorax often is helpful.

Abdomen

Like the chest wall, the immature muscles of the abdomen in a child offer less protection to internal organs. In addition, the abdominal organs are closer together. The liver and spleen are proportionally larger and more vascular, as well. These features allow for multiple organ injuries to be more common following abdominal trauma. The liver and spleen also are injured more often than in the adult patient.

Extremities

As described in Chapter 10, bones in children are softer and more porous until adolescence. As long bones mature, hormones act on the cartilage in growing bones, replacing the soft cartilage with hard bones. Epiphyseal plates (growth plates) are located at the distal ends of the long bones. This is the area where new cartilage is laid down and ossified, thus lengthening the bones. It is a point of relative weakness. With age, long bones also thicken as additional layers of bone are laid down.

LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 153-155.

Because of the soft composition of bones in pediatric patients, at first all strains and sprains should be considered a fracture. They should be managed with full immobilization of the extremity. In addition, paramedics should be wary of injuries to the growth plate that may disrupt bone growth. Careful technique during intraosseous infusion procedures is critical. This is because improper insertion into the growth plate can affect future bone growth (see Chapter 14).

Skin and Body Surface Area

The skin in children is thinner and more elastic than the skin of adults. In addition, most children younger than 2 years of age have less subcutaneous fat.[8] The child also has a larger body surface area/body mass ratio. These factors can affect injury and illness in children in several ways. For example, the thinner skin of a child allows for deeper injury to occur from heat or cold exposure. The lack of subcutaneous fat and the larger body surface area/body mass ratio also increase a child's likelihood of hypothermia, hyperthermia, and dehydration from fluid loss.

Respiratory System

The tidal volume of infants and young children is proportionally smaller than that of adolescents and adults. The metabolic oxygen requirements for normal breathing are about double those of adolescents and adults. Pediatric patients also have smaller functional residual capacity. Thus they have proportionally smaller oxygen reserves. Because of these factors, hypoxia can develop rapidly in infants and young children. The paramedic also should remember that muscles are the main support for the chest wall. These muscles can tire easily during respiratory distress. This in turn can lead to respiratory failure and ultimately arrest. The paramedic should anticipate respiratory failure if any of the following signs are present[6]:

- An increased respiratory rate, particularly with signs of distress (e.g., increased respiratory effort including nasal flaring, retractions, seesaw breathing, or grunting)
- An inadequate respiratory rate, effort, or chest excursion (e.g., diminished breath sounds or gasping), especially if mental status is depressed
- Cyanosis with abnormal breathing despite supplementary oxygen

Cardiovascular System

Cardiac output is rate-dependent in infants and small children: The faster the heart rate, the greater the cardiac output. Children are not as able as adults to increase the contractility and stroke volume of the heart. The circulating blood volume in children is proportionally larger than that in adults. Yet the child's absolute blood volume is smaller. The ability of children to use vasoconstriction to decrease size of the vessels allows them to maintain blood pressure longer than adults. However, early intervention is required to prevent irreversible or decompensated shock. Special considerations in managing these patients include the following:

- Cardiovascular reserve is vigorous, but limited.
- Loss of small volumes of fluid and blood can cause shock.
- A child may be in shock despite a normal blood pressure.
- Bradycardia is often a response to hypoxia.

As described in Chapter 36, hypotension is a late sign of shock in the pediatric patient. Thus the assessment of shock must be based on clinical signs of tissue perfusion (e.g., level of consciousness, skin color, oxygen saturation, and capillary refill). The paramedic should suspect shock in any ill or injured child who has tachycardia and evidence of decreased perfusion. Hypotension in infants and children can be defined as a *systolic* blood pressure[6]:

- <60 mm Hg in term neonates (birth to 28 days)
- <70 mm Hg in infants (1 month to 12 months)
- <70 mm Hg + (2 × age in years) in children 1 to 10 years
- <90 mm Hg in children ≥10 years of age

Nervous System

As described in Chapter 12, the nervous system develops throughout childhood. Developing neural tissue is fragile. However, compared to adults, there is a greater cerebrospinal fluid (CSF) space around the neural tissues in children, which buffers blunt forces. Their spinal column also is more pliable. As a result, children suffer spinal cord injury less frequently than adults[9] (56% of spinal cord injuries in the United States occur between the ages of 16 and 30).[10] Children also may be free of injury, even after falls from a great distance.

The anterior and posterior fontanelles in young children remain open for 9 to 18 months after birth. Therefore direct trauma to the head can lead to brain injuries that are devastating in young children.

Metabolic Differences

The way in which children and adults expend energy differs in many ways. For example, infants and children have limited glycogen and glucose stores. Their blood glucose levels can drop quite low in response to illness or injury. Pediatric patients can experience significant volume loss from vomiting and diarrhea. Children are also prone to hypothermia because of their increased body surface area. Newborns and neonates also do not have the ability to shiver or sweat to maintain body temperature. For these reasons, it is important to assess a severely ill or injured child for hypoglycemia or hypoperfusion, to minimize heat loss, and to keep all children warm during treatment and transport.

CRITICAL THINKING
Why is it important to know what injuries and illnesses are commonly seen in specific age groups?

GENERAL PRINCIPLES OF PEDIATRIC ASSESSMENT

The general principles of assessment for the pediatric patient are very similar to those for adult patients. Approach strategies and medical equipment will differ in some ways because of the patient's age, maturity, and physical development. The following is a brief overview of the general principles of pediatric assessment, including evaluation of the scene (scene size-up), primary survey, vital functions, transition phase, focused history, secondary assessment, and reassessment. Specific differences in providing care to a child are presented later in this chapter by subject matter.

Evaluation of the Scene (Scene Size-Up)

As with all other patient care events, the paramedic should begin the physical assessment of a child with a quick scene survey, noting any potential hazards. The paramedic also should note any visible mechanism of injury or illness. For example, the presence of pills, medicine bottles, or household chemicals may indicate the possibility of toxic ingestion. Injury and a history that does not coincide with the stated mechanism of injury may indicate child abuse. In addition, the paramedic should observe the relationship between the parent, guardian, or caregiver and the child to determine the appropriateness of their interaction. For example, does the interaction demonstrate concern, anger, or indifference? Other important assessments the paramedic can make during the scene size-up include the orderliness, cleanliness, and safety of the home and the general appearance of other children in the family.

NOTE
Initial patient evaluation for children should include observing the patient and involving the parent or guardian in the assessment. The parent or guardian often can help make the child more comfortable during the assessment and can usually offer key details about the child's medical history. The parent also may know whether aspects of the child's behavior or response to the illness or injury are normal or abnormal.

CRITICAL THINKING
Would you want to make a comment to the parents about an unsafe situation on the scene before transport? Why or why not?

Primary Survey

The primary survey begins with the paramedic forming a general impression of the patient. This assessment should focus on the details most valuable for determining whether life-threatening conditions exist. The pediatric assessment triangle (Figure 48-8) is a tool that can be used to quickly assess a child. The assessment triangle has three components: appearance (mental status and muscle tone); work of breathing (respiratory rate and effort); and circulation (skin signs and skin color). If the child's condition is urgent, care should proceed with rapid assessment of airway, breathing, and circulation; management; and rapid transport. If the child's condition is not urgent, care can proceed with a focused history and detailed physical examination.

CRITICAL THINKING
Think about one abnormal finding in each area of the assessment triangle. Would any single finding influence your triage decision?

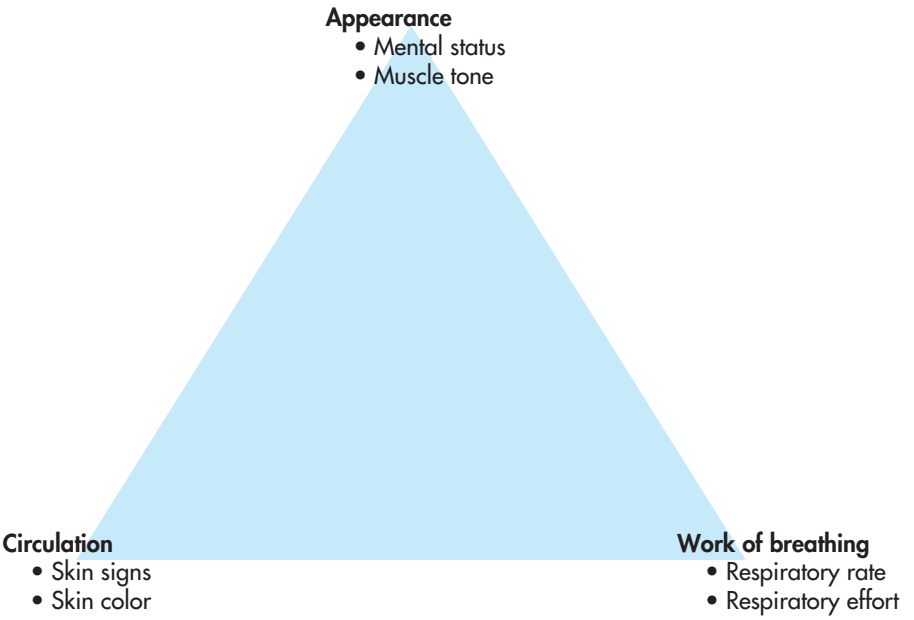

FIGURE 48-8 Pediatric assessment triangle.

Vital Functions

The AVPU scale (*alert*; responds to *verbal* stimuli; responds to *painful* stimuli; *unresponsive*) or the Modified Glasgow Coma Scale (Table 48-3) can be used to determine the child's level of consciousness and to assess for signs of inadequate oxygenation.

AIRWAY AND BREATHING

The child's airway should be patent, and breathing should proceed with adequate chest rise and fall. Signs of respiratory distress include the following:

- Abnormal breath sounds
- Absent breath sounds
- Apnea or bradypnea
- Grunting
- Head bobbing
- Irregular breathing pattern
- Nasal flaring
- Tachypnea
- Use of accessory muscles

CIRCULATION

The paramedic assesses circulation by comparing the strength and quality of central and peripheral pulses. Blood pressure should be measured in children over 3 years of age with an appropriately sized cuff, and in *all* children who are seriously ill or injured. The skin should be evaluated for color, temperature, moisture, turgor, and capillary refill. Any signs of visible hemorrhage should be noted and managed appropriately. See Table 48-1 for normal vital signs for each age group.

Transition Phase

The *transition phase* is integrated throughout assessment. This phase is used to allow the child to become more familiar with the paramedic crew and medical equipment (e.g., "get to know you" conversations and playing with stethoscope) (see Chapter 19). Use of this phase depends on the seriousness of the patient's condition and is only appropriate for a conscious child who is not acutely ill. If the patient is unconscious or acutely ill, management should proceed quickly to emergency care and transport.

Focused History

When obtaining the focused history for an infant, a toddler, or a preschooler, the paramedic often must elicit information from the parent, guardian, or caregiver. School-age and adolescent patients can provide most information by themselves. The paramedic should question patients in private (away from parents or family members) about sexual activity, pregnancy, alcohol or other drug use, or suspicion of child abuse (if appropriate for the complaint). The focused history can be obtained using the SAMPLE and OPQRST methods. (These methods are described in Chapter 18.) The paramedic should use these methods as appropriate for the patient's age. Important elements of the focused history are as follows:

1. Chief complaint
   - Nature of illness or injury
   - The length (duration) of illness or injury
   - Last meal
   - Presence of fever
   - Effects on behavior

TABLE 48-3 Pediatric Modification of Glasgow Coma Scale by Age of Patient*

Glasgow Coma Scale Score	Pediatric Modification
Eye Opening	
≥1 Year	*Birth to 1 Year*
4 Spontaneously	4 Spontaneously
3 To verbal command	3 To shout
2 To pain	2 To pain
1 No response	1 No response
Best Motor Response	
≥1 Year	*Birth to 1 Year*
6 Obeys	5 Localizes pain
5 Localizes pain	4 Flexion withdrawal
4 Flexion withdrawal	3 Flexion abnormal (decorticate)
3 Flexion abnormal (decorticate)	2 Extension (decerebrate)
2 Extension (decerebrate)	1 No response
1 No response	
Best Verbal Response	
>5 Years	*Birth to 2 Years*
5 Oriented and converses	5 Cries appropriately, smiles, coos
4 Disoriented and converses	4 Cries
3 Inappropriate words	3 Inappropriate crying/screaming
2 Incomprehensible sounds	2 Grunts
1 No response	1 No response

2-5 Years
5 Appropriate words and phrases
4 Inappropriate words
3 Cries/screams
2 Grunts
1 No response

*The Glasgow Coma Scale score is the sum of the individual scores from eye opening, best verbal response, and best motor response, using age-specific criteria. A Glasgow Coma Scale score of 13 to 15 indicates mild head injury; a score of 9 to 12 indicates moderate head injury; and a score of 8 or lower indicates severe head injury.

- Vomiting or diarrhea
- Frequency of urination

2. Medications and allergies
3. Medical history
   - Physician care
   - Chronic illnesses

Secondary Assessment

The paramedic should perform a detailed secondary assessment as described in Chapter 20. The exam should proceed from head to toe in older children. It should proceed from toe to head in younger children.[11] Depending on the patient's condition, some or all of the following assessments may be appropriate:

- *Pupils:* Are they equal and reactive to light?
- *Capillary refill* (most accurate in patients under 6 years of age): Is it less than 2 seconds (normal) or delayed?
- *Hydration:* Does the skin show normal resiliency (skin turgor)? Are there tears and saliva? Are the fontanelles in the infant sunken or flat?

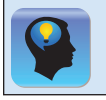
NOTE

When assessing a pediatric patient who is ill, it is important to note the presence or absence of fever, nausea, vomiting, diarrhea, and frequency of urination.

If time allows and the patient's condition warrants, noninvasive monitoring of vital signs can provide more information. Examples include the use of pulse oximetry to measure perfusion and oxygen saturation, blood pressure assessment, and measurement of body temperature. In addition, all seriously ill or injured children should receive continuous electrocardiogram monitoring. Measurement tools (e.g., blood pressure cuffs and electrodes) should be appropriate for the size of the child (Figure 48-9).

Reassessment

Reassessment should be ongoing and is appropriate for all patients. The purpose of reassessment is to monitor the patient for changes in respiratory effort, skin color and temperature, mental status, and vital signs (including pulse oximetry measurements). A key point to remember is that a child's condition can change rapidly. Thus vital signs should be assessed every 15 minutes in a child who is not critical. They should be assessed every 5 minutes in a child who is seriously ill or injured.



CRITICAL THINKING

Why is ongoing assessment critical when caring for the young child?

GENERAL PRINCIPLES OF PATIENT MANAGEMENT

The principles of patient management depend on the patient's condition. These principles may include basic airway management, advanced airway management, circulatory support, pharmacological therapy, nonpharmacological therapy, transport considerations, and psychological support, comfort measures, and communication strategies. Like the general principles of assessment discussed earlier in this chapter, the general principles of patient management for children are similar to those of adult patients. The following discussion will serve as a brief review.

Basic Airway Management

Basic and advanced airway management procedures for the pediatric patient are presented in detail in Chapter 15. These procedures may include manual positioning of the

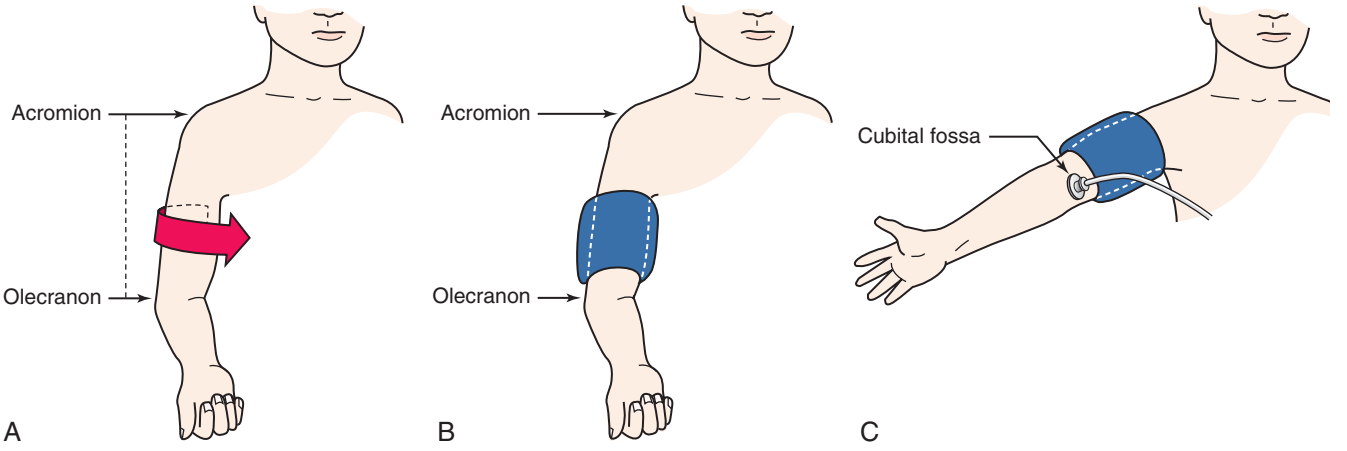


FIGURE 48-9 Determination of proper blood pressure cuff size. **A,** The cuff bladder width should be approximately 40% of the circumference of the arm measured at a point midway between the olecranon and acromion. **B,** Cuff bladder length should cover 80% to 100% of the circumference of the arm. **C,** Blood pressure should be measured with the cubital fossa at heart level. The arm should be supported. The stethoscope bell is placed over the brachial artery pulse, proximal and medial to the cubital fossa, and below the bottom edge of the cuff.

airway, removal of foreign body airway obstruction with chest compressions or abdominal thrusts, suctioning of secretions from the airway, providing supplemental oxygen, using oral or nasal airway adjuncts, and assisting ventilation with a bag-valve device.

Advanced Airway Management

Advanced airway management procedures may be needed when caring for a child who is acutely ill or seriously injured. These techniques include removing foreign body airway obstruction under direct visualization with Magill forceps, endotracheal intubation (including drug-assisted intubation), and cricothyroidotomy (per medical direction) when other methods to maintain a patent airway have failed.

Circulatory Support

Circulatory support may be required in an ill or injured child. In addition to providing basic life support with cardiopulmonary resuscitation, vascular access may be required for drug therapy and fluid resuscitation. Methods to obtain vascular access in pediatric patients are described in Chapter 14 and later in this chapter. These methods may include peripheral venous cannulation and intraosseous infusion.[6]

Pharmacological Therapy

At times, drug therapy will be required when caring for the pediatric patient. Examples include therapy for pain management; drug-assisted intubation; and patients with respiratory, cardiac, endocrinological, or neurological conditions. Drugs that are used in pediatric emergencies are described later in this chapter and in the Emergency Drug Index.

Additional Therapy

Additional therapies may be indicated depending on the type of illness or injury. These include spinal immobilization for trauma patients, hemorrhage control and bandaging and splinting, and electrical therapy (described later in this chapter). In addition, lowering body temperature with cooling methods or maintaining body temperature with blankets and warm clothing may be needed.

Transport Considerations

As described in Chapter 37, some pediatric patients will need transport to a specialty care medical facility. Examples of specialty care facilities are pediatric trauma centers, high-risk newborn care facilities, and pediatric burn centers. In addition to choosing a proper facility, the paramedic crew must consider the proper mode of caring for these patients. This includes decisions to provide rapid transport versus providing on-scene care, and the use of ground or air ambulance.

Psychological Support

It is important for the paramedic to provide psychological support to the pediatric patient and to the patient's family or caregivers. Pediatric emergencies often are emotionally charged events. Helpful strategies for approaching and communicating with pediatric patients and their caregivers are described in Chapter 17.

LOOK AGAIN
See Chapter 17: Therapeutic Communications, pp. 486-487.

SPECIFIC PATHOPHYSIOLOGY, ASSESSMENT, AND MANAGEMENT

The conditions discussed in this section are specific to major body systems and associated illness or injury. These body systems include the respiratory, cardiac, endocrine, hematological, neurological, immune, and gastrointestinal. In addition, shock, toxicology, abuse and neglect, and sudden infant death syndrome will be discussed. Other considerations for specialized care (e.g., children with cystic fibrosis, muscular dystrophy, cerebral palsy, Down syndrome) will be presented in Chapter 51.

Respiratory Compromise

Respiratory distress can be caused by many conditions that affect the upper and lower airways. These include upper and lower foreign body airway obstruction, upper airway disease (croup, epiglottitis, and bacterial tracheitis), and lower airway disease (asthma, bronchiolitis). Other causes of respiratory compromise include pneumonia, pertussis, cystic fibrosis, and bronchopulmonary dysplasia. It should be noted that most cases of cardiac arrest in children occur because of respiratory insufficiency (*asphyxial arrest*).[6] For this reason, respiratory emergencies require rapid assessment and management. The severity of respiratory compromise may be classified as respiratory distress, respiratory failure, and respiratory arrest.

NOTE

The paramedic should attempt to calm and reassure a child with respiratory compromise. It is important not to agitate the conscious patient or lay the child down (supine). Doing so may aggravate the airway condition and lead to life-threatening airway obstruction. When possible, allow the parent or other caregiver to stay with the child. The receiving hospital should be advised of the patient's status as soon as possible so that arrangements can be made for appropriate medical personnel.

Respiratory distress is the mildest form of respiratory compromise. Respiratory distress is evident by an increase in the rate and depth of breathing and by the use of accessory muscles to assist ventilation (Figure 48-10). These changes cause a slight decrease in arterial carbon dioxide levels in the blood as respiratory rate increases. As respiratory distress increases, the patient becomes exhausted. The partial pressure of carbon dioxide (P_{CO_2}) gradually increases as the patient's condition worsens. Signs and symptoms of respiratory distress include the following:

- A change in mental status from normal to irritable or anxious
- Tachypnea
- Retractions (accessory muscle use)
- Nasal flaring
- Poor muscle tone
- Tachycardia
- Head bobbing
- Grunting
- Cyanosis that improves with supplemental oxygen

If left untreated, respiratory distress may lead to respiratory failure.

Respiratory failure results from poor ventilation or lack of oxygenation. It occurs when the heart and lungs do not exchange enough oxygen and carbon dioxide. This causes a decrease in P_{O_2} and an increase in P_{CO_2} (leading to respiratory acidosis). Signs and symptoms of respiratory failure include the following:

- Irritability deteriorating to lethargy
- Marked tachypnea deteriorating to bradypnea
- Marked retractions deteriorating to agonal respirations
- Marked tachycardia deteriorating to bradycardia
- Central cyanosis

Respiratory failure in any patient is an ominous sign. Without immediate help, respiratory arrest can occur.

Respiratory arrest is the cessation of breathing. Good outcomes can be expected with early treatment that protects the airway and provides adequate ventilation and oxygenation. However, failure to treat respiratory arrest can lead to cardiopulmonary arrest. Signs and symptoms of respiratory arrest include the following:

- Unresponsiveness
- Apnea
- Absent chest wall movement
- Limp muscle tone
- Bradycardia deteriorating to asystole
- Profound cyanosis

Providing aggressive ventilatory and circulatory support for patients in respiratory distress is critical. Airway interventions may include bag-valve-mask ventilation, endotracheal intubation, gastric decompression (if abdominal distention is impeding ventilation), needle decompression for pneumothorax, and cricothyrotomy for complete upper airway obstruction that cannot be relieved by other means. The success of emergency care is indicated by an improvement in the patient's color and oxygen saturation, an improvement in the pulse rate, and an improved level of consciousness. Box 48-2 provides assessment information that is important when caring for a child with respiratory compromise.

UPPER AND LOWER FOREIGN BODY AIRWAY OBSTRUCTION

Obstruction of the upper or lower airway by a foreign body may cause a partial or full obstruction. This usually occurs in toddlers and preschoolers (1 to 4 years of age). Children develop molars around age 3, but do not chew well. As a result, obstruction often is caused by foods such as hot dogs (most common food to cause obstruction), peanut butter, hard candy, popcorn, grapes, nuts, and seeds. Other causes of upper airway obstruction include small objects such as coins and balloons. The paramedic should suspect foreign body aspiration in an otherwise healthy child with sudden onset of respiratory compromise.

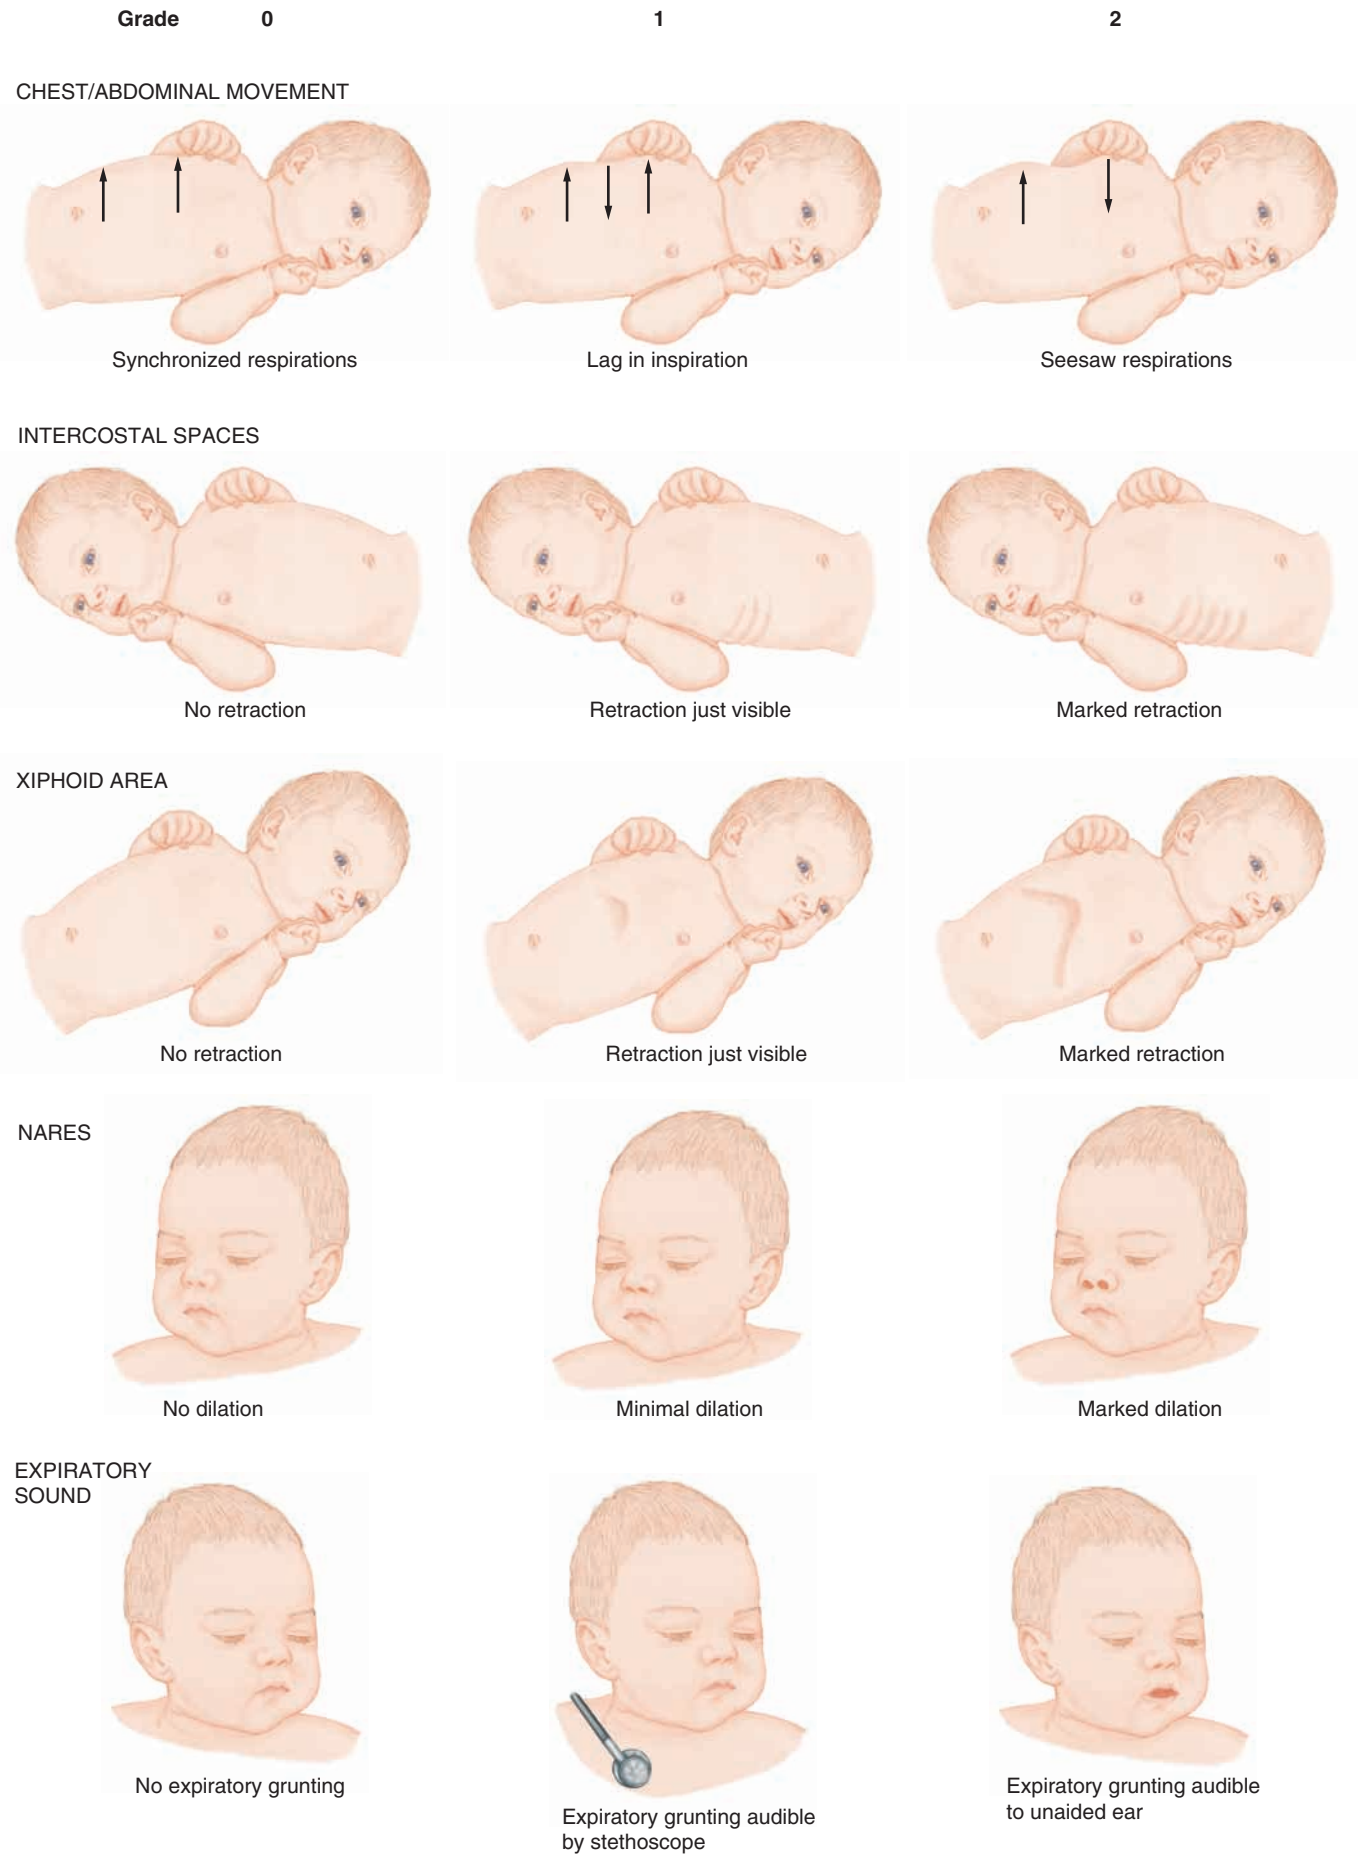

FIGURE 48-10 Assessment of respiratory distress. The Silverman-Anderson index is used to score the infant's degree of respiratory difficulty. The score for individual criteria matches the grade, with a total possible score of 10 indicating severe distress.

BOX 48-2 Assessment Information for Respiratory Compromise

History

Age
Preceding symptoms
Choking episode
Underlying disease
Recent exposure to illness
Exposure to toxins
Prematurity

Physical Findings

Mental status
Respiratory rate
Work of breathing
Presence of stridor or wheezes
Skin color
Heart rate
Tidal volume
Pulse oximetry
Capnography

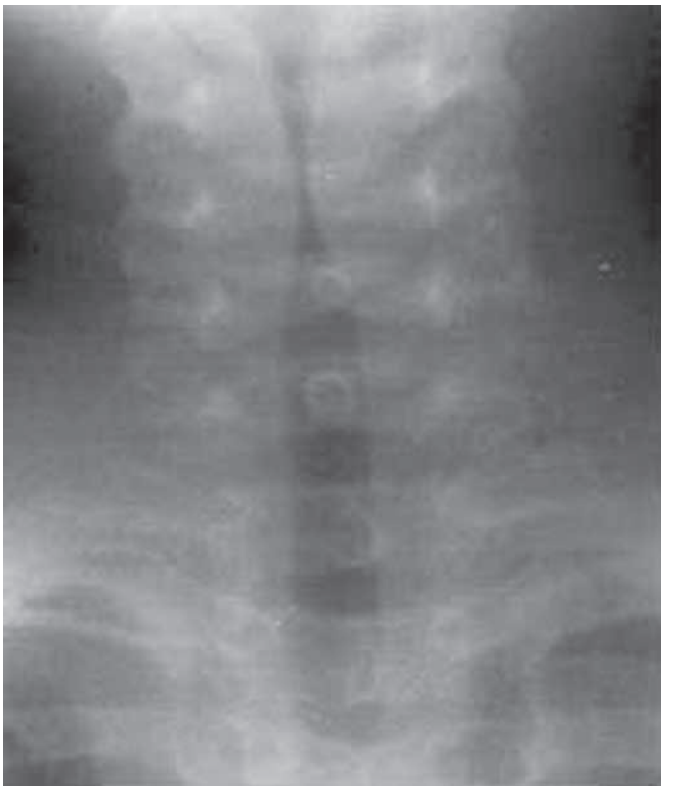

FIGURE 48-11 Frontal radiograph of neck of a child with croup. Notice the narrowing of airway showing the "steeple" sign.

NOTE

The common practice of using inflated balloons or an inflated exam glove to entertain or distract a young child while providing care should be avoided. This practice creates a choke hazard for children under 3 years of age.[12] In addition, parents and other caregivers should be advised to keep deflated balloons and broken balloon pieces away from children.

Signs and symptoms of airway obstruction include anxiety, inspiratory stridor, muffled or hoarse voice, drooling, pain in the throat, decreased breath sounds, crackles, rhonchi, and wheezing. The child may have a history of choking (observed by an adult). If a full obstruction cannot be relieved with basic and advanced methods of clearing, direct laryngoscopy to identify the obstruction and removal with McGill forceps may be indicated. Full obstruction calls for immediate intervention to relieve the obstruction. Basic and advanced methods of clearing the airway are presented in Chapter 15.

If a child with a partial obstruction is conscious and has adequate movement of air, the paramedic should not agitate the child. Rather, the paramedic should provide continuous respiratory monitoring. Also, the child should be transported immediately to the hospital. Agitation or attempts to relieve a partial obstruction may cause the foreign body to move. This may lead to full obstruction.

CROUP

Croup (laryngotracheobronchitis) is a common viral infection of the upper airway. It usually occurs in children between the ages of 6 months and 4 years. It often occurs during the late fall and early winter months. Croup usually is caused by the parainfluenza virus. However, respiratory syncytial virus, rubeola, and adenovirus also can cause croup. Croup may involve the entire respiratory tract with symptoms that are caused by inflammation in the subglottic region (at the level of the larynx extending to the cricoid cartilage) (Figure 48-11).

A child with croup usually has a history of recent upper respiratory tract infection and a low-grade fever. The patient may have hoarseness, inspiratory stridor (from subglottic edema), and a barking cough. Stridor mainly occurs on inspiration, but symptoms may be present on expiration if the lower airways are involved. However, symptoms occur mainly on inspiration. Most often, the emergency episode occurs at night after the child has gone to bed. On EMS arrival, a patient with severe croup may have all the classic signs of respiratory distress. The child may be sitting upright and leaning forward to aid breathing (variable). Also, nasal flaring, intercostal retractions, and cyanosis (a late sign of respiratory insufficiency) may be present. Children with severe croup are at risk of serious airway obstruction from the narrowed diameter of the trachea (Box 48-3).

Prehospital management of croup includes maintenance of airway, administration of cool mist or humidified or nebulized oxygen (per protocol), and transportation in a position of comfort. Symptoms may improve dramatically

BOX 48-3 Stages of Croup

Stage 1—Fever, hoarse, croupy cough, inspiratory stridor
Stage 2—Continuous stridor, intercostal retractions, labored breathing
Stage 3—Signs of hypoxia and hypercarbia with pallor, sweating, tachypnea
Stage 4—Cyanosis, apnea

Treatment

Nebulized racemic epinephrine—peak effect 20 minutes.[13] Signs and symptoms can reappear after 2 hours, when duration of effect is complete.
Cool mist therapy is controversial—not harmful as long as it does not make the child anxious.
Intubation is rarely needed.
Corticosteroids (dexamethasone) have proven to be helpful.[14]

in patients with croup after the child is exposed to cool, humidified air. (For example, this may occur after moving the patient from the residence to the emergency vehicle.) Nebulized ***racemic epinephrine*** may be used to stimulate beta2 receptors in the lungs, resulting in relaxation of the bronchial smooth muscles, thereby relieving the bronchospasm. (See the EDI.) The paramedic should make all efforts to keep the child comfortable and at ease.

EPIGLOTTITIS

Epiglottitis is inflammation of the epiglottis caused by a bacterial infection of the upper airway. Although uncommon, epiglottitis can progress rapidly and become life threatening. It can occur at any age. The disease usually is associated with *Haemophilus influenzae* type B, but *Streptococcus, Pneumococcus,* and *Staphylococcus* organisms also have been implicated. The bacterial infection causes edema and occlusion from swelling of the epiglottis and supraglottic structures (pharynx, aryepiglottic folds, and arytenoid cartilage). Epiglottitis is a true emergency. It requires prompt, expert airway management.

NOTE

The *Haemophilus influenzae* type B (Hib) vaccine has dramatically reduced the number of cases of epiglottitis in children. Before the Hib vaccine was made available in 1985, the incidence of epiglottitis was 41 cases per 100,000 persons. In recent years, this figure has declined to 0.3 cases per 100,000 persons.[15] See Appendix Figures 48-1 and 48-2 for recommended childhood and adolescent immunizations.

Epiglottitis usually begins suddenly. Typically, the child goes to bed without any symptoms and wakes up complaining of a sore throat and pain on swallowing. The child may have fever, a muffled voice (from edema of the mucosal covering of the vocal cords), and drooling from the pooled saliva that occurs because of difficult and painful swallowing (an ominous sign of impending airway obstruction). Differentiating epiglottitis from croup in the prehospital setting may be difficult. Table 48-4 lists the different characteristics of these illnesses.

TABLE 48-4 Comparison of the Symptoms of Croup and Epiglottitis

Characteristics	Croup	Epiglottitis
Occurrence	6 months to 4 years	Any age
Onset	Slow; frequently at night	Rapid
Comfortable position	Patient may lie down or sit upright	Patient prefers to sit upright
Cough	Barking cough; may have inspiratory stridor	No barking cough; may have inspiratory stridor
Drooling	No drooling	Drooling, pain on swallowing
Temperature	<104° F	>104° F
Cause	Viral	Bacterial (now uncommon because of Hib vaccination)

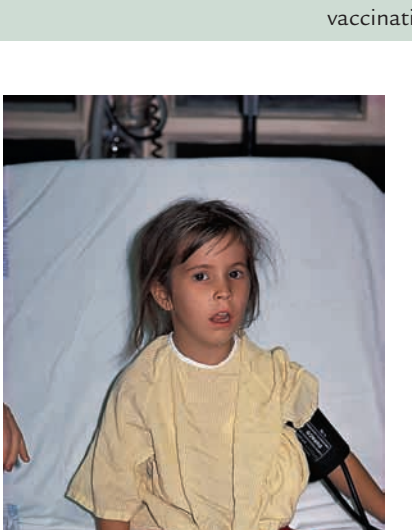

FIGURE 48-12 Acute epiglottitis at presentation.

On arrival, the paramedic usually finds a child with epiglottitis sitting upright (Figure 48-12). Often the child is leaning forward with the head hyperextended. This position aids breathing (tripod position). The tongue may be protruding, or the child may have inspiratory stridor. These children usually do not cry or struggle because all of their attention and energy is being used to maximize air exchange. Inspiratory stridor with a characteristic rattle often is present. The child also may be gasping or gulping for air.

Classic signs of respiratory distress usually are present. The preferred and definitive care for epiglottitis is in-hospital intubation and parenteral antibiotic therapy.

CRITICAL THINKING

What other childhood respiratory problems (traumatic and nontraumatic) can manifest with stridor?

Children with acute epiglottitis are in danger of full airway obstruction and respiratory arrest. Occlusion of the airway can occur suddenly. Occlusion may be caused by minor irritation of the throat, stress, and anxiety. For these reasons, gentle handling of a child suspected of having epiglottitis is essential. The following guidelines in prehospital management should be observed:

- Do not attempt to lay the child down or to change the position of comfort.
- Do not attempt to visualize the airway if the child is still ventilating adequately.
- Advise medical direction of the suspicion of epiglottitis so that appropriate personnel and resources can be made available.
- Administer 100% humidified oxygen by mask unless it provokes agitation.
- Do not attempt vascular access.
- Have the correct-sized emergency airway equipment selected and ready.
- Transport the child to the hospital in the position of comfort.

If respiratory arrest occurs before arrival at the emergency department, the paramedic must attempt intubation. The child's lungs should be hyperventilated and preoxygenated with a bag-valve device before intubation. After the airway has been established, the paramedic should obtain intravenous (IV) access if time allows.

Intubation may be difficult because the vocal cords are likely to be hidden by swollen tissues. (An uncuffed endotracheal tube one to two sizes smaller than normal may be recommended by some medical direction physicians.) The paramedic should locate the opening to the larynx by looking for mucous bubbles in the cleft between the edematous aryepiglottic folds and the swollen epiglottis. (Chest compressions during glottic visualization may produce a bubble at the tracheal opening.) In the rare instance that intubation cannot be achieved and the child cannot be ventilated adequately by a bag-valve device, medical direction may advise needle cricothyrotomy. Often a child's lungs can be ventilated through the occlusive crisis of epiglottitis by bag-valve-mask ventilation using a tight facial seal. This may call for two persons—one to maintain the seal and the other to ventilate.

BACTERIAL TRACHEITIS

Bacterial tracheitis is an uncommon infection (often caused by staphylococcus) of the upper airway and subglottic trachea that may occur after a viral illness. It generally occurs in infants and toddlers (1 to 5 years of age), but also can occur in older children. Bacterial tracheitis can lead to airway obstruction that is severe enough to cause respiratory arrest.[16] The signs and symptoms of bacterial tracheitis are those of respiratory distress or failure (depending on the severity) and may include the following:

- Agitation
- Cough that produces pus or mucus
- High-grade fever
- Hoarseness
- Inspiratory and expiratory stridor
- Throat pain

Emergency care is directed at providing airway, ventilatory, and circulatory support and rapid transport for evaluation by a physician. If airway obstruction, respiratory failure, or respiratory arrest develops, tracheal intubation is required with tracheal suction to remove mucus or pus. (Bag-valve-mask ventilation may require high pressures.) In-hospital care includes intravenously administered antibiotics that are specific for the causative organism. These will be given after the child's airway has been stabilized.

BOX 48-4 Asthma Statistics in Children

- Approximately 40% of children who have asthmatic parents will develop asthma.
- An average of 1 out of every 10 school-aged children has asthma.
- Nine million U.S. children under 18 have been diagnosed with asthma at some point in their lifetime.
- Nearly 4 million children have had an asthma attack in the previous year.
- Asthma is the third leading cause of hospitalization among children under age 15.
- In 2006, 131 children under age 15 died from asthma.[18]

ASTHMA

As described in Chapter 24, **asthma** is a chronic inflammatory disorder of the airways that may cause recurrent episodes of wheezing, breathlessness, chest tightness, and cough. Asthma is characterized by inflammation, bronchoconstriction, and mucus production that obstructs the lower airways. Asthma results from autonomic dysfunction or exposure to sensitizing agents. The hallmarks of an acute exacerbation are anxiety, dyspnea, tachypnea, and audible expiratory (and when severe, inspiratory) wheezes with a prolonged expiratory phase. (A silent chest indicates impending respiratory failure.) Asthma is common among children over 2 years of age, but can be difficult to diagnose. (Other respiratory conditions in children can cause similar signs and symptoms.) It affects about 10% of those under 10 years of age (Box 48-4). In 2008 there were an estimated 7 million children with asthma in the United States.[17] An acute exacerbation may be triggered by infection, changes in temperature, physical exercise, emotional response, and exposure to allergens.

LOOK AGAIN
See Chapter 24: Respiratory, pp. 752-755.

CRITICAL THINKING
What other signs or symptoms would lead you to believe that a child with asthma is decompensating?

The goals of prehospital management include ventilatory assistance (as needed), administration of humidified oxygen, reversal of the bronchospasm, and rapid transport for evaluation and treatment. Severe asthma may be life threatening and can progress rapidly to respiratory failure. The paramedic should be ready to initiate aggressive airway management along with ventilatory and circulatory support. Depending on local protocol, prior medication use, and the recommendations of medical direction, drug therapy may include aerosolized bronchodilators (***albuterol, ipratropium,*** or ***levalbuterol***), subcutaneously administered ***epinephrine*** or ***terbutaline*** with severe respiratory distress or failure, and sometimes corticosteroids (e.g., ***methylprednisolone***) during prolonged transports.[19] (See the Emergency Drug Index.) If the patient requires tracheal intubation, medical direction may advise the administration of ***magnesium sulfate*** and low tidal volumes (5 to 8 mL/kg) to reduce the potential for barotrauma.

BRONCHIOLITIS

Bronchiolitis (like asthma) manifests with tachypnea and wheezing. The illness is caused by viral infections that can cause inflammation of the lower airway. An example of such a virus is the respiratory syncytial virus (RSV). Bronchiolitis usually affects children under 2 years of age. It often occurs in the winter months and generally is associated with upper respiratory tract infection. Bronchiolitis sometimes is unresponsive to therapy aimed at relieving bronchospasm. Table 48-5 lists key features that may aid in the differential diagnosis.

NOTE
RSV is highly contagious, is most common in children under 1 year of age, and usually occurs epidemically in the winter months.[20]

Bronchiolitis generally is not serious and recovery is uneventful. However, sometimes it may become life threatening. Infants are at greater risk of developing respiratory failure from this condition because of the small diameter of the bronchioles. The prehospital care is aimed at providing ventilatory support with humidified oxygen. The patient should be transported rapidly for evaluation by a physician. A therapeutic trial of ***albuterol*** via nebulizer may be used as a temporary measure to reduce respiratory distress.[21]

TABLE 48-5 Differentiation of Bronchiolitis and Asthma

Clinical Features	Bronchiolitis	Asthma
Occurrence	Usually <18 months	Any age
Season	Winter, spring	Any time
Family history of asthma	Usually absent	Usually present
Cause	Virus	Allergy, infection, exercise, virus
Response to drugs	Some reversal of bronchospasm with beta agonists	Reversal of bronchospasm

Pneumonia

Pneumonia (described in Chapter 24) is an acute infection of the lower airway and lungs that involves the alveolar walls or the alveoli. Pneumonia commonly is caused by a bacterial or viral infection. Children with pneumonia may have a history of recent airway infection, such as influenza or pertussis. They also may have respiratory distress or failure (depending on the severity) and any of the following:

- Decreased breath sounds in affected area
- Fever
- Pain in the chest
- Rales localized to the affected area
- Rhonchi (localized or diffuse)
- Tachypnea

Most children with pneumonia have only mild signs and symptoms and require no immediate treatment or airway support. However, when respiratory distress is present, stabilization of the airway and provision of oxygenation are the highest priority. In severe cases, bronchodilators may be indicated. Assisted ventilations via a bag-valve device or intubation of the trachea also may be required.

Pertussis

As described in Chapter 28, pertussis primarily affects infants and young children. It is an infectious disease caused by the bacterium *Bordetella pertussis*. It is spread by direct contact with discharges from mucous membranes contained in airborne droplets. Pertussis causes inflammation of the entire respiratory tract. The major complications of pertussis in infants are pneumonia (less than 6 months of age) and apnea (less than 2 months of age). Other possible complications include weight loss, sleep disturbance, and seizures. The incidence of complications is highest in children less than 1 year of age.

Pertussis is commonly associated with episodes of violent and productive coughing with an inspiratory "whoop" or gasp. (High coughing pressure may cause pneumothorax, epistaxis, subconjunctival hemorrhage, and rib fracture.) These coughing episodes can last 1 to 2 months. Most children are vaccinated for this through a series of pertussis vaccines given in combination with diphtheria and tetanus (DPT). (See Appendix, Advanced Practice Procedures in Critical Care.) Respiratory protection for both the patient and the EMS crew is required.

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD; formerly known as *chronic lung disease of infancy*) is a rare, chronic lung disease affecting about 12,000 babies in the United States each year.[22] BPD usually occurs in premature infants who receive lung damage from oxygen toxicity and barotrauma attributable to mechanical ventilation early in life. This use of supplemental oxygen can lead to overproduction of *oxygen radicals* (agents of oxygen toxicity). These include superoxide, hydrogen peroxide, and perhydroxyl radicals. Preterm infants are particularly susceptible to oxygen radicals because the antioxidant systems are developed in the last trimester of pregnancy. Prolonged hyperoxia begins a sequence of lung injury that leads to inflammation, diffuse alveolar damage, pulmonary dysfunction, and death.[23] The classic diagnosis of BPD may be assigned at 28 days of life if the following criteria are met[24]:

- Positive-pressure ventilation during the first 2 weeks of life for a minimum of 3 days
- Clinical signs of abnormal respiratory function
- Requirements for supplemental oxygen for longer than 28 days of age to maintain PaO_2 above 50 mm Hg
- Chest radiograph with diffuse abnormal findings characteristic of BPD

Children with BPD often suffer from recurrent respiratory tract infections and exercise-induced bronchospasm. The primary goal for infants with BPD is to promote growth and development. Cornerstones of treatment are utilizing pulmonary support to maintain optimal oxygen saturation and preventing complications. In addition, nutritional support is needed to promote growth. As infants grow, lung function improves and the risk of severe cardiopulmonary complications and morbidity and mortality attributable to respiratory tract infection decline.

Treatment therapies for children with BPD may include dietary and vitamin supplementation, fluid restriction, and use of diuretics, inhaled bronchodilators, and corticosteroids. Oxygen therapy through continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP) to maintain oxygen saturation at or above 92% during eating, sleeping, and periods of crying is recommended. (Continuous pulse oximetry is often prescribed to monitor oxygen saturation levels.) While providing emergency care, airway management may include positioning of the airway, using oral or nasal adjuncts, and providing suction and assisted ventilations. In severe cases, endotracheal intubation may be required. Following stabilization, treatment of infants with BPD involves steps to minimize additional lung damage and prevent pulmonary hypertension and cor pulmonale. Infants with severe disease may be dependent on supplemental oxygen or mechanical ventilation for months. Some will have symptoms of airway obstruction for years. Therapy usually is supportive throughout the course of the disease.

BOX 48-5 Signs and Symptoms of Compensated and Decompensated Shock

Compensated (Reversible)
Cool, pale extremities
Decreased urinary output
Delayed capillary refill
Irritability or anxiety
Normal systolic blood pressure
Tachycardia
Tachypnea
Weak peripheral pulses/full central pulses

Decompensated (Often Irreversible)
Absent peripheral pulses/weak central pulses
Cool, pale, dusky, mottled extremities
Hypotension
Lethargy or coma
Marked tachycardia or bradycardia
Marked tachypnea or bradypnea
Significantly decreased urinary output
Significantly delayed capillary refill

Shock

As described in Chapter 36, shock is an abnormal condition characterized by inadequate delivery of oxygen to meet the metabolic demands of tissues. The condition may occur with increased, normal, or decreased blood pressure. Shock is categorized as *compensated* (shock without hypotension) or *decompensated* (shock with hypotension) (Box 48-5), and is further categorized as cardiogenic and noncardiogenic. *Cardiogenic shock* is characterized by adequate intravascular volume, but myocardial dysfunction limits stroke volume and cardiac output. *Noncardiac shock* can be hypovolemic shock from loss of volume. It may also be distributive shock (septic, neurogenic, or anaphylactic).

The paramedic must take into account a number of special considerations when caring for a child in shock. These include circulating blood volume, body surface area and hypothermia, cardiac reserve, respiratory fatigue, vital signs, and assessment.

TABLE 48-6 Systolic Blood Pressure Characterizing Hypotension in the Pediatric Patient

Age	Systolic Blood Pressure
Term neonates (birth to 28 days of age)	<60 mm Hg
Infants (1 to 12 months)	<70 mm Hg
Children (1 to 10 years)	<70 mm Hg (2 × age in years)
Beyond 10 years	<90 mm Hg

CIRCULATING BLOOD VOLUME

In adults, blood volume accounts for 5% to 6% of total body weight, or 50 to 60 mL/kg of body weight; in children, blood volume accounts for 7% to 8% of total body weight, or 70 to 80 mL/kg of body weight.[25] Although the percentage of circulating blood volume in a child is greater than that in an adult, a child's actual blood volume is considerably lower than an adult's. Therefore a relatively small loss of blood may be devastating. For example, a blood loss of 100 mL in an adult is a 2% loss; a 100 mL loss in an infant is a 15% to 20% loss, resulting in shock.[1]

A child with a blood or fluid deficit will maintain stable hemodynamics until all compensatory mechanisms fail (i.e., the blood pressure may be normal or only slightly decreased) (Table 48-6). At that point, shock progresses rapidly, with serious deterioration. These efficient compensatory mechanisms can mask a potentially life-threatening condition. Thus the paramedic must maintain a high degree of suspicion, based on the patient's complaint or clinical presentation. Early recognition, stabilization (airway control, fluid replacement), and rapid transport to a proper facility are critical when caring for children in shock. Treatment must be focused on ventilation, fluid administration, and improvement of the pumping action of the heart.

CRITICAL THINKING

How comfortable are you with starting an intravenous infusion on an infant or young child?

BODY SURFACE AREA AND HYPOTHERMIA

Young children have a large body surface area in proportion to body weight. Their compensatory mechanisms (e.g., shivering and sweating) also are not well developed. Children in shock quickly can develop hypothermia from exposure and concurrent metabolic acidosis, increased vascular resistance, respiratory depression, and myocardial dysfunction. Hypothermia makes resuscitation and drug therapy less effective. Thus the paramedic should maintain the patient's body temperature by using blankets, covering the child's head with towels, and using warming devices for IV fluids.

CARDIAC RESERVE

Infants and children already have high metabolic needs. As a result, they have less cardiac reserve than adults for stressful situations such as shock. An important step is to reduce the energy and oxygen requirements of a child in shock as much as possible. This can be accomplished by providing ventilatory support, reducing anxiety, and maintaining moderate ambient temperatures.

RESPIRATORY FATIGUE

Respiratory muscle fatigue may lead to hypoventilation, hypoxemia, and respiratory failure or arrest. Like other compensatory mechanisms of the child, respiratory compensation generally is at a maximum until it is depleted. At that time, deterioration can be sudden. For this reason, airway control and supplemental oxygen administration are essential in all children who are seriously ill or injured.

VITAL SIGNS AND ASSESSMENT

The paramedic must consider many factors when evaluating a child's vital signs. For example, blood pressure and pulse rate vary greatly with age, body temperature, and degree of agitation. The paramedic should measure vital signs as baseline assessments, even though they may be of limited value in assessing the circulation of a child in shock. The most effective assessment is constant monitoring of the child's mental and physical status and the response to therapy. The following nine evaluation components should be noted when assessing a child in shock:

1. Level of consciousness
   - Ability to make eye contact
   - Ability to recognize family members
   - Agitation
   - Anxiety
2. Skin
   - Capillary refill (in children under 6 years of age)
   - Color
   - Moisture
   - Temperature
   - Turgor
3. Mucous membranes
   - Color
   - Moisture
4. Nail beds
   - Capillary refill (in children younger than 6 years of age)
   - Color
5. Peripheral circulation
   - Collapse
   - Distention
6. Cardiac
   - Electrocardiogram findings
   - Location of pulses

Quality of pulses
Rate
Rhythm
7. Respiration
Depth
Rate
8. Blood pressure (in children over 3 years of age) with appropriate sized cuff
9. Body temperature

NOTE
Sustained tachycardia in the absence of obvious causes such as fever, pain, and agitation may be an early sign of cardiovascular compromise. Bradycardia, however, may be a preterminal cardiac rhythm indicating advanced shock and often is associated with hypotension.[6]

HYPOVOLEMIA

One common cause of hypovolemia in children is dehydration resulting from vomiting and diarrhea. Another is blood loss resulting from trauma or internal bleeding. Children are also at risk of intravascular volume depletion as a result of burns (see Chapter 39).

Dehydration. Profound fluid and electrolyte imbalances can occur in children as a result of vomiting, diarrhea, poor fluid intake, fever, or burns. Dehydration compromises cardiac output and systemic perfusion. This occurs if the child loses the fluid equivalent of 5% or more of total body weight. For the adolescent, losses of 5% to 7% of total body weight can compromise perfusion (Figure 48-13). If allowed to progress, dehydration can result in renal failure, shock, and death. The severity of the dehydration and fluid loss can be estimated from a history of the child's weight loss and the physical examination (Figure 48-14). Table 48-7 provides signs and symptoms related to degrees of dehydration.

Airway and ventilatory support (if needed) are the initial steps in treatment for the dehydrated child. Next, treatment is directed at replacing and maintaining blood volume and perfusion. Intravenous therapy should be initiated with isotonic crystalloids such as lactated Ringer's solution or normal saline.[6] A fluid bolus of 20 mL/kg (administered in less than 20 minutes)[1] should be given even if blood pressure is normal.[6] Fluid boluses may be repeated if the patient's systemic perfusion fails to improve. After physician evaluation and initial shock resuscitation, the fluid administration rate and type of fluid replacement are determined by the volume and type of fluid deficit (isotonic,

FIGURE 48-13 Severe dehydration.

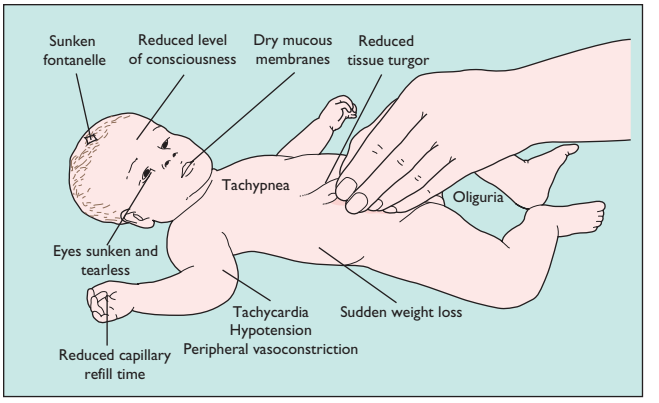

FIGURE 48-14 Clinical features of dehydration in an infant.

TABLE 48-7 Assessment of Degree of Dehydration

Clinical Parameters	Mild	Moderate	Severe
Body weight loss	Infant: 5% (50 mL/kg)	10% (100 mL/kg)	15% (150 mL/kg)
Skin turgor	Slightly decreased	Moderately decreased	Greatly decreased
Fontanelle (infant)	Possibly flat or depressed	Depressed	Significantly depressed
Mucous membranes	Dry	Very dry	Parched
Skin perfusion	Warm with normal color	Cool (extremities), pale	Cold (extremities), mottled or gray
Heart rate	Mildly tachycardic	Moderately tachycardic	Extremely tachycardic
Peripheral pulses	Normal	Diminished	Absent
Blood pressure	Normal	Normal	Reduced
Sensorium	Normal or irritable	Irritable or lethargic	Unresponsive

TABLE 48-8 Classification of Hemorrhagic Shock in Pediatric Trauma Patients Based on Systemic Signs

System	Very Mild Hemorrhage*	Mild Hemorrhage†	Moderate Hemorrhage‡	Severe Hemorrhage§
Cardiovascular	Normal or mildly increased heart rate	Tachycardia	Significant tachycardia	Severe tachycardia
	Normal pulse rate	Peripheral pulses may be diminished	Thready peripheral pulses	Thready central pulses
	Normal blood pressure	Normal blood pressure	Hypotension	Significant hypotension
	Normal pH	Normal pH	Metabolic acidosis	Significant acidosis
Respiratory	Normal rate	Tachypnea	Moderate tachypnea	Severe tachypnea
Central nervous system	Slight anxiousness	Irritability, confusion	Irritability or lethargy	Lethargy
		Combative affect	Diminished pain response	Coma
Skin	Warm, pink color	Cool extremities, mottling	Cool extremities, mottling or pallor	Cold extremities, pallor or cyanosis
	Brisk capillary refill	Delayed capillary refill	Prolonged capillary refill	Prolonged capillary refill
Kidneys	Normal urine output	Oliguria, increased specific gravity	Oliguria, increased blood urea nitrogen level	Anuria

*Indicates <15% blood volume loss.
†Indicates 15% to 25% blood volume loss.
‡Indicates 25% blood volume loss.
§Indicates 40% blood volume loss.

FIGURE 48-15 Capillary refill in a child in shock.

hypotonic, hypertonic) and the patient's response to therapy.

CRITICAL THINKING
What are some ways to determine the child's weight for fluid and drug dosing?

Blood Loss. As stated before, even a small amount of blood loss can be serious for the pediatric patient (Table 48-8). After the paramedic achieves control of external hemorrhage (if present), secures the patient's airway, and provides high-concentration oxygen, the child's circulatory status may require support with IV therapy.

As with other causes of hypovolemia, volume replacement is needed. Isotonic crystalloid solutions such as normal saline or lactated Ringer's solution should be used. The first bolus should be 20 mL/kg.[1] If the volume loss is in the 20% range, vital signs should improve after this infusion. If improvement occurs, IV therapy should be continued at a maintenance rate during patient transport. The child may show little response to the first bolus. For example, a slight improvement in color and capillary refill and a decreased heart rate may be evident (Figure 48-15). If this is the case or if the patient does not respond to the initial infusion, the paramedic should give a second bolus of 20 mL/kg.[6]

NOTE
Establishing an intravenous line in a child through a peripheral vein (described in Chapter 14) can be difficult even in the most controlled settings. As a result, medical direction may advise that the paramedic establish an intraosseous infusion for the child in shock.

DISTRIBUTIVE SHOCK

As described previously, distributive shock is used to refer to septic shock, neurogenic shock, and anaphylactic shock. This type of shock results in peripheral pooling because of loss of vasomotor tone. The vasodilation that occurs causes the blood pressure to fall. Vasodilation also allows plasma to leak from the vascular space. This type of shock is fairly uncommon in children.

Septic shock usually is caused by a systemic bacterial infection. Septic shock sometimes is associated with illnesses such as meningitis and pneumonia. Toxins released by the pathogen affect arterioles, capillaries, and venules, altering microcirculatory pressure and capillary permeability. These children usually appear very ill. They may have signs and symptoms that include those of decompensated shock. Characteristic findings in septic shock include skin that is warm in the early stages, and skin that is cool in the late stages of the illness.

Neurogenic shock results from sudden peripheral vasodilation caused by a traumatic injury. Most often this injury is to the spinal cord. The loss of sympathetic impulses and resultant vasodilation increase the size of the vascular compartment. The normal intravascular volume is not enough to fill the vascular compartment and to perfuse tissues. Characteristic findings in neurogenic shock include warm skin, bradycardia, and impaired neurological function.

Anaphylactic shock occurs when a person is exposed to a substance that produces a severe allergic reaction (see Chapter 27). Common causes of allergic reactions include antibiotic agents, foods, and insect stings. The bodily response to the antigen causes a release of histamine. This release results in peripheral vasodilation and the leakage of intravascular fluid into the interstitial space, resulting in a decrease in intravascular volume. Characteristic findings in anaphylactic shock include a rapid onset of skin signs (hives, allergic rash, and erythema), upper airway obstruction or dyspnea, signs of shock, and gastrointestinal distress.

Emergency care for patients with distributive shock is directed at ensuring the patient's vital functions through airway, ventilatory, and circulatory support, and rapid transport to an appropriate medical facility. Medical direction may advise IV fluid therapy and drugs to manage specific forms of distributive shock. (For example, ***dopamine*** may be given for neurogenic shock; ***epinephrine*** should be given for anaphylactic shock.) Aids that often are used to calculate drug and fluid doses for pediatric patients were described in Chapter 14. These aids include the Pedi-Wheel and the Broselow tape (Figure 48-16).

FIGURE 48-16 Pediatric Broselow tape.

Congestive Heart Failure. Congestive heart failure in children may result from cardiomyopathy, myocarditis, and congenital heart diseases. To review, *myocarditis* is inflammation of the heart. *Cardiomyopathy* refers to degeneration of the heart muscle that causes a reduction in the force of heart contractions. Both conditions decrease the force of contractions and the amount of blood circulated to the lungs and to the rest of the body. In children, congestive heart failure usually results from viral infection or congenital abnormalities that affect both ventricles of the heart (described in the following sections). Symptoms include fatigue, chest pain, and dysrhythmias. In severe cases, they include signs of heart failure and cardiogenic shock, such as the following:

- Crackles
- Hypotension
- Jugular vein distention (difficult to determine in young children)
- Peripheral edema
- Tachycardia
- Tachypnea

Patients in stable condition are managed with supportive care, oxygen administration, and transport for evaluation by a physician. Children who are hypotensive and show other signs and symptoms of decompensation may require vascular access for the administration of drugs (e.g., antidysrhythmics, diuretics, and vasopressors). Intravenous fluid therapy should be given to children in shock with signs of CHF in small boluses of 5 to 10 mL/kg.[1] This will help to avoid volume overload

Rhythm Disturbances

Most children are born with healthy hearts. (Congenital heart defects are presented in Chapter 47.) When rhythm disturbances occur, they usually are the result of hypoxia, acidosis, hypotension, or structural heart disease.[6] The most common dysrhythmias in pediatric patients are sinus

LOOK AGAIN
See Chapter 14: Venous Access and Medication Administration, pp. 345-347.

tachycardia, supraventricular tachycardia, bradycardia, and asystole. Pulseless ventricular tachycardia or ventricular fibrillation is the initial rhythm in 5%-15% of pediatric cardiac arrests and is reported in up to 27% of pediatric in-hospital arrests at some point during the resuscitation.[6] The recommended management for these dysrhythmias is outlined in Figures 48-17 to 48-19. Drug treatments and specific guidelines for use of airway equipment during pediatric life support are listed in Tables 48-9 and 48-10.

TABLE 48-9 Medications for Pediatric Resuscitation and Dysrhythmias

Medication	Dose	Remarks
Adenosine	0.1 mg/kg (maximum 6 mg) Repeat: 0.2 mg/kg (maximum 12 mg)	Monitor ECG Rapid IV/IO bolus
Amiodarone	5 mg/kg IV/IO; repeat this dose up to total dose of 15 mg/kg Maximum (single dose): 300 mg	Monitor ECG and blood pressure Adjust administration rate to urgency (give more slowly when perfusing rhythm present) Use caution when administering with other drugs that prolong QT (consider expert consultation)
Atropine	0.02 mg/kg IV/IO 0.04-0.06 mg/kg ET* Repeat once if needed Minimum dose: 0.1 mg Maximum single dose: Child 0.5 mg	Higher doses may be used with organophosphate poisoning
Calcium chloride (10%)	20 mg/kg IV/IO (0.2 mL/kg)	Slowly
Epinephrine	0.01 mg/kg (0.1 mL/kg 1:10,000) IV/IO 0.1 mg/kg (0.1 mL/kg 1:1000) ET† Maximum dose: 1 mg IV/IO	May repeat every 3-5 min in arrest
Glucose	0.5-1 g/kg IV/IO	$D_{10}W$: 5-10 mL/kg $D_{25}W$: 2-4 mL/kg
Lidocaine	Bolus: 1 mg/kg IV/IO Maximum dose: 100 mg Infusion: 20-50 mcg/kg/min ET†: 2-3 mg/kg	
Magnesium sulfate	25-50 mg/kg IV/IO over 10-20 min; Maximum dose: 2 g	
Naloxone	<5 yr or ≤≤20 kg: 0.1 mg/kg IV/IO ≥≥5 yr or >20 kg: 2 mg IV/IO	Use lower doses to reverse respiratory depression associated with therapeutic opioid use (1-5 mcg/kg)
Procainamide	15 mg/kg IV/IO over 30-60 min	Monitor ECG and blood pressure Use caution when administering with other drugs that prolong QT (consider expert consultation)
Sodium bicarbonate	1 mEq/kg per dose IV/IO slowly	After adequate ventilation

ECG, Electrocardiogram; *ET,* endotracheal tube; *mcg,* micrograms; *IO,* intraosseous; *IV,* intravenous.
*Flush with 5 mL of normal saline and follow with 5 ventilations.

Dysrhythmias and basic and advanced life support procedures (including cardiopulmonary resuscitation) are addressed in Chapter 22. The reader should refer to that chapter for review. The following discussions outline the unique aspects of abnormal rhythms in children.[6]

NOTE
Even though short-term initial resuscitation rates for infants and children in cardiac arrest have improved, survival to hospital discharge remains very low, at about 6%.[6]

BRADYDYSRHYTHMIAS

Clinically significant bradycardia is defined as a heart rate less than 60 beats/min (or a rapidly dropping heart rate) associated with poor systemic perfusion. This bradycardia occurs despite adequate oxygenation and ventilation. Bradydysrhythmias may be caused by hypoxemia, acidosis, hypotension, hypoglycemia, central nervous system injury, or excessive vagal stimulation (e.g., from endotracheal intubation or pharyngeal suctioning). In infants and children, sinus bradycardia, sinus node arrest with slow junctional or idioventricular rhythm, and atrioventricular block are the most common preterminal rhythms. The paramedic should consider drug-induced causes (e.g., digitalis toxicity) and myocarditis with bradycardia caused by heart block. Infants and children with a history of heart surgery may have injury at the atrioventricular node or conduction system. This injury would produce sick sinus syndrome or heart block. All symptomatic bradycardias require treatment. Important electrocardiogram findings include the following:

- Heart rate is less than 60 beats/min.
- P waves may or may not be visible.
- QRS complex duration may be normal or prolonged.
- The P wave and QRS complex often are unrelated.

Treatment. The initial management of bradycardia should ensure that breathing is adequate and the patient is receiving supplemental oxygen (Figure 48-17). (Mechanical problems with oxygen delivery should be assessed before drug administration.) If pulses, perfusion, and respirations are adequate, no emergency treatment is necessary.[6] Monitor and proceed with evaluation. If drug therapy is required, ***epinephrine*** is the drug of choice. Bradycardia

TABLE 48-10 Equipment Selection for Pediatric Tracheal Intubation

Age	Weight (kg)	Blade Size	Blade Type	Tracheal Tube Size (mm)	Tracheal Tube	Tracheal Tube Length (cm at lip)	Stylet (F)
Newborn/ small infant (0-3 months)	3-5	0-1	Straight	2.5-3.5†	Uncuffed	10-10.5	6
Infant (3-6 months)	6-7	1	Straight	3.5 3.0	Uncuffed Cuffed	10-10.5	6
Infant (7-10 months)	8-9	1	Straight	3.5 3.0	Uncuffed Cuffed	10.5-12	6
Toddler (11-18 months)	10-11	1	Straight	4 3.5	Uncuffed Cuffed	11-12	6
Small child (19-35 months)	12-14	2	Straight	4.5 4.0	Uncuffed Cuffed	12.5-13.5	6
Child (3-4 years)	15-18	2	Straight or curved	5 4.5	Uncuffed Cuffed	14-15	6
Child (5-6 years)	19-22	2	Straight or curved	5.5 5.0	Uncuffed Cuffed	15.5-16.5	14
Large child (7-9 years)	24-30	2-3	Straight or curved	6	Cuffed	17-18	14
Adult (10-12 years)	32-40	3	Straight or curved	6.5	Cuffed	18.5-19.5	14

Based on Broselow Resuscitation Tape.
*Use 2.5 for premature infant. Use 3.0-3.5 for term infant.

caused by heart block or increased vagal tone (both of which are rare in pediatric patients) should be managed with ***atropine.*** In cases where bradycardia is caused by dysfunction in the sinus node, external cardiac pacing may be lifesaving. Pacing is not useful for asystole or bradycardia attributable to postarrest hypoxic/ischemic myocardial insult or respiratory failure.[6] External cardiac pacing is uncomfortable. Its use in children is reserved for profound symptomatic bradycardia that does not respond to advanced life support and basic life support treatments.

PULSELESS ELECTRICAL ACTIVITY

Pulseless electrical activity often precedes asystole. It usually is caused by prolonged periods of hypoxia, ischemia, or hypercarbia. Reversible causes of pulseless electrical activity include the *H's* and *T's* (described in Chapter 22). To review, the *H's* are hypovolemia, hypoxemia, hypothermia, hyper/hypokalemia, hydrogen ion excess (acidosis), and hypoglycemia. The *T's* are tension pneumothorax, pericardial tamponade, toxins, and thromboembolus (Box 48-6). Important electrocardiogram findings include the following:

- A slow, wide-complex rhythm
- The presence of some electrical activity (other than ventricular tachycardia/ventricular fibrillation) and the absence of a detectable pulse

Treatment. Pulseless electrical activity (PEA) is managed in the same way as asystole (Figure 48-18) with drug therapy (***epinephrine***) and cardiopulmonary resuscitation. Defibrillation is not effective in the treatment of PEA and asystolic arrest.[6] Reversible causes of the condition should be considered and corrected if possible. Identification and treatment of the underlying cause is the only true means of reversal of pulseless electrical activity. Early recognition and treatment of pulseless electrical activity that results in a return of a pulse before arrival in the emergency department is associated with improved chances for survival.

NOTE

The survival of children under 18 years of age who suffer cardiac arrest in the out-of-hospital setting is rare. Of those who are discharged, only a small percentage remain neurologically intact.[26] Paramedics should be prepared to deal with intense emotion related to unsuccessful resuscitation and seek appropriate support services (see Chapter 2).

SUPRAVENTRICULAR TACHYCARDIA

Supraventricular tachycardia is the most common nonarrest dysrhythmia during childhood and is the most common dysrhythmia that produces cardiovascular instability during infancy.[6] Two factors can help distinguish supraventricular tachycardia from sinus tachycardia caused by shock. They include patient history (e.g., dehydration or hemorrhage associated with shock) and heart rate. (Sinus tachycardia is usually less than 220 beats/min in infants, usually less than 180 beats/min in children, and usually greater than those rates with supraventricular tachycardia.)

BOX 48-6 The H's and T's: Potentially Reversible Causes of PEA[1]

"H's"

Hypovolemia:
- Poor skin color, rapid heart rate, flat neck veins.
- Intervention: Rapid 20 mL/kg bolus of isotonic crystalloid

Hypoxemia:
- Cyanosis, slow heart rate
- Intervention: Oxygen, secure airway (Consider DOPE, displaced ETT, obstructed ETT, pneumothorax, equipment failure such as ventricular malfunction or disconnect), suction if needed

Hypothermia:
- Cold skin, low core body temperature (CBT)
- Intervention: Use rapid rewarming techniques; warm IV fluids

Hyper/Hypokalemia:
- Hyperkalemia: Peaked T waves, history of renal disease
- Intervention: In-hospital infusion of sodium bicarbonate
- Hypokalemia: Flat T waves
- Intervention: In-hospital infusion of potassium

Hydrogen ion excess:
- Metabolic acidosis: Small-amplitude QRS, may have history of renal disease
- Intervention: In-hospital correction of electrolyte imbalance

Hypoglycemia:
- Altered level of consciousness
- Intervention: Check serum glucose level, give dextrose if confirmed

"T's"

Tension pneumothorax:
- Deviated trachea, neck vein distention, absent breath sounds
- Interventions: Needle decompression

Tamponade:
- Distended neck veins, rapid heart rate
- Intervention: Volume bolus; in-hospital pericardiocentesis

Toxins:
- Drug overdose, bradycardia, tachycardia
- Intervention: Naloxone; may require special therapies

Thrombosis:
- ST segment elevation—STEMI (rare in children) or pulmonary embolism

Important electrocardiogram findings in supraventricular tachycardia include the following:

- Heart rate is greater than 220 beats/min in infants and greater than 180 beats/min in children.
- The rhythm usually is regular because associated atrioventricular block is rare.
- P waves may not be identifiable, especially when the ventricular rate is high. If present, P waves usually are negative in leads II, III, and aV_F.
- QRS complex duration is normal in most children (<0.09 second).[6] Supraventricular tachycardia with aberrant conduction (wide-complex supraventricular tachycardia) may be difficult to distinguish from ventricular tachycardia (but this form of ventricular tachycardia is rare in infants and children).

Treatment. Signs and symptoms during supraventricular tachycardia are affected by the child's age, duration of supraventricular tachycardia, prior ventricular function, and ventricular rate (see Figure 48-19). If the child is hemodynamically stable and cooperative, vagal maneuvers such as applying ice/water to the child's face for infants and young children, and blowing through a straw, vagal maneuvers or massaging the carotid sinus in older children may be successful in terminating the rhythm.[6] Unstable supraventricular tachycardia is best managed with synchronized cardioversion or drug therapy. (***Adenosine*** is the drug of choice.)

Wide-complex tachycardias with signs of compromised tissue perfusion and impaired level of consciousness require immediate care. The paramedic should treat these tachycardias as if they are ventricular tachycardia. Urgent treatment includes synchronized cardioversion if pulses are present, and defibrillation if pulses are absent.

VENTRICULAR TACHYCARDIA AND VENTRICULAR FIBRILLATION

As stated before, ventricular tachycardia and ventricular fibrillation are uncommon in children. If present, the paramedic should consider causes of these dysrhythmias that include congenital heart disease, cardiomyopathies, myocarditis, reversible causes (e.g., drug toxicity), metabolic causes (e.g., hypoglycemia), or hypothermia. Important electrocardiogram findings include the following:

1. Ventricular tachycardia
   - Ventricular rate at least 120 beats/min and regular
   - Wide QRS complex
   - P waves that often are unidentifiable
2. Ventricular fibrillation
   - No identifiable P wave, QRS complex, or T wave
   - Ventricular fibrillation waves that may be coarse or fine

NOTE

Automated external defibrillators (AEDs) with pediatric cable-pad systems with a dose attenuator have been approved by the Food and Drug Administration. They may be used in infants and children up to 25 kg (approximately 8 years of age). These children must have no signs of circulation (Class IIb) and shockable rhythms (ventricular fibrillation and pulseless ventricular tachycardia). The device also should be able specifically to identify pediatric dysrhythmias that require a shock. In infants less than 1 year of age, a manual defibrillator is preferred. If a manual defibrillator is not available, an AED with a dose attenuator may be used. An AED without a dose attenuator may be used if neither a manual defibrillator nor a defibrillator with a dose attenuator is available (Class IIb, LOE C).[6] For a lone rescuer responding to a child with no signs of circulation, 1 minute of cardiopulmonary resuscitation is still advised before any other action, such as activating EMS or using an automated external defibrillator.

BOX 48-7 Terminating Resuscitative Efforts

Most children who have a cardiac arrest will not survive, even with a transient return of spontaneous circulation. Clinical variables associated with survival include length of CPR, number of epinephrine doses, age, witnessed versus unwitnessed cardiac arrest, and the first and subsequent rhythm. Prolonged resuscitation is indicated, however, in infants and children with recurring or refractory ventricular fibrillation or ventricular tachycardia. Prolonged resuscitation is also recommended if the arrest resulted from toxic drug exposure or a primary hypothermic insult.[6] In the absence of these conditions, medical direction may advise that resuscitative efforts be discontinued. Family members should be given the option to be present during the resuscitation efforts, If possible, one person should be assigned to the family to answer questions and provide comfort measures. (As with adults, resuscitation should not be initiated in children who have obvious signs of death, such as rigor mortis.)

Treatment

Ventricular Tachycardia With a Pulse. Hemodynamically stable ventricular tachycardia should be managed under the advice of medical direction and with caution (see Figures 44-18 and 44-19). The initial efforts are aimed at determining the origin of the tachycardia and obtaining a thorough history. Drug therapy usually is delayed in the stable patient until arrival in the emergency department. In-hospital, administration of ***amiodarone*** or ***procainamide,*** may be considered. (These drugs should not routinely be administered together.) Ventricular tachycardia that produces a palpable pulse and signs of shock (low cardiac output, poor perfusion) requires immediate synchronized cardioversion.

Pulseless Ventricular Tachycardia and Ventricular Fibrillation. Pulseless ventricular tachycardia and ventricular fibrillation are managed with immediate defibrillation, cardiopulmonary resuscitation, intubation with ventilatory support, and drug therapy (e.g., ***epinephrine*** and ***vasopressin, amiodarone,*** and ***lidocaine***). Infant patches (4.5 cm) generally should be used during defibrillation for infants up to about 1 year of age or weighing 10 kg. Adult patches (8 to 10 cm) generally should be used for patients older than 1 year of age or weighing more than 10 kg (Box 48-7).[6]

Postresuscitation Stabilization

The postresuscitation phase begins after initial stabilization of the patient with shock or respiratory failure or after return of spontaneous circulation in a patient who was in cardiac arrest. The goals of postresuscitation stabilization are as follows[6]:

- Preserve brain function.
- Maintain oxygen saturation to at least 94%.
- Avoid secondary organ injury.

TABLE 48-11 Summary of Postresuscitation Care

Vital Function	Intervention
Airway	Tracheal intubation with confirmation of tube position and repeat confirmation on movement/transport
	Secure tube before transport
	Gastric decompression
Breathing	Titrate inspired oxygen for Spo_2 ≥94%
	Provide mechanical ventilation targeting normal ventilation goals (Pco_2 35-40 mm Hg)
	Monitor continuous pulse oximetry and capnography, if available
Circulation	Ensure adequate intravascular volume (volume titration)
	Optimize myocardial function and systemic perfusion (inotropes, vasopressors, vasodilators)
	Monitor capillary refill, blood pressure, continuous electrocardiogram, urine output; measure arterial blood gas and lactate to assess degree of acidosis, if available
	Ideally maintain two routes of functional vascular access
Disability	Perform secondary assessment including brief neurological assessment
	Avoid hyperglycemia; treat hypoglycemia (monitor glucose)
	If seizures are observed, medicate with anticonvulsant agents
	Obtain laboratory studies (if available): arterial blood gases, glucose, electrolytes, hematocrit, chest radiograph
Exposure	Avoid and correct hyperthermia (monitor temperature)
	Consider therapeutic hypothermia (<32° C to 34°C)

From American Heart Association. 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*, 122 (18 Supplement 3), S639-S946, 2010.

- Seek and correct causes of illness.
- Manage pain with analgesics (e.g., ***morphine***) or sedatives (***lorazepam, midazolam***) as ordered by medical direction.[6]
- Enable the patient to arrive at an appropriate care facility in the best possible physiological state.

Postresuscitation stabilization focuses on preserving neurological function and avoiding multisystem organ failure (Table 48-11). Postresuscitation stabilization requires knowledge and experience in the evaluation of all organ systems. It includes stabilizing the airway and supporting oxygenation, ventilation, and perfusion;

SHOW ME THE EVIDENCE

A group of American and Canadian researchers performed a review of current knowledge related to pediatric cardiac arrest in preparation for proposed interventional studies. They extracted data from 41 published research articles related to pediatric resuscitation outcomes that met their inclusion criteria. They found return of spontaneous circulation in 30.8% of patients and survival to discharge in 12.1% of patients. Only four articles used validated neurological outcome scores to describe neurological function at discharge. Of those, 131 of 3272 (4%) were discharged with good neurological status. Cardiac arrest was most common in children less than 1 year of age (47.5%). Higher survival rates were noted in those with witnessed versus unwitnessed arrest. Survival from cardiac arrest related to submersion was higher than in arrest from other causes. The authors concluded that more research is needed using uniform data collection methods so the effectiveness of interventions can be studied in a reliable manner.

From Donoghue AJ, Nadkarni V, Berg RA, et al: Out-of-hospital pediatric cardiac arrest: an epidemiologic review and assessment of current knowledge, *Ann Emerg Med* 46(6):512-522, 2005.

BOX 48-8 Causes of Altered Mental Status in Children

Electrolyte or glycemic imbalance
Infection
Intracranial bleeding
Intracranial mass
Intussusception (telescoping intestines)
Seizure
Toxins
Trauma
Uremia
Important history to obtain: Age, fever, vomiting, photophobia, headache, prior seizures, extremity shaking, staring episodes, trauma, ataxia, ingestions, oral intake, bloody stool, urine output, baseline development level
Important physical findings: Vital signs, photophobia, nuchal rigidity, Glasgow Coma Scale score, palpation of ventricular shunt, full neurological examination

performing a thorough secondary assessment; and obtaining a medical history. Family members should be kept abreast of what has been done and how the patient is responding to care. Frequent reports also should be provided to the receiving hospital (Box 48-7).

Meningitis

As described in Chapter 28, *meningitis* is inflammation of the fluid-containing membranes (meninges) that surround the brain and spinal cord. Meningitis normally occurs as a complication of bacterial or viral infection. Meningitis can be life threatening (10% to 15% of cases of bacterial meningitis are fatal).[16] Meningitis can rapidly progress to permanent brain damage, impaired vision or hearing, neurological dysfunction, and death. The highest incidence of meningitis is 6 months to 2 years of age. The greatest time for risk is immediately after birth and again at 3 to 8 months of age.[27] Most commonly, meningitis develops over 1 to 4 days. However, in severe cases, a child who looks healthy can rapidly become seriously ill within a day.

The signs and symptoms of meningitis depend on the child's age and are not always obvious. Classic symptoms in infants younger than 3 months include decreased liquid intake, vomiting, irritability, lethargy, fever, bulging fontanelle, and seizures. Signs and symptoms for older children and adults include nausea and vomiting, headache, photophobia, fever, altered mental status, lethargy, seizures, and neck stiffness (nuchal rigidity) or pain. Other classic presentations which may aid in diagnosis are:

- *Brudzinski's sign:* Knees automatically brought up toward the body when the neck is bent forward or pain in the legs when bent
- *Kernig's sign:* Inability to straighten the lower legs when the thigh is flexed on the abdomen
- *Rash:* Petechial or purpuric rash may appear if meningococcus is the causative agent

Prehospital care is primarily supportive. Universal precautions should be employed. A surgical mask should be applied to the patient while providing care and during transport. In some cases, seizure control or IV fluid replacement will be necessary. In-hospital care will be based on the causative agent.

Seizure

A seizure (described in Chapter 25 Chapter 47) is an episode of sudden abnormal electrical activity in the brain. It results in abnormalities in motor, sensory, or autonomic function usually associated with abnormal behavior, changes in level of consciousness, or both (Box 48-8). Common causes of seizure in adults and children include noncompliance with a drug regimen for the treatment of epilepsy, head trauma, intracranial infection, brain tumor, metabolic disturbance, or poisoning. The most common cause of new onset of seizure in children is fever.

See Chapter 25: Neurology, pp. 785-788.

CRITICAL THINKING

Are you comfortable using the pediatric paddles on the defibrillators you will be using in clinicals and on the ambulance?

FEBRILE SEIZURES

A **febrile seizure** is a seizure associated with fever but without evidence of intracranial infection or other definable cause; such seizures usually occur between the ages of

6 months and 5 years.[33] About 2% to 5% of children under 7 years of age experience a febrile seizure. About 30% of those who have a seizure experience a recurrence. More than half of febrile seizures occur in children ages 9 to 20 months. In 60% of cases, a family history of febrile seizures is a factor.[33]

Febrile seizures usually are associated with an underlying viral infection (most often of the upper respiratory tract), gastroenteritis, roseola, otitis media, or another febrile illness. The seizures usually occur in vulnerable patients during a rapid rise in body temperature. However, the intensity of the seizure is not related to the severity of the fever.

Febrile seizures may manifest with generalized tonic-clonic activity. Or they may have a more subtle presentation. As a rule, classic febrile seizures are of short duration. (They usually last less than 5 minutes.) They also have an uncomplicated and short postictal period. Seizures that last longer than 20 minutes call for extensive investigation. These should never be considered benign. Regardless of the suspected cause, all children who have suffered a seizure should be transported for evaluation by a physician per protocol.

Assessment and Management. In most cases the seizure has stopped before emergency medical services arrives. In many instances, the child is in a postictal state. As in any emergency, the first priorities are airway management and ventilatory and circulatory support. This includes airway positioning, suctioning of the airway, and administration of oxygen. Repeated assessment of the adequacy of ventilation is necessary. Special emphasis should be placed on respiratory rate and depth. If the airway cannot be maintained with manual maneuvers, airway adjuncts should be used.

After initial stabilization of the patient's condition, the paramedic should assess vital signs and obtain a history. Important elements of the history include the following:

- Previous seizures
- Number of seizures in this episode
- Duration of seizure activity
  - Tonic-clonic—from onset of symptoms until clonic activity stops
  - Absence—time from loss of consciousness to return of consciousness
  - Complex partial—from loss of consciousness or start of motor activity, automatism until child is responsive
- Description of seizure activity
  - Areas of body involved
  - Area of the body the seizure activity originated (e.g., foot, mouth, generalized)
  - Positional change
  - Length of tonic and clonic phases
  - Absence of movement or muscle tone in selected body areas
- Presence of vomiting during the seizure (aspiration risk)
- Color change during seizure
- Appearance of face during the seizure
- Appearance of eyes during the seizure
  - Pupils
  - Gaze
- Condition of the child when first found
- Recent illness
- Potential for toxic ingestion
- Potential head injury (as primary cause or secondary complication)
- Significant medical problems
- Recent headache or stiff neck (which may suggest meningitis)
- Medication use and compliance with anticonvulsant medication

During transport to the emergency department, the paramedic should continuously monitor the child and be alert for recurrent seizures. The characteristics of the postictal period (level of consciousness, movement, speech, sensory or motor impairment) should be noted. Medical direction may advise that a febrile patient be given an antipyretic if the patient is alert. The antipyretic will reduce the fever en route to the receiving hospital. The paramedic should not apply ice or submerge the patient in a cool bath in an effort to reduce fever.

STATUS EPILEPTICUS

Status epilepticus is continuous seizure activity that lasts 30 minutes or longer or a recurrent seizure without an intervening period of consciousness. Such a seizure is a true emergency. It can lead to hypotension and cardiovascular, respiratory, and renal failure, in addition to permanent brain damage. Children in status epilepticus should be managed with the following initial interventions:

1. Provide adequate airway, ventilatory, and circulatory support. Intubation for airway protection or mechanical ventilation seldom is needed. Intubation should be withheld unless the child fails to respond to the initial management.
2. Per protocol, obtain vascular access through an IV or intraosseous route. Measure the blood glucose level to screen for hypoglycemia. If the value is less than 60 mg/dL (40 mg/dL in an infant[4]), administer ***dextrose*** 10%, or dextrose 25% (per medical direction). (Hypoglycemia also can be treated with an intramuscular injection of ***glucagon*** if IV or intraosseous access cannot be established.) If seizures do not stop, consult medical direction regarding IV, intraosseous, or rectal administration of the anticonvulsants ***diazepam*** or ***lorazepam.*** (***Lorazepam*** may also be given intramuscularly [IM].)
3. Attach a cardiac monitor. Observe for rhythm or conduction abnormalities that may suggest hypoxia.

Diazepam. ***Diazepam*** breaks active seizures in 70% of cases.[33] The drug has a short duration of action (15 minutes). It may require repeat administration to a maximum of three doses. In addition, the paramedic should be ready for sudden respiratory depression or hypotension when using this drug. If IV or intraosseous access cannot be obtained,

BOX 48-9 Procedure for Rectal Administration of Diazepam

1. Carefully restrain the child. If possible, place the child in a knee-chest or decubitus position with the legs flexed at the hip and knee.
2. Draw the calculated diazepam dose into a syringe. A higher dose of 0.5 mg/kg is required because absorption is incomplete.
3. Introduce a lubricated 1-mL syringe just beyond the external sphincter (aimed just above the junction of the skin and mucous membranes and directed toward the rectal wall).
4. Inject the solution into the rectum and clear the syringe with 1 mL of normal saline.
5. Facilitate drug retention by squeezing the buttocks together with manual pressure.
6. Transport the patient for evaluation by a physician. Remove excessive clothing. En route, continually monitor the patient for recurrent seizures and the need for airway, ventilatory, and circulatory support.

diazepam may be administered rectally (Box 48-9) and ***lorazepam*** or ***midazolam*** may be given intramuscularly.[13] Transport of the patient should not be delayed so as to attempt vascular access.

Lorazepam. An alternative to the IV or intraosseous administration of ***diazepam*** is ***lorazepam.*** The drug has a long duration of action (6 to 8 hours), and is preferred by some physicians. ***Lorazepam*** may be injected intramuscularly. It also may be given intravenously, intraosseously, or rectally. The side effects are similar to those of ***diazepam*** in terms of cardiorespiratory and central nervous system depression. The paramedic should be alert for these complications.

NOTE

Midazolam is being used by some emergency medical services systems to treat status epilepticus and refractory seizures in pediatric patients. ***Midazolam*** also is used when seizures do not respond to ***diazepam*** or ***lorazepam.*** The drug may be administered intramuscularly, intravenously, buccally, or intranasally. The use of ***midazolam*** to control pediatric seizures is controversial; it has a short half-life; it may cause respiratory depression.[13]

Hypoglycemia

As described in Chapter 26, hypoglycemia is an abnormally low concentration of glucose in the blood. In children, hypoglycemia is usually the result of excessive response to glucose absorption, illness, physical exertion, or decreased dietary intake. In diabetic children, hypoglycemia usually is caused by too large an insulin dose, a delayed or missed meal, or vigorous physical activity. The condition most commonly occurs in the prehospital setting in infants and children with type 1 diabetes, a disease that affects about 0.2% of all school-age children; about 15,000 children in the United States under age 20 are diagnosed with type 1 diabetes each year.[28]

The signs and symptoms of hypoglycemia can be classified as *mild, moderate,* and *severe.* Mild symptoms include hunger, weakness, tachypnea, and tachycardia. Moderate symptoms include sweating, tremors, irritability, vomiting, mood disorders, blurred vision, stomachache, headache, and dizziness. Severe symptoms include decreased level of consciousness and seizure activity. This is an emergency that requires prompt treatment with ***dextrose*** to prevent brain damage.

The prehospital care is directed first at ensuring adequate airway, ventilatory, and circulatory support. A blood glucose measurement should be obtained in any child with an altered level of consciousness that has no explainable cause. Conscious children who are mildly hypoglycemic should receive an oral glucose solution or paste. Unconscious children or those with moderate or severe hypoglycemia require IV/intraosseous ***dextrose*** or intramuscular ***glucagon*** administration. This should be followed by a repeat blood glucose measurement in 10 to 15 minutes. All children with signs and symptoms of hypoglycemia should be transported for physician evaluation.

Hyperglycemia

Hyperglycemia is an abnormally high concentration of glucose in the blood. It results from an absence or resistance to insulin. The low insulin level prevents glucose from entering the cells. This causes glucose to build up in the blood. If not treated, hyperglycemia can lead to dehydration, diabetic ketoacidosis, and coma. In children with type 1 diabetes, the condition often is the result of too small an insulin dose in relation to food intake, failure to take ***insulin,*** illness, or a malfunctioning insulin-delivery system (e.g., insulin pump).

The signs and symptoms of hyperglycemia are classified as *early* or *late.* Early signs and symptoms include increased thirst (polydipsia), increased hunger (polyphagia), and increased urination (polyuria). (Weight loss also is considered an early sign of the illness.) Late signs and symptoms associated with dehydration and early ketoacidosis include weakness, abdominal pain, generalized aches, loss of appetite, nausea, vomiting, signs of dehydration (with the exception of urinary output), altered mental status (lethargy), fruity breath odor, tachypnea, hyperventilation, and tachycardia. If untreated, Kussmaul's respirations and coma may occur.

Children suspected of being hyperglycemic should receive adequate airway, ventilatory, and circulatory support. This should be followed by glucose testing. These patients often require IV fluid therapy if signs of dehydration are present (Figure 48-20). The administration of ***insulin*** usually is reserved as an in-hospital procedure.

FIGURE 48-20 Severe dehydration and weight loss from diabetic ketoacidosis.

CRITICAL THINKING
Why do you think type 1 diabetes may stay undetected until a child is seriously ill?

NOTE
It is estimated that about 2 million children ages 12 to 19 (and 57 million adults) in the United States have a pre-diabetic condition linked to obesity and inactivity.[29] This condition, known as *pre-diabetes,* refers to blood glucose levels that are higher than normal but not yet high enough to be diagnosed as diabetes. Pre-diabetes increases risk for full-blown diabetes and cardiovascular disease. In addition, persons with pre-diabetes tend to have higher levels of bad (LDL) cholesterol and triglycerides. It has been suggested that intensive lifestyle interventions in this age group may prevent or delay pre-diabetes from progressing to type 2 diabetes. These interventions include physical activity and improvements in diet.

Blood Disorders

As described in Chapter 32, there are a number of conditions and diseases that can cause blood disorders in children and adults. These disorders may affect the oxygen-carrying capacity of hemoglobin, blood clotting mechanisms, immune function, and infection risk. Common blood disorders presenting in children include sickle cell disease (presenting as acute chest syndrome, splenic sequestration, vasoocclusive crisis, and priapism), bleeding disorders (e.g, thrombocytopenia, hemophilia, von Willebrand's disease), leukemia, leukopenia, lymphoma, and others. After obtaining a thorough patient history (often provided by the parent or caregiver), important assessment findings include[20]:

- History of chest pain
- Weakness
- Abdominal pain
- Extremity pain
- Trauma
- Bleeding
- Swollen joints
- Swollen glands
- Fever
- Bruising

Depending on the condition of the patient and nature of the illness, prehospital care may include IV hydration, fluid resuscitation, bleeding control, pain control, and transport for physician evaluation. In children who have a high risk of infection (e.g., children with leukopenia and other white blood cell diseases), obtaining routine IV access should be avoided in the prehospital setting.

DID YOU KNOW?
Childhood Leukemia
Leukemia in children often is described as being acute or chronic. Almost all childhood leukemia is acute. The two main types of acute leukemia in children are *acute lymphocytic leukemia* (ALL) and *acute myelogenous leukemia* (AML), both of which can be further divided into subtypes. Of the estimated 3500 children (ages birth to 14 years) who will develop leukemia in the United States each year, about 3 out of 4 will be diagnosed with acute lymphocytic leukemia. Most of the remaining cases will be acute myelogenous leukemia. Chronic leukemias are rare in children.

Acute lymphocytic leukemia starts from the lymphoid cells in the bone marrow. Acute myelogenous leukemia (also called acute myeloid leukemia, acute myelocytic leukemia, or acute nonlymphocytic leukemia) accounts for most of the remaining cases. This leukemia originates from the cells that form white blood cells (other than lymphocytes), red blood cells, or platelets. ALL is most common in early childhood, peaking between 2 and 4 years of age. AML is most common during the first 2 years of life, and again during teenage years. The 5-year survival rate for children with ALL is now greater than 80%. The 5-year survival rate for children with AML is now 50% to 70%.[30]

Gastrointestinal Disorders

Abnormalities in the gastrointestinal (GI) tract can lead to illnesses in the pediatric patient that can cause vomiting and bleeding. These abnormalities may be the result of *gastrointestinal embryology* (the formation of the GI tract during fetal development). They may also result from illness and infection. Important components of the patient's history for children with GI disorders include[20]:

- Blood or bile in emesis
- Epistaxis
- Diarrhea
- Constipation
- Fever
- Medications
- Prematurity
- ABO incompatibility
- Liver disease

DID YOU KNOW?

GI Embryology

The primitive gut forms during the fourth week of gestation into the *midgut, foregut,* and *hindgut*. The midgut gives rise to the distal duodenum, jejunum, ileum, appendix, ascending colon, and proximal transverse colon. Errors in midgut development include omphaloceles (protrusion of the intestines through the umbilicus), umbilical hernias, and gastroschisis (extrusion of the viscera without involving the umbilicus).

The foregut develops into the pharynx, lower respiratory system, esophagus, stomach, proximal duodenum, liver and biliary tree, and pancreas. Errors in foregut development include esophageal atresia and tracheoesophageal fistula.

The hindgut matures into the distal transverse colon, descending colon, sigmoid colon, rectum, and proximal anal canal. Although rare, the most common error in hindgut development is neonatal bowel obstruction (*Hirschsprung's disease*) attributable to improper muscle movement in the bowel.

Depending on the cause of the child's illness, physical findings may include an elevation or decrease in heart rate and blood pressure, signs of dehydration (dry mucous membranes, absence of tears, decreased urinary output, delayed capillary refill), icterus (jaundice), abdominal distention or abdominal mass, hepatomegaly (enlarged liver), and pallor.

NOTE

Jaundice (yellowing of the skin, mucous membranes, and sclera) is the most common condition that requires medical attention in newborns.[31] It develops from elevation in the level of bilirubin (the pigment of bile). Physiological jaundice can occur during the first week of life. It is due to two causes: (1) the breakdown of fetal red blood cells, which release bilirubin into the blood; (2) the immaturity of the newborn's liver, which cannot effectively metabolize the bilirubin and prepare it for excretion into the urine. Physiological jaundice is common and normally resolves with time. All other forms of jaundice in the neonate are considered pathological. Pathological jaundice is a prolonged jaundice that results from illness in the newborn and a rapid rise in serum bilirubin concentration. It usually appears within 24 hours after birth. Illnesses that can cause pathological jaundice include sepsis, rubella, toxoplasmosis, and erythroblastosis.

GI DISORDERS THAT CAUSE VOMITING

Vomiting is a protective mechanism that removes toxic materials from the GI tract before they are absorbed. Vomiting is controlled by the emetic center, located in the reticular formation of the brainstem. The emetic center can be stimulated by chemoreceptors, cranial nerves, vagal and enteric input, and the central nervous system. Three disorders that can cause vomiting in the pediatric patient are gastroenteritis, intestinal malrotation, and pyloric stenosis.

As described in Chapter 29, *gastroenteritis* is inflammation of the stomach and intestines that can accompany many conditions of the GI tract. In infants and children, gastroenteritis is most often due to viral infections that can cause diarrhea, with or without vomiting. In the very young and very old, gastroenteritis can cause life-threatening dehydration that may require volume replacement therapy.

LOOK AGAIN

See Chapter 29: Abdominal and Gastrointestinal Disorders, pp. 895-896.

GI DISORDERS THAT CAUSE BLEEDING

Bleeding can occur from the upper and lower GI tract in children of all ages (Box 48-10). For example, upper GI bleeding can occur in newborns who swallow maternal

BOX 48-10 Causes of GI Bleeding[16,20]

Neonate
Swallowed maternal or nasopharyngeal blood
Anal fissure
Necrotizing enterocolitis
Malrotation
Hirschsprung's disease
Coagulopathy

Infants and Toddlers
Allergic colitis
Infectious enteritis
Intussusception
Congenital diverticulum (*Meckel's diverticulum*)
GI duplication (congenital growth of a twin segment of intestine)

School-Age Children
Infectious enteritis
Juvenile polyps
Hemolytic uremic syndrome
Henoch-Schönlein purpura (systemic inflammation of blood vessels)

Adolescents
Infectious diarrhea
Juvenile polyps
Inflammatory bowel disease

BOX 48-11 Signs and Symptoms of Infection in Pediatric Patients

Bulging fontanelle (infants)
Chills
Cool or clammy skin
Cough
Dehydration
Fever
Hypoperfusion
Hypothermia (neonates)
Irritability
Lethargy
Malaise
Nasal congestion
Poor feeding
Respiratory distress
Seizure
Severe headache
Sore throat
Stiff neck
Tachycardia
Tachypnea
Vomiting or diarrhea (or both)

blood. Lower GI bleeding can occur in adolescents from inflammatory bowel disease. The child's condition, signs, and symptoms will be related to the site and cause of the bleeding. Prehospital care may range from supportive care and transportation for physician evaluation to providing advanced life support for the management of shock and hypovolemia. Following stabilization, patients with disorders that cause vomiting or bleeding are managed with bowel rest, antibiotics (if needed), and volume replacement.

Infection

Children with infection may have a variety of signs and symptoms. The symptoms depend on the source and extent of infection and the length of time since the patient was exposed (Box 48-11). Often the parent or caregiver provides a history of recent illness. (This may include, for example, fever, upper respiratory tract infection, or otitis media.) When caring for any patient who may have an infectious disease, the paramedic must strictly adhere to body substance isolation because of the unknown cause of the infection.

Most children with infection need only supportive care while being transported for evaluation by a physician. However, in very sick children, support of the airway, ventilation, and circulation may be needed. If signs of decompensated shock are present, IV therapy may be needed. Active seizure activity may require the use of anticonvulsant agents. When possible, a child in stable condition should be transported in the child's position of comfort. The child also should be transported in the company of the parent or caregiver.

Poisoning and Toxic Exposure

As discussed in Chapter 34, most poisoning in the United States involves children and is a major cause of preventable death in children under 5 years of age.[5] Common sources of poisoning (unintentional and intentional) include the following:

- Acetaminophen
- Alcohol
- Anticholinergics
- Aspirin
- Barbiturates
- Cold medicines
- Corrosives
- Digitalis, beta-blocker agents
- Hydrocarbons
- Narcotics
- Organic solvents (inhaled)
- Organophosphates
- Sedatives
- Vitamins (especially iron)

The signs and symptoms of poisoning vary, depending on the toxic substance and the length of time since the child was exposed. These signs and symptoms may include cardiac and respiratory depression, central nervous system stimulation or depression, gastrointestinal irritation, and behavioral changes. Emergency care should be directed first at ensuring adequate airway, ventilatory, and circulatory support (Box 48-12). The paramedic should contact medical direction and the poison control center for specific treatments. All pills, substances, and containers associated with the poisoning should be transported with the child to the receiving hospital. As described in Chapter 34, no efforts should be made in the prehospital setting to induce vomiting. Gastric lavage also is contraindicated unless ingestion of poison has been less than 1 hour before EMS arrival.

CRITICAL THINKING
For what critical signs or symptoms of poisoning should you be alert?

Pediatric Trauma

Blunt trauma and penetrating trauma are major causes of injury and death in children.[5] These and other significant injuries in children often result from falls, motor vehicle crashes, pedestrian-vehicle collisions, drowning/submersion incidents, penetrating injuries, burns, and abuse. The following common injuries highlight the value of injury prevention programs (see Chapter 3):

Falls: Falls are the single most common cause of injuries in children. Fortunately, serious injury or death from truly unintentional falls is uncommon, that is, unless the fall is from a significant height.

BOX 48-12 Toxicological Emergencies in Pediatric Patients

The most important agents associated with cardiac arrest or requiring advanced life support in children are cocaine, narcotics, tricyclic antidepressants, calcium channel blockers, beta-adrenergic blockers, and opioids. Regardless of the drug, the initial approach in toxicological emergencies is to ensure adequate oxygenation, ventilation, and circulation. Subsequent priorities include reversing the adverse effects of the toxin (if possible) and preventing further absorption of the agent (see Chapter 34). This is an overview of these drugs, their effects, and specific treatment that may be required in the prehospital setting. (*Note:* All drug therapy referenced in this box is based on patient presentation and should be guided by medical direction.)

Cocaine

Effects are complex and are related to route of administration and form of cocaine used.

Signs and Symptoms

May include tachycardia (including ventricular tachycardia/ventricular fibrillation [VT/VF]), tremor, diaphoresis, mydriasis, mood elevation, movement disorders, hypertension, and acute coronary syndrome (chest pain and dysrhythmias)

Specific Treatment

Cool to prevent hyperthermia
Oxygen administration and ventilatory support
Continuous electrocardiogram monitoring
Benzodiazepines (diazepam or lorazepam) for anticonvulsant and central nervous system depressant effect
Nitroglycerin to reduce coronary vasoconstriction
Sodium bicarbonate and lidocaine for ventricular dysrhythmias and cocaine-induced myocardial infarction
Epinephrine to increase coronary perfusion pressure during cardiac arrest
Do not give beta blockers

Cyclic Antidepressants (and Other Sodium Channel Blocking Agents)

Effects result from inhibition of fast sodium channels in the brain and myocardium.

Signs and Symptoms

May include cardiac rhythm disturbances, including preterminal sinus bradycardia and heart block with junctional or ventricular wide-complex escape beats

Specific Treatment

Oxygen administration and ventilatory support
Continuous electrocardiogram monitoring
Do not give amiodarone, sotalol, procainamide, quinidine, flecainide, propafenone
Sodium bicarbonate and lidocaine to increase myocardial contractility and to manage ventricular dysrhythmias
Normal saline boluses (10 mL/kg) to manage hypotension
Vasopressors (norepinephrine or epinephrine) to maintain vascular tone and blood pressure

Calcium Channel Blockers

Effects result from inhibiting the influx of calcium into cells, leading to bradydysrhythmias and hypotension.

Signs and Symptoms

May include bradycardia, hypotension, and altered mental status (including syncope, seizure, coma) from cerebral hypoperfusion

Specific Treatment

Oxygen administration and ventilatory support
Continuous electrocardiogram monitoring
Normal saline boluses (5 to 10 mL/kg) to manage hypotension (avoid pulmonary edema)
Calcium chloride 10% (Class IIb) and atropine to overcome channel blockade
High-dose vasopressor therapy with norepinephrine or epinephrine to treat bradycardia and hypotension
Insulin-glucose therapy to maintain serum glucose concentration (avoid hypoglycemia)

Beta-Adrenergic Blockers

Effects result from competition at beta-adrenergic receptors, resulting in bradycardia and decreased cardiac contractility.

Signs and Symptoms

May include hypotension with bradycardia, varying degrees of heart block, and altered mental status (including seizures and coma)

Specific Treatment

Oxygen administration and ventilatory support
Continuous electrocardiogram monitoring
Treat for shock
Epinephrine infusions and glucagon may be effective in managing beta-adrenergic blockade and overdose
Insulin-glucose therapy to maintain serum glucose concentration (avoid hypoglycemia)
Calcium chloride to improve heart rate if glucagon and catecholamine are not effective (Class IIb)

Opioids

Effects produce central nervous system depression.

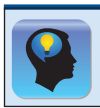
Signs and Symptoms

May include altered level of consciousness, hypoventilation, apnea, and respiratory failure

Specific Treatment

Oxygen administration and ventilatory support
Continuous electrocardiogram monitoring
Naloxone to reverse narcotic toxicity (normalize partial pressure of P_{CO_2} with ventilations before administration)

Adapted from American Heart Association: Guidelines 2005 for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, *Circulation* 112: IV-1 to IV-211, 2005.



CRITICAL THINKING
Why are children at risk for injuries related to falls?

Motor vehicle crashes: Motor vehicle crashes are the leading cause of permanent brain injury, serious injury, and death in children. Among infants less than 1 year old, death from motor vehicle crashes is second only to mechanical suffocation.[5]

Pedestrian-vehicle collisions: Pedestrian-vehicle collisions can result in serious injury or death in children. The initial injury is caused by impact with the vehicle. (The impact usually occurs to the extremity or trunk.) The child often is thrown from the force of the first impact. This causes additional injury (e.g., head and spine) upon a second impact with other objects. These objects may include the ground, another vehicle, or nearby objects (see Chapter 37).

Drowning/submersion: Drowning/submersion incidents are the third leading cause of death in children from birth to 4 years of age. Each year, about 1000 children die from drowning[12]; 5% to 20% of children who are hospitalized for submersion suffer severe, permanent brain damage.

Penetrating injuries: Although blunt trauma is more common, penetrating injuries are a major cause of trauma in children. They occur especially during adolescence. Penetrating injuries that are intentional (e.g., from violent crime) are more common in inner cities; however, unintentional penetrating injuries in rural areas also occur often. Stab wounds and firearm injuries make up about 10% to 15% of all pediatric trauma admissions. The risk of death from these injuries increases with the age of the patient. As with penetrating injuries to adults, the appearance of the external wounds cannot be used to determine the extent of internal injury in children.

Burns: Children less than 4 years of age and children with disabilities are at the greatest risk of burn-related death and disability.[32] Survival from burn trauma is determined by the size and depth of the burn, the presence of inhalation injury, and the nature of other injuries that may have occurred during the event (see Chapter 39).

CRITICAL THINKING
What types of situations cause burn injuries to children in the home?

Child abuse: Injuries to children may result from physical abuse, sexual abuse, emotional abuse, and child neglect. Physical abuse often is associated with domestic disturbances, younger-aged parents, substance abuse, and community violence. Abuse of children also occurs in all levels of society. When caring for a child who may have been abused, thorough documentation of pertinent findings, treatment, and interventions is critical for legal purposes. (Child abuse is described later in this chapter.)

SPECIAL CONSIDERATIONS FOR SPECIFIC INJURIES

Special considerations for managing pediatric injury are addressed in the chapters of Part 9: Trauma. The following is a review of some of the more important elements in assessment and management for children with head and neck injury, traumatic brain injury, chest injury, abdominal injury, extremity injury, and burns.

Head and Neck Injury

1. The larger relative mass of the head and lack of neck muscle strength provide increased momentum in acceleration-deceleration injuries.
2. The fulcrum of cervical mobility in the younger child is at the C2 to C3 level (70% of fractures in children younger than 8 years of age occur in C1 or C2).[33]
3. Head injury is the most common cause of death in pediatric trauma victims.[33]
4. Diffuse head injuries are common in children; focal injuries are rare.
5. Soft tissues, skull, and brain are more compliant in children than in adults.
6. Because of open fontanelles and sutures, infants up to 12 to 18 months of age may be more tolerant to increased intracranial pressure (ICP) and can have delayed signs.
7. Subdural bleeding in an infant can produce hypotension (rare).
8. Significant blood loss can occur through scalp lacerations, and such bleeding should be controlled immediately.
9. The modified Glasgow Coma Scale (GCS) should be used for assessing infants and young children.

Traumatic Brain Injury

1. Early recognition and aggressive management can reduce mortality and morbidity.
2. The modified Glasgow Coma Scale (GCS) should be used for assessing infants and young children.
3. Signs of increased ICP include elevated blood pressure, bradycardia, irregular respirations progressing to Cheyne-Stokes respirations, and bulging fontanelle in infants.
4. Signs of herniation include asymmetrical pupils and abnormal posturing.
5. Management includes the following:
   a. Administer high-concentration oxygen for mild to moderate head injury (GCS score of 9 to 15). Monitor pulse oximetry.
   b. Intubate and ventilate at normal breathing rate with 100% oxygen for severe head injury (GCS score less than 8).[6]
   c. Hyperventilate only with signs of increased ICP.
   d. Some authorities recommend the use of ***lidocaine*** before intubation to blunt the rise in ICP. This, however, is controversial. Use of ***lidocaine*** should be guided by medical direction.

CRITICAL THINKING
What are some early signs of increasing intracranial pressure in a child?

Chest Injury

1. Chest injuries in children less than 14 years of age usually are the result of blunt trauma.[33]
2. Because of flexibility of the chest wall, severe intrathoracic injury (such as severe pulmonary contusion) can be present without signs of external injury such as rib fractures.
3. Tension pneumothorax is poorly tolerated and is an immediate threat to life.
4. Flail segment is an uncommon injury in children; when noted without a significant mechanism of injury, child abuse should be suspected.
5. Many children with cardiac tamponade have no physical signs other than hypotension.

Abdominal Injury

1. Musculature is minimal and poorly protects the viscera.
2. Organs most commonly injured are the liver, kidneys, and spleen.
3. Onset of symptoms may be rapid or gradual.
4. Because of the small size of the abdomen, palpation should be performed in one quadrant at a time.
5. Any child who is hemodynamically unstable without an obvious source of blood loss should be considered to have an abdominal injury until it is proved otherwise.
6. The majority of children with abdominal injury have abdominal bruising or ecchymosis.

Extremity Injury

1. Extremity injury is relatively more common in children than adults.
2. Growth plate injuries are common.
3. Compartment syndrome is an emergency in children.
4. Management includes the following:
   a. Control any sites of active bleeding.
   b. Perform splinting to prevent further injury and blood loss.
   c. Use of a pneumatic antishock garment or pelvic binding with a sheet may be helpful for an unstable pelvic fracture with hypotension (per protocol).
5. Most femur fractures result from falls or other unintentional injuries; however, child abuse should be considered.

Burns

1. Burns may be thermal, chemical, or electrical.
2. Management priorities include the following:
   a. Prompt management of the airway is required because swelling can develop rapidly.
   b. If intubation is indicated, an endotracheal tube one half size smaller than expected may be required.
   c. Suspect musculoskeletal injuries in electrical burn patients, and perform spine immobilization. (Spinal cord injury can be present in children without vertebral abnormality.)

TRAUMA MANAGEMENT CONSIDERATIONS FOR PEDIATRIC PATIENTS

In addition to the general patient care guidelines appropriate for all injured persons, injured children require special consideration for airway control, immobilization techniques, fluid management, and pain relief. The following discussion reviews the highlights of management guidelines presented in the chapters of Part 9: Trauma.

Airway Control. The airway of an injured child should be maintained in an in-line or neutral position. (The sniffing position is appropriate for older children and adults.) (Padding may need to be placed under the shoulders in some children. This will help to maintain a neutral airway position.) High-concentration oxygen should be given to all patients. Jaw-thrust positioning and suctioning can be used to keep the airway open. Endotracheal intubation (followed by insertion of a gastric tube) should be performed when airway and ventilation remain inadequate. Cricothyroidotomy rarely is indicated for traumatic upper airway obstruction.

All paramedics who provide care for infants and children must be able to provide effective oxygenation and ventilation using the bag-mask technique. Endotracheal intubation sometimes may be needed when caring for injured children. When tracheal intubation is required, endotracheal tube placement should be confirmed by monitoring exhaled carbon dioxide, especially in children with a perfusing rhythm.

Immobilization. Spinal immobilization devices must be the right size for infants and children. Equipment that may be used includes the following:

- Child safety seat
- Long spine board
- Padding
- Pediatric immobilization device
- Rigid cervical collar
- Straps, cravats
- Tape
- Towel/blanket roll/sandbags
- Vest-type/short spine board

NOTE
Spine boards are extrication devices meant to assist emergency personnel in moving patients. As a stand-alone device, they do not provide adequate immobilization of the spine.

The patient should be placed supine (unless positioned in an infant carrier) and immobilized in a neutral in-line position. This is achieved most effectively by using a

backboard with a recess for the head or by using padding under the back from the shoulders to the buttocks.[1]

Fluid Management. Management of the child's airway and breathing takes priority over management of circulation. Circulatory compromise is less common in children than adults. When vascular access is indicated, the paramedic should consider the following[1]:

- Large-bore IV catheters should be inserted into large peripheral veins.
- Transport should not be delayed to obtain vascular access.
- Intraosseous access in children can be used if IV access fails.
- An initial fluid bolus of 20 mL/kg of lactated Ringer's solution or normal saline should be given. This will help to manage volume depletion.
- Vital signs should be reassessed and the bolus (20 mL/kg) repeated if needed; vital signs that do not improve after a second bolus indicate the need for rapid surgical intervention.

Pain Relief. Injuries are often painful. Relief from pain should be a priority when providing care to an injured child (see Box 48-13 and Figure 48-21). Drugs that may be used to manage some forms of pain and to alter the emotional response in pediatric patients include ***fentanyl, ketamine, ketorolac, morphine,*** or ***nitrous oxide*** (in the absence of hemorrhage).[34] Other indications for pain relief or sedation in pediatric patients include some airway management procedures (e.g., drug-assisted intubation), entrapment requiring extended extrication time, and cardioversion or other uncomfortable procedures.

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) is the leading cause of death in American infants under 1 year of age.[35] The syndrome is defined as the sudden death of a seemingly healthy infant that remains unexplained by history and an autopsy. Sudden infant death syndrome affects about 0.57 per 1000 live births each year in the United States.[36] The syndrome cannot be predicted or prevented. However, positioning during sleep appears to be a factor (Box 48-14).

NOTE

Infants may experience episodes termed **apparent life-threatening events** (ALTEs). These are clinical events in which young infants (usually less than 6 months of age) may experience abrupt changes in breathing, color, or muscle tone. Common causes of ALTEs include viral respiratory tract infection (e.g., RSV), gastroesophageal reflux disease, or seizure. There is no scientific evidence that links ALTEs as events that may lead to SIDS.[37]

ALTE requires medical evaluation. Abusive head injury, intentional suffocation, and Munchausen syndrome by proxy have been associated with ALTEs. Medical disorders associated with an ALTE may be respiratory, metabolic, neurological, and endocrinological in origin. In about 50% of cases no cause is identified.[16]

BOX 48-13 Pain Management

Pain management is important when caring for children. It should be considered when indicated to relieve pain associated with traumatic injury such as fractures and burns. Children do not always express their pain as clearly as adults. As a result, they are less likely to receive appropriate pain therapy in an emergency situation. Thus the paramedic should perform a systematic pain assessment. A memory aid for one type of pain assessment is QUESTT*:

- *Q:* Question the child about his or her pain, using age-appropriate language (e.g., "owie" or "boo-boo" for young children).
- *U:* Use pain rating scales (e.g., the Faces Pain Rating Scale for young children; a numerical pain scale from 0 to 10 for older children).
- *E:* Evaluate the child's behavior (e.g., facial grimace, rigidity, crying, and anxious behavior).
- *S:* Secure the parent or caregiver's involvement in assessing the child's pain. (The parent will have seen the child in pain or discomfort before and will be aware of subtle changes.)
- *T:* Take cause of the pain into account (e.g., type of injury and expected intensity of pain).
- *T:* Take action to provide comfort and to relieve pain (e.g., narcotic and nonnarcotic drugs, comfort measures such as application of cold, elevation, and distraction techniques).

*From Wong D, Hess C: *Clinical manual of pediatric nursing,* ed 5, St Louis, 2000, Mosby.

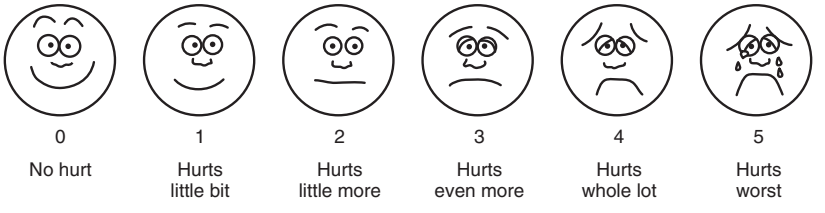


FIGURE 48-21 Wong-Baker Pain Scale. Explain to the child that each face is for a person who feels happy because there is no pain (hurt) or sad because there is some or a lot of pain. Face 0 is very happy because there is no hurt. Face 1 hurts just a little bit. Face 2 hurts a little more. Face 3 hurts even more. Face 4 hurts a whole lot, but Face 5 hurts as much as you can imagine, although you do not have to be crying to feel this bad. Ask child to choose the face that best describes the child's own pain. Record the number under chosen face on patient care report.

BOX 48-14 Sleep Positions and Other Factors That May Reduce the Risk of Sudden Infant Death Syndrome

In 1994 the Association of SIDS and Infant Mortality Programs joined with the U.S. Public Health Service, the American Academy of Pediatrics, the SIDS Alliance, and others to launch a national public health campaign titled *Back to Sleep* to reduce the risk of sudden infant death syndrome (SIDS). This initiative was based on research reports from Australia, New Zealand, England, Norway, and the United States. The data indicated that placing healthy newborns to sleep on the back or side was a means of reducing the risk of SIDS. In 1996 this recommendation was revised to endorse "back sleeping" as the best position for infants. Since the inception of this campaign, the SIDS rate has declined 50% in the United States, the greatest decline in the SIDS rate since statistics began to be compiled. Although such a dramatic decline suggests that a change in the sleeping position to back sleeping may reduce the risk of SIDS, it also has demonstrated that sleeping position, in and of itself, is not a cause of SIDS. Other recommendations for reducing the risk include the following:

- Starting medically recommended prenatal care early
- Avoiding drugs, alcohol, and smoking during pregnancy
- Forbidding smoking around the infant
- Breastfeeding when possible
- Avoiding overdressing or overheating the baby
- Maintaining regular well-baby health visits
- Obtaining immunizations on schedule
- Maintaining immunizations
- Placing the baby to sleep on a firm mattress and avoiding the use of beanbag cushions; waterbeds; soft, fluffy blankets; comforters; sheepskins; pillows; stuffed toys; or other soft materials

From *Back to Sleep Public Education Campaign,* National Institutes of Health, Eunice Kennedy Shriver, National Institute of Child Health and Human Development, www.nichd.nih.gov/sids/sids.cfm, accessed 10-16-10.
NOTE: Paramedics can play an important role in prevention by conveying this information to parents, other caregivers, and family members.

Sudden infant death syndrome occurs during periods of sleep. It usually occurs between midnight and 6 AM. The typical age for SIDS is the first year of life, but most SIDS deaths occur within the first 6 months.[35]

The seasonal distribution for SIDS is October through March (in the northern hemisphere). The infant often has a history of minor illness, such as a cold, within 2 weeks before death. Signs that may be present include lividity; frothy, blood-tinged drainage from the nose and mouth; and rigor mortis. With most SIDS cases, no external signs of injury are found. Often evidence indicates that the baby was active just before the death (e.g., rumpled bed clothes, unusual position or location in the bed).

PATHOPHYSIOLOGY

The cause of SIDS is unknown. Studies have failed to confirm a number of physiological, environmental, genetic, and social factors as causes. The studies have confirmed, however, that SIDS is not caused by external suffocation, regurgitation or aspiration of vomitus, hereditary factors, or allergies. (A small percentage of SIDS deaths are thought to be abuse related.[38]) Various physiological aspects that have been suggested to explain SIDS include immaturity of the central nervous system following a prenatal event, idiopathic apnea, brainstem abnormalities, upper airway obstruction, hyperactive upper airway reflexes, cardiac conduction disorders, abnormal responses to hypoxia and hypercarbia, abnormal responses to hyperthermia, and alterations in fat metabolism. Although no specific cause has been identified, a number of risk factors have been associated with the syndrome. These factors include the following[39]:

- Maternal smoking
- Young maternal age (under age 20)
- Infants of mothers who received poor or no prenatal care
- Infants born with low levels of serotonin
- Social deprivation
- Premature births and low-birth-weight infants
- Infants of mothers who used cocaine, methadone, or heroin during pregnancy

Sudden infant death syndrome is confirmed by excluding other causes of death. Autopsy findings that occur in most SIDS deaths include smooth muscle thickening in small pulmonary arteries and right ventricular hypertrophy. Both of these are thought to occur following hypoxia and constriction of the pulmonary vasculature. Other findings include brainstem tumors and low serotonin levels, which may be associated with respiratory center dysfunction. The presence of neuroepithelial bodies in the tracheobronchial tree along with distal atelectasis has also been found in SIDS victims. About 80% of SIDS victims also have intrathoracic petechiae, especially on the thymus, pleura, and pericardium.[38]

NOTE

It has recently been discovered that the brains of infants who die of sudden infant death syndrome produce low levels of serotonin. Researchers theorize that this newly discovered serotonin abnormality may reduce an infant's capacity to respond to breathing challenges, such as low oxygen levels or high levels of carbon dioxide. These high levels may result from rebreathing exhaled carbon dioxide that accumulates in bedding while sleeping face down.[40]

MANAGEMENT

EMS providers can do little to help the SIDS infant. The main role of the paramedic is to offer emotional support for parents or other caregivers and loved ones. If the infant possibly could be viable, resuscitation should proceed as for any other infant in cardiac arrest. Even though resuscitation most likely will be unsuccessful, it is important for the parents or other caregivers to see that everything possible is being done for their child. The paramedic should follow

pediatric resuscitation protocols and should consult with medical direction on decisions to initiate or continue efforts.

A variety of grief reactions should be expected from those who witness the event (parents, family members, neighbors, babysitters). These reactions may vary from shock and disbelief to anger, rage, and self-blame. Arrangements should be made for a relative or neighbor to stay with the family or accompany them to the hospital so that they are not left alone. Many areas have SIDS resource services. These services provide immediate counseling and support for the family of an infant who dies of SIDS.

Sudden infant death syndrome victims may appear to have been abused or neglected. The mysterious nature of SIDS deaths and classic signs such as postmortem lividity and frothy fluid in the infant's nose and mouth give such an appearance. Regardless of the circumstances, the paramedic should avoid comments or questions that may imply a suspicion of improper child care. Determining the cause of death is not the duty of the emergency medical services crew. (However, careful scene observation is crucial.) The paramedic should document all findings objectively, accurately, and completely. Medical direction and other authorities (per protocol) should be advised if inappropriate child care is suspected.

The death of an infant has a powerful effect on all who are involved. Rescuers commonly have a range of emotional reactions after a SIDS death. Some emergency medical services, working with medical direction and SIDS resource agencies, provide counseling and formal debriefing programs. If these services are not available, the emergency medical services crew should discuss the event openly with others involved in the response (e.g., co-workers and law enforcement officers). This may help relieve normal feelings of anxiety and stress.

CRITICAL THINKING

What factors do you think influence the reactions of each crew member to a child who dies from sudden infant death syndrome?

Child Abuse and Neglect

More than 3 million cases of suspected child abuse and neglect are reported each year in the United States. (These reports can include multiple children.) In 2007, about 5.8 million children were involved in an estimated 3.8 million reports and allegations.[41] In the United States, child abuse and neglect results in about five deaths per day; the majority of deaths are children under 4 years of age. Paramedics should follow local protocol in reporting suspected abuse. They should discuss any suspicions of child abuse or neglect with medical direction as well. Agencies that may be involved in cases of child abuse or neglect include state, regional, and local child protection services. Also included are hospital-based social service departments and child protection programs.

Child abuse and neglect is a crime that must be reported by law in all 50 states. In some states persons have a legal duty to report child abuse or neglect (*mandated reporter*). Failure to report these cases may result in criminal prosecution and may be punishable by fine or imprisonment or both. As a rule, reporting in good faith provides immunity from legal liability as a consequence of reporting, which may be raised as a defense if one is sued for negligent reporting.

ELEMENTS OF CHILD ABUSE

Child abuse and neglect is the maltreatment of children by their parents, guardians, or other caregivers. Forms of maltreatment include infliction of physical injury (battered child syndrome, shaken baby syndrome), sexual exploitation, and infliction of emotional pain and neglect (medical neglect, safety neglect, nutritional and social deprivation). A number of factors come into play in the potential for child abuse. These include a caregiver with the potential to abuse, a child with particular characteristics that place him or her at risk for abuse, and an element of crisis.

Characteristics of Abusers. Child abuse usually reflects a pattern of unstable behavior. Child abuse is typically not a single act of violence. In many cases the abuser is the child's parent. However, other caregivers may be responsible. (For example, others may include family members, a boyfriend or girlfriend of the child's mother or father, an unrelated babysitter, or a sibling of the abused child.) In the case of physical abuse, most abusers tend to be unhappy, angry adults. They often are under extreme stress. They usually are isolated. Often they are incapable of using support agencies or an extended family in times of crisis. Often the abusers were the victim of physical or emotional abuse as children. Abusers come from all ethnic, geographical, religious, educational, occupational, and socioeconomic groups. Other factors that are characteristic of abusers include poverty and alcohol or other drug dependence. Other facts about child abuse are provided in Box 48-15.

CRITICAL THINKING

Can you make a determination that someone is not an abuser if they do not fit this profile based on your prehospital assessment?

Characteristics of an Abused Child. Abused children often have certain characteristics that increase their risk for abuse.[42] Common traits include demanding and difficult behavior, decreased level of functioning (e.g., a handicapped child or preterm infant requiring extra parenting), hyperactivity, and precociousness with intellectual ability equal to or superior to the parent. Often the parent sees the abused child as "special" or "different" from other siblings. Other factors that tend to increase the potential for child abuse are age (the child is usually under 5 years old), gender (boys are involved more often than girls), and illegitimacy.

BOX 48-15 Facts About Child Abuse and Neglect[41]

- It is estimated that between 60% and 85% of child fatalities attributable to maltreatment are not recorded as such on death certificates.
- 90% of child sexual abuse victims know the perpetrator in some way; 68% are abused by family members.
- 31% of women in prison in the United States were abused as children.
- Over 60% of people in drug rehabilitation centers report being abused or neglected as a child.
- About 30% of abused and neglected children will later abuse their own children, continuing the horrible cycle of abuse.
- The estimated annual cost of child abuse and neglect in the United States for 2009 is $104 billion.
- Abused children are 25% more likely to experience teen pregnancy.
- 14% of all men in U.S. prisons were abused as children.
- 36% of all women in prison were abused as children.
- Children who experience child abuse and neglect are 59% more likely to be arrested as a juvenile, 28% more likely to be arrested as an adult, and 30% more likely to commit violent crime.
- Abused teens are 3 times less likely to practice safe sex, placing them at greater risk for sexually transmitted infections (STIs).
- Children who have been sexually abused are 2.5 times more likely to abuse alcohol.
- Children who have been sexually abused are 3.8 times more likely to develop drug addictions.
- Nearly two thirds of the people in treatment for drug abuse reported being abused as children.

Crises That May Precipitate Abuse. Physical abuse or neglect can occur constantly during a child's life. More often, though, abuse and neglect are intermittent and unpredictable. The abuse often is triggered by stressors in the adult caregiver's life, especially when the caregiver expects the child to fill emotional needs created by the stress. Failure of the child to respond in an ideal way to the caregiver's needs may lead to abuse. Common crises associated with an episode of child abuse include the following:

- Financial stress
- Loss of employment
- Eviction from housing
- Marital or relationship stress
- Physical illness in a child that leads to intractable crying
- Death of a family member
- Diagnosis of an unwanted pregnancy
- Birth of a sibling

HISTORY OF INJURIES SUSPICIOUS FOR ABUSE

Physical abuse or neglect often is hard to determine. The ultimate diagnosis usually begins with suspicions based on unexplained injuries, discrepant history, delays in seeking medical care, and repeated episodes of suspicious injuries. If at any time an injured child indicates that an adult caused him or her physical harm, the paramedic should take this report seriously and advise medical direction. The paramedic should contact the proper authorities as well. In many cases these accusations are true. The following are 15 indicators of possible abuse[43]:

1. Any obvious or suspected fractures in a child under 2 years of age
2. Injuries in various stages of healing, especially burns and bruises
3. More injuries than are usually seen in other children of the same age
4. Injuries scattered on many areas of the body
5. Bruises or burns in patterns that suggest intentional infliction
6. Suspected increased intracranial pressure in an infant
7. Suspected intraabdominal trauma in a young child
8. Any injury that does not fit the description of the cause
9. An accusation that the child injured himself or herself intentionally
10. Long-standing skin infections
11. Extreme malnutrition
12. Extreme lack of cleanliness
13. Inappropriate clothing for the situation
14. Child who withdraws from parent
15. Child who responds inappropriately to the situation (e.g., quiet, distant, and withdrawn)

PHYSICAL FINDINGS SUGGESTIVE OF ABUSE

Some physical findings, such as multiple, widely dispersed bruises; welts; and burns, are suggestive of abuse. Such physical findings, along with a vague history or delays in seeking medical care for the child, should alert the paramedic to the possibility of abuse or neglect (Figure 48-22).

Bruises

- Bruises that predominate on the buttocks or lower back are almost always related to punishment.
- Genital area or inner thigh bruises may be inflicted for toileting mishaps.
- Facial bruises or a number of petechiae on the earlobe may be caused by slapping.
- Bruises of the upper lip and labial frenulum may be caused by forced feedings or from forcing a pacifier into the mouth of a screaming infant.
- Human hand marks resulting from squeezing are pressure bruises in shapes resembling fingertips, fingers, or the entire hand of the abuser.
- Human bite marks result in paired, crescent-shaped bruises. These bruises often contain individual teeth marks. The size of the arc distinguishes adult bites from child bites.

CRITICAL THINKING

Consider an infant under 3 months of age. Based on the physical capabilities of this age group, where would you expect to see "normal bruises"?

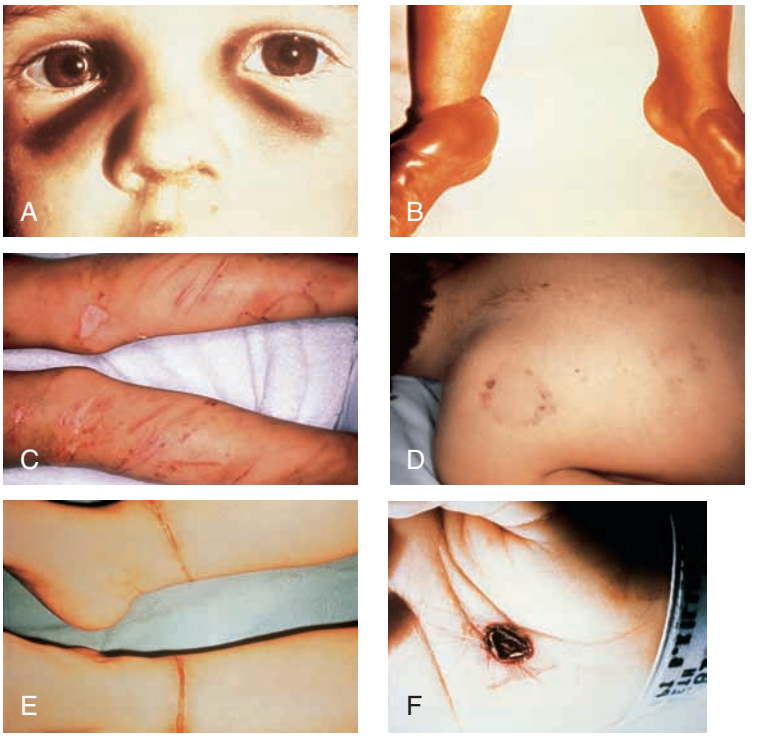

FIGURE 48-22 Cutaneous manifestations of child abuse. **A,** "Raccoon eyes," or periorbital bruising, is a possible indication of basilar skull fracture. **B,** Dunking/submersion burns of the feet. **C,** Welts and abrasions to legs as a result of an electrical cord. **D,** Human bites. **E,** Fresh abrasions of restraint injury. **F,** Fresh cigarette burn to palm.

NOTE

Identifying the age of bruises within 24 hours of the actual injury has been proven highly inaccurate, even among highly trained professionals.[44] Therefore, paramedics should not attempt to identify the age of a bruise or report the age of a bruise based on examination of the injured area. Doing so can lead to liability should litigation occur. The paramedic should, however, document what was observed, including color, size, location of any bruises, without reference to age.

Welts

- Strap marks 1 to 2 inches wide are almost always caused by a belt.
- Bizarre-shaped welts or bruises usually are inflicted by a blunt object that resembles its shape (e.g., a toy or shoe).
- Choke marks may be seen on the neck with or without associated petechiae of the face.
- Circumferential bruising or abrasions on the ankles or wrists may be caused by rope, cord, or a dog leash.

Burns

- Cigarette burns often are found on the palms, soles, or abdomen.
- A lighted cigarette, a hot match, or burning incense sometimes is applied to the hand to stop the child from sucking the thumb or to the genital area to discourage masturbation.
- Burns may be inflicted with lighters or other sources of open flame (e.g., a gas stove) to teach a child not to play with fire.
- Dry contact burns may result from forcibly holding a child against a heating device (e.g., a radiator, hot iron, or electric hot plate).
- The most common abusive hot-water burns or scalds occur from forcible immersion of the hands, feet, or buttocks in scalding water. These injuries often involve both arms or both legs, or they may be circular burns restricted to the buttocks; such burns are incompatible with falling or stepping into a tub of hot water.

Bites

- Human bites have different characteristics than animal bites and are usually more superficial injuries. For example, a human bite appears as 2 joined "c" shapes; a dog's bite has more of an oval or "u" shape.
- Human bites also may be seen with sexual assault.

Other less visible injuries may indicate child abuse. These include brain injury, abdominal visceral injury, and bone fractures.

Subdural Hematoma. Brain injury is the leading cause of death in battered children. The various pathological lesions include cerebral contusions, intraparenchymal

hemorrhage, and subdural or even epidural hematomata. Subdural hematomata are among the most common injuries associated with intentionally inflicted head injury in children. They should be suspected in any young child who is in a coma or having convulsions. They should be suspected particularly if the child has no history of seizure disorder. In many cases, bleeding into the brain tissue occurs as a result of skull fractures or scalp bruises. These commonly result from a direct blow from a hand or by being thrown against a wall or door.

Subdural hematomata also can result from vigorous shaking of the child (*shaken baby syndrome*). The acceleration and deceleration forces on the brain associated with shaking cause tearing of the bridging cerebral veins. This leads to bleeding into the subdural space. Signs and symptoms of the shaken baby syndrome include retinal hemorrhages, irritability, altered level of consciousness, vomiting, and a full fontanelle.

CRITICAL THINKING

Why is it critical that your documentation be clear, objective, and complete in cases of suspected abuse?

Abdominal Visceral Injury. Intraabdominal injuries are the second most common cause of death in battered children. These injuries usually are produced by a blunt force such as a punch or blow to the abdomen. Children with an abdominal injury often have recurrent vomiting, abdominal distention, absent bowel sounds, and localized tenderness with or without abdominal bruising. Caregivers routinely deny a history of trauma to the child's abdomen in these cases.

Bone Injury. More than 20% of physically abused children have a positive result on radiological bone survey from previous abusive episodes.[33] Injuries that may be obvious only through radiography include fractures of the ribs, lateral portion of the clavicle, scapula, sternum, and extremities. Multiple fractures in various stages of healing are highly suspicious for physical abuse.

INJURIES FROM SEXUAL ABUSE

Sexual abuse of a child is a symptom of a seriously disturbed family relationship. Sexual abuse usually is associated with physical or emotional neglect or abuse. Often the sexually abusive adult received similar abuse as a child. The adult may justify this behavior in his or her mind. Family relationships are complex, and silent complicity by at least one parent often is involved.

Injuries from sexual abuse may be physical and psychological. Sexual abuse may include vaginal intercourse, sodomy (anal intercourse), oral-genital contact, or molestation (fondling, masturbation, or exposure). In many cases the victimized child is a girl. More than half of the victims are under 12 years of age at the time of the first offense.[45] Many of these incidents are chronic and occur without force. Thus an emergency medical services response seldom is initiated. If, however, a physical injury results from the abuse, emergency care may be summoned. Physical findings suggestive of sexual abuse include the following:

- Pregnancy or venereal disease in a child 12 years of age or younger
- Painful urination or defecation
- Tenderness or lacerations of the perineal area
- Bleeding from the rectum or vagina
- Presence of dried blood, semen, or pubic hair in the genital area of a child

Emergency care for child victims of sexual abuse should be limited to managing injuries that pose a threat to life and giving emotional support during transport. These children undergo extensive interviews and examination by the emergency department physician and others. The paramedic should carefully document any statements made by the patient, family member, or caregiver. Any findings should be reported to medical direction. These children require compassionate support. A sexually abused child should never be made to feel that he or she is responsible for any of the abuse. The child also should not be given the impression that discussion of the event is inappropriate. If possible, a paramedic of the same gender should interview and care for the child.

All patients, regardless of age, who report sexual assault should be transported for physician evaluation to a medical facility staffed with nurses or physicians who are trained in forensic collection of evidence. Most regions coordinate an intensive interview by a social worker and a physical examination by a physician. This assessment is provided at hospital-based programs that have specialized training in the assessment and care of sexually abused children. Ideally, the paramedic should contact medical direction to identify a child protection center where these services can be provided. It is preferable that victimized children be interviewed and undergo physical examination only when needed.

INFANTS AND CHILDREN WITH SPECIAL NEEDS

Some infants and children are born with or develop conditions that pose special needs. These children may require special medical equipment to sustain life. Examples of these conditions include infants born prematurely, those who have altered functions from birth, and those who have chronic or acute disease of the lung, heart, or central nervous system. Often these children are cared for at home by family and home health services. Many are dependent on special medical equipment such as tracheostomy tubes, home artificial ventilators, central venous lines, gastrostomy tubes, and shunts (see Chapter 52). The parents and other family members of a child with special medical needs often are "experts" in caring for the child and maintaining the required medical equipment. Their knowledge, skills, and experience are valuable. The paramedic should use the

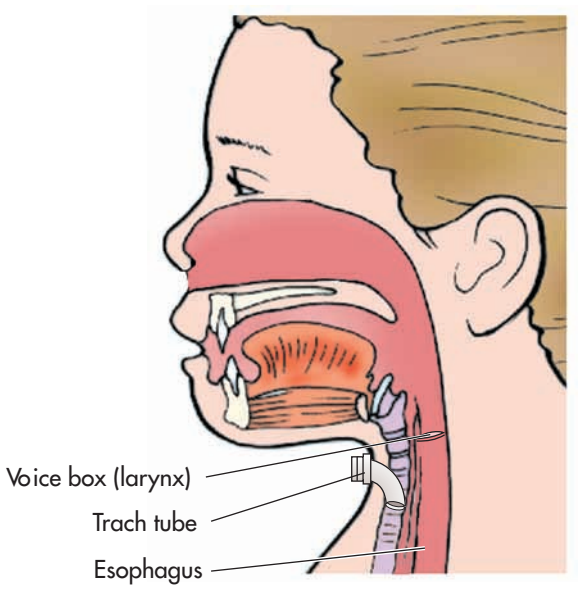

FIGURE 48-23 Pediatric tracheostomy tube.

FIGURE 48-24 Home ventilator.

skills and expertise of these parents when managing these emergencies.

CRITICAL THINKING

How can an emergency medical services agency prepare crews to care for these special needs children before a call is even received?

Tracheostomy Tubes

In a patient with a complete tracheostomy, the airway surgically bypasses the larynx at the level of the trachea. The larynx is no longer connected to the trachea. Modern tracheostomy tubes are flexible and relatively comfortable for the patient. They have few associated risks (Figure 48-23). Complications that can occur with the tracheostomy tube include obstruction, air leak, bleeding, dislodgment, and infection. All of these may lead to inadequate ventilation. (Bleeding around a tracheostomy usually occurs within 24 hours of the surgery and is not commonly seen in the prehospital setting.[33]) Aseptic technique and respiratory support are always high priorities in caring for these patients.

MANAGEMENT

The tracheostomy tube may become blocked or dislodged. In these cases, the paramedic must clear the tube with sterile water or saline or remove and reinsert it as described in Chapter 15. (Medical direction may advise that a tracheostomy tube be replaced with an endotracheal tube as a temporary measure.) Tracheal suctioning (using sterile technique) may be required to remove secretions and mucus. If tracheal intubation becomes necessary in these patients, it must be performed via the stoma.

NOTE

Tracheal suctioning is a difficult procedure and often is traumatic for the patient. It can easily lead to hypoxia. Tracheal suctioning should be performed only when absolutely necessary. It should be performed briefly, for only a period of 10 to 15 seconds. After that, high-concentration supplemental oxygen should be administered by mask to the stoma or via a bag-valve mask.

Home Artificial Ventilators

When a child needs help breathing, he or she may be put on a mechanical ventilator (Figure 48-24). This can simulate the normal movement of the diaphragm and thoracic cage. The type of home ventilator used depends on the patient's specific needs. Ventilators are classified by function. This is based on the amount of air and pressure they are set to deliver during certain phases of the respiratory cycle. Complications can occur from malfunction of the machine and alarms, airway obstruction, and respiratory distress (Table 48-12).

MANAGEMENT

Because of the variety of artificial ventilators, the paramedic should never try to troubleshoot a ventilator problem. The paramedic also should not try to adjust the settings of the ventilator. Rather, the emergency medical services crew should always treat the patient and not try to correct the malfunction of the machine. Steps in managing a patient with a home artificial ventilator problem are presented in Chapter 52.

TABLE 48-12 Complications Seen With Home Artificial Ventilators

Complication	Possible Cause
Airway obstruction	Bronchospasm, mucus or secretions, tracheostomy or endotracheal tube malfunction, patient cough, fear, anxiety
Barotrauma	
Pneumothorax	High-pressure volumes
Atelectasis	Improper deep breathing, pneumothorax
Cardiovascular impairment	Reduction in venous return to heart caused by positive intrathoracic pressure, which compresses pulmonary circulation
Gastrointestinal complications	Swallowing air, gastrointestinal bleeding, gastric distention
Tracheal trauma	Cuff pressure on trachea
Respiratory tract infection	Bypass of natural defenses of upper airway, poor aseptic technique
Oxygen toxicity	High concentration of oxygen over prolonged periods

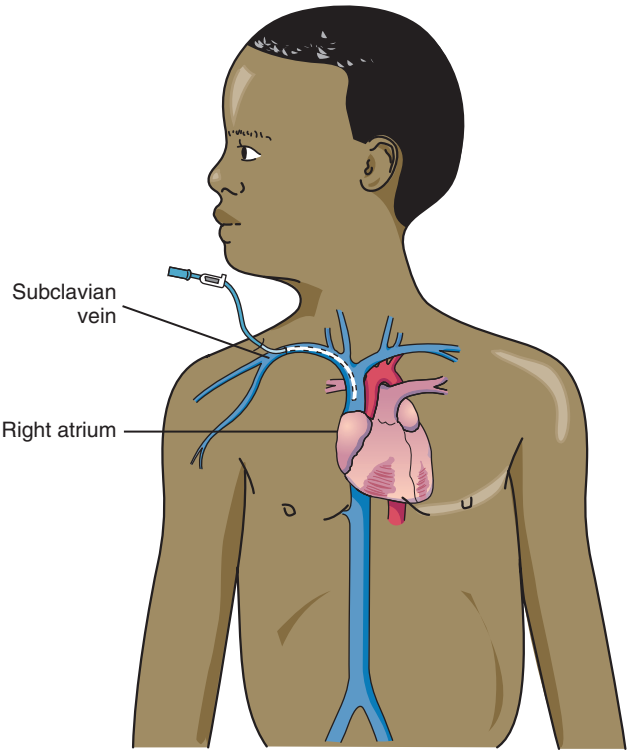

FIGURE 48-25 Central venous line.

Central Venous Lines

Some patients with chronic illnesses need prolonged and frequent access to venous circulation for drug or fluid therapy. This is made possible through vascular access devices. These devices are seen often in the prehospital setting in child and adult patients who are cared for in the home (Figure 48-25). These devices include surgically implanted medication delivery devices (e.g., Port-A-Cath), peripheral vascular access devices (e.g., peripherally inserted central catheters, Intracath), and central venous access devices (e.g., Broviac, Groshong, Hickman) (see Chapter 14 and Chapter 52). Complications that may occur with vascular access devices include a cracked line, air embolism, bleeding, obstruction, and local infection. Patients with vascular access devices often have a serious illness such as cancer or acquired immunodeficiency syndrome. The effects of these illnesses may complicate the assessment and management of emergencies associated with central venous lines.

MANAGEMENT

A torn or leaking catheter (cracked line) may allow fluids or drugs to infiltrate into the surrounding tissues. This can lead to an air embolism. A torn catheter is evidenced by leaking fluid, a complaint of a burning sensation, or swollen and tender skin near the insertion site. If a torn catheter is suspected, the paramedic should stop the infusion immediately and clamp the catheter between the tear and the patient. The patient who develops an altered level of consciousness (indicating a possible air embolism) should be positioned on the left side.[33] The patient's head should be slightly lowered to help prevent the embolism from traveling to the brain. High-concentration oxygen, IV access, and rapid transport for evaluation by a physician are indicated. Any bleeding at the site should be controlled with direct pressure.

Occasionally, the lumen port becomes obstructed by a blood clot that disrupts the flow of fluids or drugs. (Signs and symptoms of obstruction include a sluggish flow and swelling and tenderness at the site.) When this occurs, the patient should be transported to the hospital so that the catheter can be cleared with thrombolytics or replaced. Attempts to clear a vascular access device require special training and authorization from medical direction. The technique is described in Chapter 52.

Gastric Tubes and Gastrostomy Tubes

A gastric tube (Figure 48-26) is used as a temporary measure to provide liquid feeding to a patient who cannot swallow or absorb nutrients (often used for feeding premature infants). The tubes are inserted through the nose or mouth into the stomach and can cause irritation to the nasal and mucous membranes. They are designed for short-term use.

A gastrostomy tube (Figure 48-27) provides a permanent route for gastric feeding in patients who usually cannot be fed by mouth (e.g., a patient with facial burns or paralysis). The tube is surgically placed into the stomach. The tube can be visualized in the upper left quadrant of the abdomen. The opening (stoma) has a flexible, silicone "button." (This is covered with a protective cap.) The stoma allows for regular feedings.

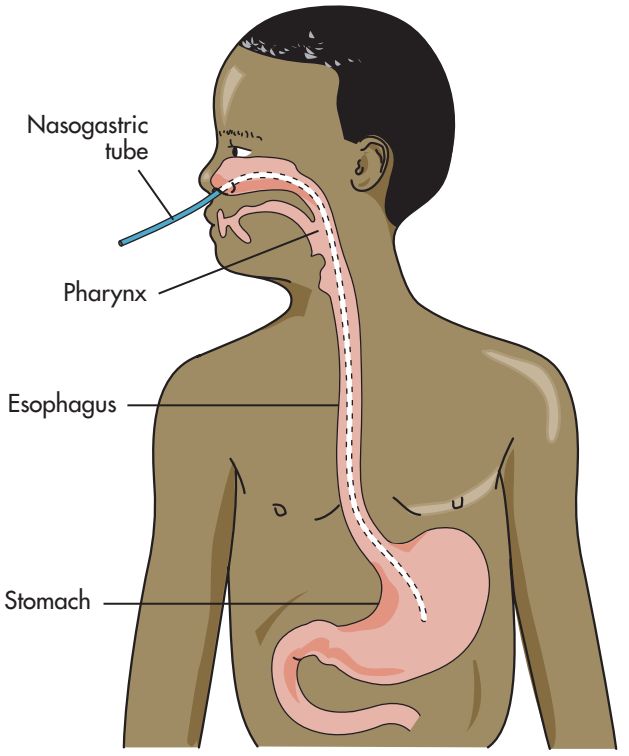

FIGURE 48-26 Nasogastric tube.

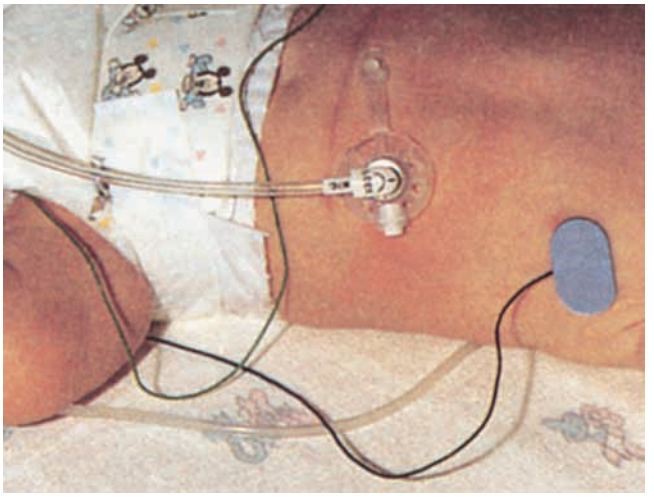

FIGURE 48-27 Gastrostomy tube.

MANAGEMENT

Serious complications with gastric or gastrostomy tubes are rare. They seldom require emergency care. Potential complications include obstruction, pulmonary aspiration, gastrointestinal disturbances (vomiting and diarrhea), irritation to the mucous membrane, and electrolyte imbalances. All of these can result in inadequate nutrition and fluid needs. Emergency care mainly is supportive. Care may include transport for evaluation by a physician. If not contraindicated, the patient will be most comfortable lying on the right side with the head elevated.

FIGURE 48-28 Untreated hydrocephalus.

Shunts

A **shunt** is a tube or device that is implanted surgically in the body. The shunt redirects body fluid from one cavity or vessel to another. An example of a shunt is one used to relieve abnormal fluid pressures from excess cerebrospinal fluid around the brain in children with **hydrocephalus** (Figure 48-28).

NOTE

The term hydrocephalus is derived from the Greek words "hydro" meaning water and "cephalus" meaning head. As the name implies, it is a condition in which the primary characteristic is excessive accumulation of fluid around the brain. (Although hydrocephalus was once known as "water on the brain," the "water" is actually cerebrospinal fluid.) The excessive accumulation of CSF results in an abnormal widening of the ventricles in the brain. This widening creates potentially harmful pressure on brain tissues. Hydrocephalus may be congenital or acquired. Congenital hydrocephalus (present at birth) may be caused either by events during fetal development or by genetic abnormalities. Acquired hydrocephalus develops at the time of birth or at some point afterward. This type of hydrocephalus can affect individuals of all ages and may be caused by injury or disease.

The shunt for hydrocephalus consists of two catheters, a reservoir, and a valve to prevent backflow (Figure 48-29). The first catheter is inserted through the skull. It drains fluid from the ventricles of the brain. The second catheter is passed into another body cavity (usually the abdomen or right atrium of the heart through the jugular vein), where the excess fluid is absorbed. The two catheters are connected by a reservoir and valve which is placed under the scalp. The reservoir usually can be palpated over the mastoid area, just behind the ear.

MANAGEMENT

Complications from this procedure include the need for catheter replacement as the child grows (requiring several surgeries in the first 10 years of life), obstruction from

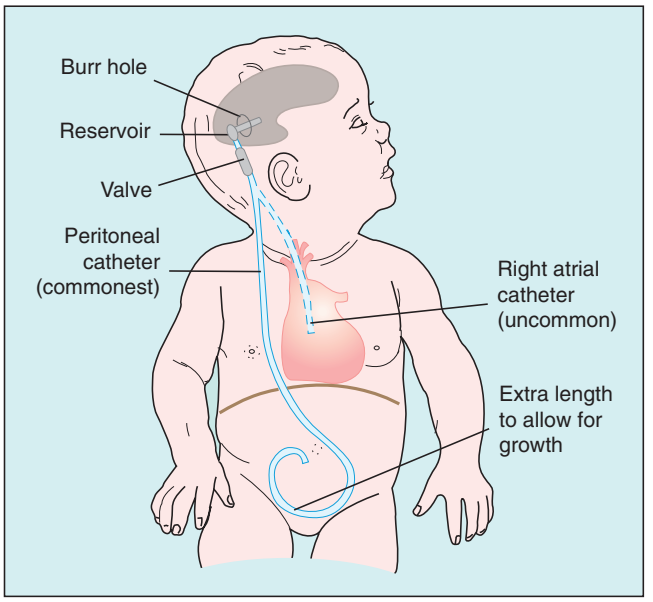

FIGURE 48-29 Ventricular shunt for drainage of symptomatic hydrocephalus.

clotted blood or fluid, and catheter displacement. Infection may occur, but is most common during the first 6 months after surgical placement. The signs and symptoms of obstruction or displacement are those of increased ICP. They include the following:

- Headache
- Nausea and vomiting
- Visual disturbances, in particular limitation in extraocular movements
- Cushing's triad (elevated systolic pressure, irregular respirations, bradycardia), which are signs of impending brainstem herniation

Children who have complications from a ventricular shunt need emergency surgery to prevent brainstem herniation. The paramedic first should ensure adequate airway, ventilatory, and circulatory support for these patients. Medical direction may recommend endotracheal intubation and hyperventilation to lower ICP, followed by IV access. These patients are prone to respiratory arrest. They need immediate transport to a proper facility for evaluation by a physician. If possible, the patient's head should be elevated during transport.

SUMMARY

- Paramedics must continually maintain their knowledge of pediatric emergency care.
- The Emergency Medical Services for Children (EMSC) program was designed to enhance and expand emergency medical services for acutely ill and injured children. The program has defined 12 basic components of an effective Emergency Medical Services for Children system.
- Children have unique anatomical, physiological, and psychological characteristics, which change during their development.
- Airway structures are narrower and less stable than those of adults. This increases the risk of upper and lower airway obstruction related to injury or illness.
- Principles of assessment are similar to those used for adults, but pediatric-sized equipment and specific adaptations to the examination should be made.
- Some childhood diseases and disabilities can be predicted by age group.
- Many elements of the initial evaluation can be done by observing the child. The child's parent or guardian also should be involved in the initial evaluation. The three components of the pediatric assessment triangle are appearance, work of breathing, and circulation.
- Paramedics must recognize and distinguish between respiratory distress, respiratory failure, and respiratory arrest.
- Obstruction of the upper or lower airway by a foreign body usually occurs in toddlers or preschoolers. Obstruction may be partial or complete.
- Croup is a common inflammatory respiratory illness. It usually is seen in children between the ages of 6 months and 4 years. Symptoms are caused by inflammation in the subglottic region.
- Epiglottitis is a rapidly progressive, life-threatening bacterial infection. It causes edema and swelling of the epiglottis and supraglottic structures. It often affects children between 3 and 7 years of age.
- Bacterial tracheitis is an infection of the upper airway and subglottic trachea usually seen in infants and toddlers; it often occurs with or after croup.
- Asthma is common in children over 2 years of age. Asthma is characterized by bronchoconstriction that results from autonomic dysfunction or sensitizing agents.
- Bronchiolitis is a viral disease frequently caused by respiratory syncytial virus infection of the lower airway; it usually affects children 6 to 18 months of age.
- Pneumonia is an acute infection of the lower airways and lungs involving the alveolar walls and the alveoli.
- Pertussis is a bacterial respiratory tract infection associated with a long course of illness, a violent cough with a characteristic "whoop," and a risk of pneumonia and death, especially in infants.
- Bronchopulmonary dysplasia is a chronic lung disease resulting from intervention with oxygen and ventilation in a neonate. It causes alveolar damage and chronic pulmonary dysfunction that can lead to death.
- Several special differences must be remembered when caring for a child in shock. These include circulating blood volume, body surface area and hypothermia,

cardiac reserve, and vital signs and assessment. A child in shock may appear normal and stable until all compensatory mechanisms fail. At that point, pediatric shock progresses rapidly, with serious deterioration.

- When dysrhythmias occur in children, they usually result from hypoxia or structural heart disease.
- Goals of postresuscitation stabilization in children include preserving brain function, avoiding secondary injury, identifying causes of illness, managing pain, and transporting to an appropriate facility.
- Meningitis is inflammation of the meninges. It can lead to neurological damage, hearing or vision impairment, and death.
- The most common causes of seizure in adult and pediatric patients are noncompliance with a drug regimen for the treatment of epilepsy, in addition to head trauma, intracranial infection, metabolic disturbance, or poisoning. The most common cause of new onset of seizure in children is fever.
- Hypoglycemia and hyperglycemia should be suspected whenever a child has an altered level of consciousness with no explainable cause. Consider diabetes as a possible cause in children even in the absence of a history of diabetes.
- Blood disorders that may affect children include sickle cell disease, leukemia, clotting disorders, and others.
- GI disorders in children can lead to serious illness including life-threatening dehydration and death.
- Children with infection may have a variety of signs and symptoms. These depend on the source and extent of infection and the length of time since the patient was exposed.
- Most poisoning events in the United States involve children. Signs and symptoms of accidental poisoning vary, depending on the toxic substance and the length of time since the child was exposed.
- Blunt and penetrating trauma is a chief cause of injury and death in children. Head injury is the most common cause of death in pediatric trauma patients. Early recognition and aggressive management can reduce morbidity and mortality caused by traumatic brain injury in children.
- Because of the pliability of the chest wall, severe intrathoracic injury can be present without signs of external injury. The liver, kidneys, and spleen are the most frequently injured abdominal organs. Extremity injuries are more common in children than adults.
- Sudden infant death syndrome is the leading cause of death in American infants under 1 year of age. The syndrome is defined as the sudden death of a seemingly healthy infant. The death cannot be explained by history and an autopsy.
- Child abuse and neglect is the maltreatment of children by their parents, guardians, or other caregivers. Forms of maltreatment include infliction of physical injury, sexual exploitation, and infliction of emotional pain and neglect.
- Some infants and children are born with or develop conditions that pose special needs. These children may require special medical equipment to sustain life. Often these children are cared for at home. Many are dependent on specialized medical equipment such as tracheostomy tubes, home artificial ventilators, central venous lines, gastrostomy tubes, and shunts. They may have emergencies associated with airway obstruction, impaired ventilation, infection, or increased intracranial pressure.

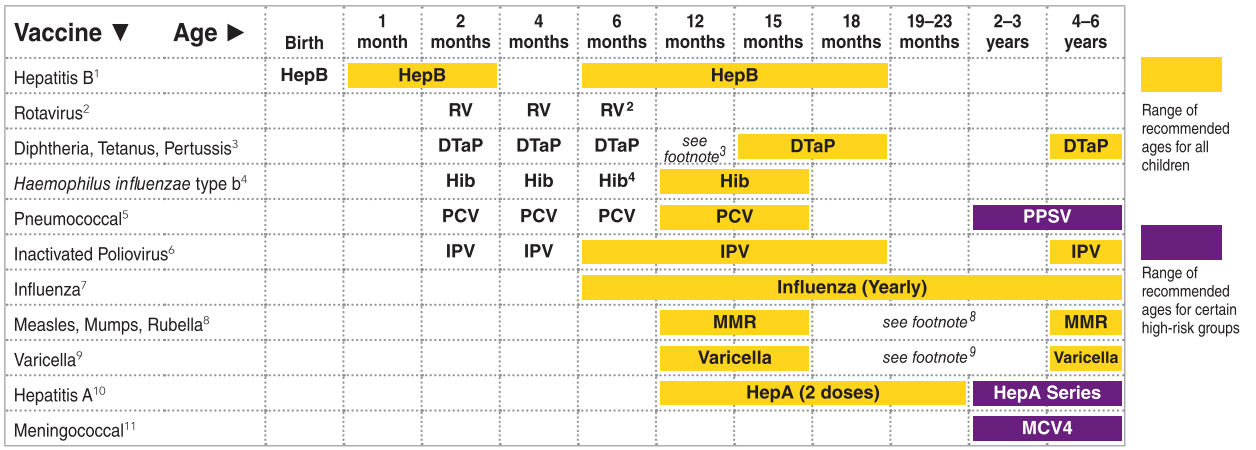
APPENDIX 48-1

Recommended Childhood and Adolescent Immunization Schedules

Recommended Immunization Schedule for Persons Aged 0 Through 6 Years—United States • 2011

For those who fall behind or start late, see the catch-up schedule



This schedule includes recommendations in effect as of December 21, 2010. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Considerations should include provider assessment, patient preference, and the potential for adverse events. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations: **http://www.cdc.gov/vaccines/pubs/acip-list.htm**. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS) at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967**.

1. **Hepatitis B vaccine (HepB).** (Minimum age: birth)
   At birth:
   - Administer monovalent HepB to all newborns before hospital discharge.
   - If mother is hepatitis B surface antigen (HBsAg)-positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
   - If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if HBsAg-positive, administer HBIG (no later than age 1 week).

   Doses following the birth dose:
   - The second dose should be administered at age 1 or 2 months. Monovalent HepB should be used for doses administered before age 6 weeks.
   - Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg 1 to 2 months after completion of at least 3 doses of the HepB series, at age 9 through 18 months (generally at the next well-child visit).
   - Administration of 4 doses of HepB to infants is permissible when a combination vaccine containing HepB is administered after the birth dose.
   - Infants who did not receive a birth dose should receive 3 doses of HepB on a schedule of 0, 1, and 6 months.
   - The final (3rd or 4th) dose in the HepB series should be administered no earlier than age 24 weeks.
2. **Rotavirus vaccine (RV).** (Minimum age: 6 weeks)
   - Administer the first dose at age 6 through 14 weeks (maximum age: 14 weeks 6 days). Vaccination should not be initiated for infants aged 15 weeks 0 days or older.
   - The maximum age for the final dose in the series is 8 months 0 days
   - If Rotarix is administered at ages 2 and 4 months, a dose at 6 months is not indicated.
3. **Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).** (Minimum age: 6 weeks)
   - The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
4. ***Haemophilus influenzae* type b conjugate vaccine (Hib).** (Minimum age: 6 weeks)
   - If PRP-OMP (PedvaxHIB or Comvax [HepB-Hib]) is administered at ages 2 and 4 months, a dose at age 6 months is not indicated.
   - Hiberix should not be used for doses at ages 2, 4, or 6 months for the primary series but can be used as the final dose in children aged 12 months through 4 years.
5. **Pneumococcal vaccine.** (Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPSV])
   - PCV is recommended for all children aged younger than 5 years. Administer 1 dose of PCV to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
   - A PCV series begun with 7-valent PCV (PCV7) should be completed with 13-valent PCV (PCV13).
   - A single supplemental dose of PCV13 is recommended for all children aged 14 through 59 months who have received an age-appropriate series of PCV7.
   - A single supplemental dose of PCV13 is recommended for all children aged 60 through 71 months with underlying medical conditions who have received an age-appropriate series of PCV7.
   - The supplemental dose of PCV13 should be administered at least 8 weeks after the previous dose of PCV7. See *MMWR* 2010:59(No. RR-11).
   - Administer PPSV at least 8 weeks after last dose of PCV to children aged 2 years or older with certain underlying medical conditions, including a cochlear implant.
6. **Inactivated poliovirus vaccine (IPV).** (Minimum age: 6 weeks)
   - If 4 or more doses are administered prior to age 4 years an additional dose should be administered at age 4 through 6 years.
   - The final dose in the series should be administered on or after the fourth birthday and at least 6 months following the previous dose.
7. **Influenza vaccine (seasonal).** (Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV])
   - For healthy children aged 2 years and older (i.e., those who do not have underlying medical conditions that predispose them to influenza complications), either LAIV or TIV may be used, except LAIV should not be given to children aged 2 through 4 years who have had wheezing in the past 12 months.
   - Administer 2 doses (separated by at least 4 weeks) to children aged 6 months through 8 years who are receiving seasonal influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.
   - Children aged 6 months through 8 years who received no doses of monovalent 2009 H1N1 vaccine should receive 2 doses of 2010–2011 seasonal influenza vaccine. See *MMWR* 2010;59(No. RR-8):33–34.
8. **Measles, mumps, and rubella vaccine (MMR).** (Minimum age: 12 months)
   - The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose.
9. **Varicella vaccine.** (Minimum age: 12 months)
   - The second dose may be administered before age 4 years, provided at least 3 months have elapsed since the first dose.
   - For children aged 12 months through 12 years the recommended minimum interval between doses is 3 months. However, if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.
10. **Hepatitis A vaccine (HepA).** (Minimum age: 12 months)
    - Administer 2 doses at least 6 months apart.
    - HepA is recommended for children aged older than 23 months who live in areas where vaccination programs target older children, who are at increased risk for infection, or for whom immunity against hepatitis A is desired.
11. **Meningococcal conjugate vaccine, quadrivalent (MCV4).** (Minimum age: 2 years)
    - Administer 2 doses of MCV4 at least 8 weeks apart to children aged 2 through 10 years with persistent complement component deficiency and anatomic or functional asplenia, and 1 dose every 5 years thereafter.
    - Persons with human immunodeficiency virus (HIV) infection who are vaccinated with MCV4 should receive 2 doses at least 8 weeks apart.
    - Administer 1 dose of MCV4 to children aged 2 through 10 years who travel to countries with highly endemic or epidemic disease and during outbreaks caused by a vaccine serogroup.
    - Administer MCV4 to children at continued risk for meningococcal disease who were previously vaccinated with MCV4 or meningococcal polysaccharide vaccine after 3 years if the first dose was administered at age 2 through 6 years.

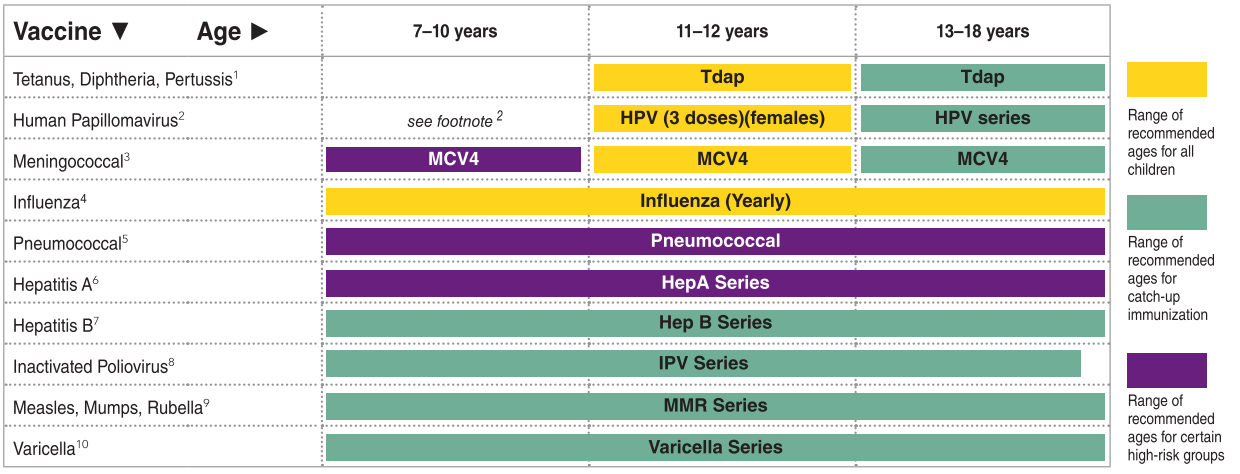
The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the Advisory Committee on Immunization Practices (**http://www.cdc.gov/vaccines/recs/acip**), the American Academy of Pediatrics (**http://www.aap.org**), and the American Academy of Family Physicians (**http://www.aafp.org**).

Department of Health and Human Services • Centers for Disease Control and Prevention

APPENDIX FIGURE 48-1 Centers for Disease Control and Prevention—United States, 2011.

Recommended Immunization Schedule for Persons Aged 7 Through 18 Years—United States • 2011

For those who fall behind or start late, see the schedule below and the catch-up schedule



This schedule includes recommendations in effect as of December 21, 2010. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Considerations should include provider assessment, patient preference, and the potential for adverse events. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations: **http://www.cdc.gov/vaccines/pubs/acip-list.htm**. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS) at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967.**

1. **Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).** (Minimum age: 10 years for Boostrix and 11 years for Adacel))
   - Persons aged 11 through 18 years who have not received Tdap should receive a dose followed by Td booster doses every 10 years thereafter.
   - Persons aged 7 through 10 years who are not fully immunized against pertussis (including those never vaccinated or with unknown pertussis vaccination status) should receive a single dose of Tdap. Refer to the catch-up schedule if additional doses of tetanus and diphtheria toxoid–containing vaccine are needed.
   - Tdap can be administered regardless of the interval since the last tetanus and diphtheria toxoid–containing vaccine.
2. **Human papillomavirus vaccine (HPV).** (Minimum age: 9 years)
   - Quadrivalent HPV vaccine (HPV4) or bivalent HPV vaccine (HPV2) is recommended for the prevention of cervical precancers and cancers in females.
   - HPV4 is recommended for prevention of cervical precancers, cancers, and genital warts in females.
   - HPV4 may be administered in a 3-dose series to males aged 9 through 18 years to reduce their likelihood of genital warts.
   - Administer the second dose 1 to 2 months after the first dose and the third dose 6 months after the first dose (at least 24 weeks after the first dose).
3. **Meningococcal conjugate vaccine, quadrivalent (MCV4).** (Minimum age: 2 years)
   - Administer MCV4 at age 11 through 12 years with a booster dose at age 16 years.
   - Administer 1 dose at age 13 through 18 years if not previously vaccinated.
   - Persons who received their first dose at age 13 through 15 years should receive a booster dose at age 16 through 18 years.
   - Administer 1 dose to previously unvaccinated college freshmen living in a dormitory.
   - Administer 2 doses at least 8 weeks apart to children aged 2 through 10 years with persistent complement component deficiency and anatomic or functional asplenia, and 1 dose every 5 years thereafter.
   - Persons with HIV infection who are vaccinated with MCV4 should receive 2 doses at least 8 weeks apart.
   - Administer 1 dose of MCV4 to children aged 2 through 10 years who travel to countries with highly endemic or epidemic disease and during outbreaks caused by a vaccine serogroup.
   - Administer MCV4 to children at continued risk for meningococcal disease who were previously vaccinated with MCV4 or meningococcal polysaccharide vaccine after 3 years (if first dose administered at age 2 through 6 years) or after 5 years (if first dose administered at age 7 years or older).
4. **Influenza vaccine (seasonal).**
   - For healthy nonpregnant persons aged 7 through 18 years (i.e., those who do not have underlying medical conditions that predispose them to influenza complications), either LAIV or TIV may be used.
   - Administer 2 doses (separated by at least 4 weeks) to children aged 6 months through 8 years who are receiving seasonal influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.
   - Children 6 months through 8 years of age who received no doses of monovalent 2009 H1N1 vaccine should receive 2 doses of 2010-2011 seasonal influenza vaccine. See *MMWR* 2010;59(No. RR-8):33–34.
5. **Pneumococcal vaccines.**
   - A single dose of 13-valent pneumococcal conjugate vaccine (PCV13) may be administered to children aged 6 through 18 years who have functional or anatomic asplenia, HIV infection or other immunocompromising condition, cochlear implant or CSF leak. See *MMWR* 2010;59(No. RR-11).
   - The dose of PCV13 should be administered at least 8 weeks after the previous dose of PCV7.
   - Administer pneumococcal polysaccharide vaccine at least 8 weeks after the last dose of PCV to children aged 2 years or older with certain underlying medical conditions, including a cochlear implant. A single revaccination should be administered after 5 years to children with functional or anatomic asplenia or an immunocompromising condition.
6. **Hepatitis A vaccine (HepA).**
   - Administer 2 doses at least 6 months apart.
   - HepA is recommended for children aged older than 23 months who live in areas where vaccination programs target older children, or who are at increased risk for infection, or for whom immunity against hepatitis A is desired.
7. **Hepatitis B vaccine (HepB).**
   - Administer the 3-dose series to those not previously vaccinated. For those with incomplete vaccination, follow the catch-up schedule.
   - A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB is licensed for children aged 11 through 15 years.
8. **Inactivated poliovirus vaccine (IPV).**
   - The final dose in the series should be administered on or after the fourth birthday and at least 6 months following the previous dose.
   - If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.
9. **Measles, mumps, and rubella vaccine (MMR).**
   - The minimum interval between the 2 doses of MMR is 4 weeks.
10. **Varicella vaccine.**
    - For persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007;56[No. RR-4]), administer 2 doses if not previously vaccinated or the second dose if only 1 dose has been administered.
    - For persons aged 7 through 12 years, the recommended minimum interval between doses is 3 months. However, if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.
    - For persons aged 13 years and older, the minimum interval between doses is 4 weeks.

The Recommended Immunization Schedules for Persons Aged 0 Through 18 Years are approved by the Advisory Committee on Immunization Practices (**http://www.cdc.gov/vaccines/recs/acip**), the American Academy of Pediatrics (**http://www.aap.org**), and the American Academy of Family Physicians (**http://www.aafp.org**).

APPENDIX FIGURE 48-2 Centers for Disease Control and Prevention—United States, 2011.

CHAPTER

49 Geriatrics

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Explain the physiology of the aging process as it relates to major body systems and homeostasis.
2. Describe general principles of assessment specific to older adults.
3. Describe the pathophysiology, assessment, and management of specific illnesses that affect selected body systems in the geriatric patient.
4. Identify specific problems with sensations experienced by some geriatric patients.
5. Discuss effects of drug toxicity and alcoholism in the older adult.
6. Identify factors that contribute to environmental emergencies in the geriatric patient.
7. Discuss prehospital assessment and management of depression and suicide in the older adult.
8. Describe epidemiology, assessment, and management of trauma in the geriatric patient.
9. Identify characteristics of elder abuse.

KEY TERMS

adverse drug event An injury resulting from the use of a drug.

Alzheimer's disease A disease characterized by confusion, memory failure, disorientation, speech disturbances, and inability to carry out purposeful movements.

biliary disease Disorders of the liver and gallbladder caused by abnormalities in bile composition, biliary anatomy, or function.

cataract A loss of transparency of the lens of the eye that results from changes in the delicate protein fibers within the lens.

cerebral atrophy Refers to brain issue that becomes smaller in size with age.

confabulation The invention of stories to make up for gaps in memory.

continence The ability to control bladder or bowel function.

decubitus ulcers Skin lesions caused by many factors, including unrelieved pressure, friction, humidity, shearing forces, temperature, age, incontinence, and medication.

delirium An abrupt disorientation for time and place, usually with illusions and hallucinations.

dementia A slow, progressive loss of awareness of time and place. It usually involves an inability to learn new things or recall recent events.

elder abuse The infliction of physical pain, injury, debilitating mental anguish, unreasonable confinement, or willful deprivation by a caregiver of services that are necessary to maintain mental and physical health of a geriatric person.

fecal impaction An accumulation of hardened feces in the rectum or sigmoid colon that the person is unable to move.

frailty A biological syndrome of decreased reserve and resistance to stressors, resulting from cumulative declines across multiple physiological systems, and causing vulnerability to adverse outcomes.

gerontology The study of the problems of all aspects of aging.

glaucoma A condition in which intraocular pressure increases and causes damage to the optic nerve.

hyperthyroidism A condition characterized by increased activity of the thyroid gland.

hypothyroidism A condition characterized by decreased activity of the thyroid gland.

incontinence The inability to control bladder or bowel function.

kyphosis An abnormal condition of the vertebral column characterized by increased convexity in the curvature of the thoracic spine as viewed from the side.

organic brain dysfunction Physical disorders that affect cognition.

osteoarthritis A form of arthritis in which one or many joints undergo degenerative changes.

osteoporosis A disorder characterized by a reduction in bone density; it occurs most often in postmenopausal women.

Parkinson's disease A disease caused by degeneration or damage (of unknown origin) to nerve cells within the basal ganglia in the brain.

pressure ulcers Sores or ulcers in the skin over a bony prominence that occur most frequently on the sacrum, elbows, heels, outer ankles, inner knees, hips, and shoulder blades of high-risk patients, especially those who are obese, elderly, or suffering from chronic diseases, infections, injuries, or a poor nutritional state.

retinopathy A group of inflammatory eye disorders often caused by diabetes, hypertension, and atherosclerotic vascular disease.

tinnitus A ringing sound in the ears.

The "graying" of American society includes the prospect that the health care needs of older adults will continue to increase in all areas. This includes prehospital care. About 25% of Americans will be 65 years of age or older by the year 2030 and will represent 70% of all ambulance transports.[1] This chapter addresses anatomical and physiological changes that accompany the aging process, special considerations in assessing and managing geriatric patients, and common emergencies that may result from normal aging and chronic illness.

(Courtesy Ray Kemp, St. Charles, Mo.)

DEMOGRAPHICS, EPIDEMIOLOGY, AND SOCIETAL ISSUES

More than 34 million Americans (12% of the U.S. population) are 65 years of age or older. The size of this group has soared during the last 100 years. At the same time, fertility rates in the United States have dropped. Thus there will be fewer persons under 65 years of age to support the cost of health care and living expenses of those over 65 years of age.

By the year 2050, nearly 25% of Americans will be eligible for Medicare. Also, the population over 85 years of age will have grown from 4 million to 19 million. This creates many challenges. Society will need to provide quality, cost-effective health care and support the increasing health and living expenses for the elderly. To meet the needs of this aging population properly, society must achieve the following[2]:

- The public must become better educated about the needs of the elderly because caregiving often becomes the responsibility of families and friends.
- Current and new health care professionals must be educated on the special needs of the aging population.
- The aging of the U.S. population demands continued and expanded research efforts into chronic diseases that affect the elderly and their families.
- Health care professionals need to reform heath care financing, delivery, and administrative structures to accommodate the predominance of chronic illness among the aging population.
- Health care professionals must develop solutions for the long-term care needs of the growing aging population. These solutions must address the emotional and financial needs of older adults and their families. They also must address the financial influence of long-term care in the United States.

Other key issues to consider in caring for the aging population include legal ones such as advance directives, durable power of attorney, and do not resuscitate orders. These were discussed in Chapter 6.

LIVING ENVIRONMENTS AND REFERRAL SOURCES

Many older Americans enjoy independent living. They enjoy this lifestyle with the help of spousal or family support and home health care programs. Others live dependently in nursing care facilities, assisted-living environments, and nursing homes. The elderly often receive assistance in independent and dependent living environments. They receive this help through local, state, and national programs and other resource agencies (Box 49-1). The paramedic should be familiar with the programs in the community that offer assistance to the elderly.

BOX 49-1 Sampling of Support and Assistance Programs for the Geriatric Patient

Community-based services
Home health care services
Hospice programs
In-home services
Institutional services
Multipurpose senior centers
Nutrition services
Religious and pastoral services
State advisory councils
State and national aging organizations
Volunteer organizations

PHYSIOLOGICAL CHANGES OF AGING

Gerontology is the study of the problems of all aspects of aging. The aging process proceeds at different rates in different persons. In addition, organ systems age at differing rates within the individual. However, in certain areas, predictable functional declines occur in all persons with increasing age. As a general guideline, these changes begin to occur at a rate of 5% to 10% for each decade of life after 30 years of age. The aging process affects all body systems. However, the effects on specific organ systems particularly relevant to the older adult occur in the respiratory, cardiovascular, renal, nervous, and musculoskeletal systems (Table 49-1).

CRITICAL THINKING

Consider your family members and friends who are in their 40s, 60s, or 80s. What age-related changes have you noticed?

NOTE

Frailty can be defined as a biological syndrome of decreased reserve and resistance to stressors, resulting from cumulative declines across multiple physiological systems, and causing vulnerability to adverse outcomes.[3] This concept distinguishes frailty from physical disability that is associated with advancing age.

Characteristics of frailty are low physical activity, muscle weakness, slowed performance, fatigue or poor endurance, and unintentional weight loss. Most frail older adults are women (partly because women outlive men), are more than 80 years old, and often receive care from an adult child. Because of the rapid rate of growth in the population 65 years and older, the number of frail elderly persons is increasing every year.[4]

Respiratory System Changes

Respiratory function in the older adult generally declines as the lung tissue ages. Reduced pulmonary capacity results from changes in lung and chest wall compliance. With aging, the chest wall becomes stiffer as the bony thorax becomes more rigid. Lung elastic recoil also decreases. Despite the loss of elasticity, which would tend to increase total lung capacity, total lung capacity remains the same. This is due to the opposing loss of chest wall compliance and weakened respiratory muscles. The diameter of the alveoli increases. The distal airways tend to collapse on expiration. These changes lead to an increase in residual volume and a decrease in vital capacity. Consequently, by 75 years of age, vital capacity may decrease by as much as 50%, maximum breathing capacity by as much as 60%, and maximum work rate and maximum oxygen uptake by as much as 70%.[5]

The arterial partial pressure of oxygen (PaO_2) also slowly decreases with age. But arterial carbon dioxide pressure stays the same. (This is most likely related to the much greater reserve in carbon dioxide elimination than in oxygen absorption.) At 30 years of age the PaO_2 of a healthy person breathing ambient air at sea level is about 90 mm Hg (90 torr). At 70 years of age the expected PaO_2 is 70 mm Hg (70 torr). These findings, along with the normal decline in chemoreceptor function, produce a diminished ventilatory response to hypoxia and hypercapnia.

Other factors that affect the respiratory system are the loss of cilia in the airways and a diminished cough reflex and impaired gag reflex. These can impair the bodily defense against inhaled bacteria and particulate matter. The decline in these defense mechanisms makes infectious pulmonary diseases of the older adult more common. It also makes these infections harder to resolve.

Cardiovascular System Changes

Cardiac function declines with age as a result of nonischemic physiological changes and the high incidence of atherosclerotic coronary artery disease.[6] Differentiation of the changes that are solely due to aging from those associated with ischemia is difficult because coronary artery disease is so prevalent in the older adult. However, even with aging alone, structural and physiological changes occur that limit cardiac function in the cardiovascular system. These changes include a diminished ability to raise the heart rate even in response to exercise or stress, a decrease in compliance of the ventricle, a prolonged duration of contraction, and a decreased responsiveness to catecholamine stimulation. Between 30 and 80 years of age, resting cardiac output decreases about 30%. Combined with the progressive increase in peripheral vascular resistance that occurs after 40 years of age, this decrease in cardiac output yields a significant drop in organ perfusion.[3] Myocardial hypertrophy, coronary artery disease, and hemodynamic changes predispose the geriatric patient to dysrhythmias, heart failure, and sudden cardiac

TABLE 49-1 Physiological Changes of Aging

Change	Result
Overall Appearance	
Skin	
Loss of elasticity	Wrinkling, thinning of skin
Loss of collagen	Increased susceptibility to injury
Shrinking of sweat glands	Dryness
Pigment deposition	Age spots
Sun damage	Senile keratosis
Eyes	
Clouding of lens	Cataracts (decreased visual acuity)
	Poor peripheral vision
Pigment deposition	Arcus senilis (bluish circle that forms around outer edge of iris)
Cardiovascular System	
Increased internal thickening of arteries	Hypertension
	Increased risk of stroke or heart attack
	Varicosities and clots
	Dysrhythmias
Increased cholesterol deposits (atherosclerotic heart disease)	Coronary artery disease and peripheral vascular disease
Decreased rate of cardiac hypertrophy	Decreased cardiac output
Decreased cardiac output	Loss of exercise tolerance
	Diminished activity
	Increased work to heart
	Increased risk of myocardial infarction
Pulmonary System	
Decreased elasticity	Diminished breathing capacity
Decreased compliance and surface area	Decreased maximal oxygen uptake
Decreased ciliary activity	Increased risk of infection/toxicity
Gastrointestinal Tract	
Decreased hydrochloric acid production	Difficulty with digestion
	Food absorption problems and constipation
Delay in intestinal motility	Feeling full early, causing weight loss
Decreased saliva flow	Dry mouth, difficulty chewing
Fewer taste buds	Loss of food enjoyment, decreased appetite
Gum atrophy (shrinkage)	Tooth loss
Decreased liver function	Risk of toxicity from drugs
	Alcohol damage
	Loss of blood clotting
Central Nervous System	
Decreased cortical cell count	Memory impairment (dementia)
Increased synapse time	Decreased complex learning
Decreased nerve conduction velocity	Slower psychomotor skills
	Increased reflex time leading to risk of falling
Brain atrophy (shrinkage)	Prone to subdural hematomata
Vision	
Growth of lens	Decreased focusing ability
Cataract deposition	Hyperopia (farsightedness)
	Opacification of vision
Decreased pupil size	Decreased acuity and color perception
Loss of accommodation (focusing ability)	Decreased depth perception
	All cause increased risks of accidents and falls

TABLE 49-1 Physiological Changes of Aging—cont'd

Change	Result
Hearing	
Ossicle degeneration	Loss of high-frequency range of hearing
Atrophy (shrinkage) of auditory meatus	Loss of high-frequency range of hearing
Atrophy (shrinkage) of cochlear hair cells and auditory neurons	Decreased keenness and pitch discrimination
	Decreased sense of balance
	All cause increased risks of accidents and falls
Renal Function	
Decreased glomerular function	Decreased renal clearance
Decreased renal blood flow	Increased risk of toxicity from all drugs and toxins processed in kidneys
Genitourinary System	
Loss of bladder control	Urinary infections
Prostate enlargement	Tumors and urinary retention
Endocrine Function	
Decrease in thyroid, ovarian, and testicular function	Decreased energy, decreased metabolic rate
	Decreased heat/cold tolerance
	Decreased reproductive function
Increased insulin	Predisposition for hypoglycemia
Musculoskeletal System	
Decreased muscle mass	Loss of strength
Increased joint/tendon breakdown	Arthritis, stiffness, loss of flexibility
	Increased risk of falls
	Loss of bone strength and size
Bone demineralization	Increased risk of fracture
Psychological/Social	
Loss of physical function	Decreased activity
Loss of friends/family	Depression
Loss of social support	Increased isolation and anxiety
	Increased risk of suicide attempts
Immune System	
Loss of T-cell function	Increased infection

From MedicAlert: *Geriatric emergencies: an EMT teaching manual,* Turlock, Calif, 1994, MedicAlert Foundation.

arrest when the cardiovascular system is placed under unexpected stress.

Changes also occur in the electrical conduction pathways of the heart. These changes occur as cells in the sinoatrial and atrioventricular nodes and the rest of the conduction system lose the ability to function. These physiological changes often lead to dysrhythmias. These include chronic atrial fibrillation, sick sinus syndrome, and various types of bradycardias and heart blocks. All of these can contribute to the decline in cardiac output.

CRITICAL THINKING

What lifestyle choices can slow down these physiological changes of aging?

Renal System Changes

Structural and functional changes in the kidneys occur during the aging process. For example, renal blood flow decreases an average of 50% between 30 and 80 years of age.[5] This reduction in renal blood flow is associated with a proportional decrease in the glomerular filtration rate of about 8 mL/min per decade. Renal mass decreases by about 20% between 40 and 80 years of age. The steady decline in kidney function places the geriatric patient at greater risk for renal failure from trauma, obstruction, infection, and vascular occlusion.

As the patient ages, significant impairment develops in renal concentrating ability, sodium conservation, free water clearance (diuresis), glomerular filtration, and renal plasma flow. Hepatic blood flow decreases as well. This limits the

effectiveness of liver metabolism. Decreases in kidney and liver function and loss of muscle and body water make the geriatric patient more susceptible to electrolyte disturbances. They also make the geriatric patient more likely to experience problems with medications or drugs.

DID YOU KNOW?

Beers List

In 1993 a gerontologist named Mark H. Beers developed a national guideline and reference guide for pharmacists and physicians to improve medication use in the elderly. (The list is updated frequently.) This guide is known as the *Beers List*. In the guide, there are two tables developed by Dr. Beers. Table 1 lists 48 individual medications or classes of medications to avoid or use within specified dose and duration ranges in elderly patients. Examples of Table 1 drugs include flurazepam (Dalmane), amitriptyline (Elavil), and meperidine (Demerol). Table 2 lists medications to avoid in elderly patients with 20 different diseases or conditions, including specific concomitant diseases. For example, if the patient is diagnosed with blood clotting disorders or receiving anticoagulant therapy, aspirin has a high risk. If the patient is diagnosed with Parkinson's disease, metoclopramide (Reglan) has a high risk. The application of the Beers criteria for identifying potentially inappropriate medication use helps physicians and pharmacists to plan interventions for decreasing both drug-related costs and overall costs and thus minimize drug-related problems.[7]

ADVERSE DRUGS EVENTS IN OLDER ADULTS

Adverse drug events (ADEs), including reactions and interactions, in older people are a common cause of hospital admission, and are an important cause of morbidity and death. Even after excluding errors in drug administration, noncompliance, overdose, drug abuse, therapeutic failures, and possible ADEs, the overall incidence of serious ADEs in the general hospitalized population in the United States is believed to be between 6% and 7%.[8] Studies suggest that more than 80% of ADEs causing admission or occurring in the hospital are dose-related. Therefore, many ADEs are predictable and some are potentially **avoidable.**[9] Cardiovascular medications followed by diuretics, nonopioid analgesics, hypoglycemics, and anticoagulants are some of the most common medication categories associated with preventable ADEs. Electrolyte/renal, gastrointestinal tract, hemorrhagic, metabolic/endocrine, and neuropsychiatric events were the most common types of preventable adverse drug events.[10]

Nervous System Changes

Although it was long thought that mental dysfunction in the geriatric patient was caused solely by senility, it is now well known that intellectual functioning deteriorates selectively and may result from many organic causes.[11] For example, beginning at about 30 years of age, the total number of neurons in certain cortical areas decreases gradually, so by 70 years of age, a 10% reduction in brain weight has occurred.[5] These factors, decreased cerebral blood flow, and changes in the location and amounts of specific neurotransmitters probably contribute to changes in the central nervous system (CNS). The velocity of nerve conduction in the peripheral nervous system decreases with aging as well. This may lead to changes in motor or position sense and delays in reaction time and motor responses. Other gradual changes in the patient's nervous system can result in decreased visual acuity and auditory keenness. They also can result in changes in sleep patterns.

Toxic or metabolic factors that can affect mental functioning include the use of medications (e.g., anticholinergics, antihypertensives, antidysrhythmics, and analgesics); electrolyte imbalances; hypoglycemia; acidosis; alkalosis; hypoxia; liver, kidney, and lung failure; pneumonia; congestive heart failure (CHF); cardiac dysrhythmias; infection; and the development of benign or malignant tumors.

Musculoskeletal System Changes

As the body ages, muscles shrink, muscles and ligaments calcify, and intervertebral disks become thin. Osteoporosis is common in geriatric patients (especially in women). An estimated 68% of geriatric patients show some degree of **kyphosis** ("humpback posture") (Figure 49-1). These musculoskeletal changes result in a decrease in total muscle mass, a decrease in height of 2 to 3 inches, widening and weakening of certain bones, and a posture that impairs mobility and alters the balance of the body. As a result, falls are common. Moreover, the falls often are associated with significant morbidity and mortality.

Prevention strategies (described in Chapter 3) that can decrease injuries associated with falls include the following:

- Using assistive devices (e.g., walker or cane)
- Removing scatter rugs and securing loose carpeting

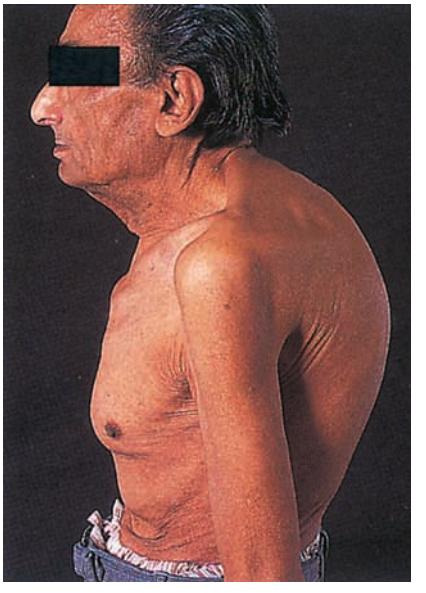

FIGURE 49-1 Kyphosis.

- Removing items that may cause tripping
- Providing and using handrails
- Ensuring adequate lighting
- Removing clutter from the environment
- Arranging furniture for walking ease
- Using nonslip decals in the bathtub or shower
- Providing handrails on bathtubs, showers, and commodes
- Suggesting patients consult with their physician regarding medicines if they are taking medication that increases the risk of falls

CRITICAL THINKING

Consider a patient who has significant kyphosis. What aspects of care will you need to alter to immobilize the spine of this patient?

Other Physiological Changes

Other physiological changes that occur with aging include a decrease in lean body mass, an increase in body fat, a decrease in total body water, a decreased ability to maintain internal homeostasis, a decrease in the function of immunological mechanisms, nutritional disorders, and decreases in hearing and visual acuity.

As an individual approaches 65 years of age, lean body mass may decrease as much as 25%, and fat tissue may increase as much as 35%.[5] These changes in body composition can affect the dosage and frequency of administration of fat-soluble drugs. This is because there is more drug per weight of metabolically active tissue and a larger reservoir for accumulation of the drug. Likewise, the decrease in total body water is likely to increase the concentration of water-soluble drugs.

The ability of the body to maintain normal temperature through thermoregulatory mechanisms declines over time. The decline begins at about 30 years of age. Because of this, the geriatric patient is at greater risk for cold- and heat-related conditions. These include hypothermia, heat exhaustion, and hyperthermia. Several factors contribute to the increased risk of thermoregulatory disorders, including impaired sympathetic nervous system function, causing decreased capacity for peripheral vasoconstriction, lowered metabolic rate, poor peripheral circulation, and chronic illness. Because of the decline in many body functions, including blood pressure, cardiac output, and temperature regulation, a specific illness or injury often puts the geriatric patient "over the edge" without adequate compensatory mechanisms to manage the event.

Aging causes a decrease in primary antibody response and cellular immunity and elevations in the amount of abnormal immunoglobulins and immune complexes.[5] These physiological changes increase the risk of infection, autoimmune disorders, and perhaps cancer. In addition, infections may not produce the usual signs and symptoms.

NOTE

Changes in the immunological systems of the elderly make them more prone to infections, and exacerbations of chronic disease processes. As the thymus ages, T-cell production is reduced and leukocytes are not activated. As a result, infections may not produce fever that would normally be seen in younger patients with viral, bacterial, or occult infection.

About one in eight deaths in geriatric patients results from cancer.[12] In younger patients, cancer often is the main or only disease from which they suffer. However, geriatric patients often have more than one disease and disability. Thus signs and symptoms such as a change in bowel habits, rectal bleeding, malaise, fatigue, weight loss, and anorexia may result from other maladies. Treatment with chemotherapy often results in immunosuppression. This increases the risk of infection and often masks the typical signs and symptoms associated with infection.

Many geriatric patients consume less than the minimum daily requirement of most vitamins,[13] which may be a result of loneliness and depression, decreased sensitivity to taste, decreased appetite, financial difficulties, physical infirmity, decreased vision, or a combination of these elements. All of these elements may act to reduce the motivation to shop for and prepare fresh food. Other factors associated with poor nutrition are poor dentition and reduced mastication, decreased esophageal motility, frequent hypochlorhydria (low stomach acid secretion), and decreased intestinal secretions that reduce absorption. Geriatric patients easily can become victims of malnutrition. Malnutrition in turn can cause dehydration, hypoglycemia, and numerous other complications.

CRITICAL THINKING

What effects can poor nutrition have on body function?

GENERAL PRINCIPLES IN ASSESSMENT OF THE GERIATRIC PATIENT

Normal physiological changes and underlying acute or chronic illness may make evaluation of an ill or injured geriatric patient a challenge. In addition to the components of a normal physical assessment (described in Chapter 20), the paramedic should consider special characteristics of geriatric patients that can complicate the clinical evaluation:

- Geriatric patients are likely to suffer from more than one illness at a time.
- Chronic problems can make assessment for acute problems difficult.
- Signs or symptoms of chronic illness can be confused with signs or symptoms of an acute problem.

- Aging can affect an individual's response to illness or injury.
- Pain may be diminished or absent.
- The patient or paramedic can underestimate the severity of a condition.
- Social and emotional factors may have a greater influence on health in geriatric patients than in any other age group.
- The patient fears losing autonomy.
- The patient fears the hospital environment.
- The patient has financial concerns about health care.

Patient History

Gathering a history from a geriatric patient usually requires more time than with younger patients (see Chapter 18). In addition to a longer medical history because of the patient's age, chronic illness, and medication use, the geriatric patient may have physical impediments such as hearing loss and visual impairment. Questioning a patient who is fatigued or easily distracted also may lengthen the interview process. The paramedic should use the following techniques when communicating with geriatric patients:

- Always identify yourself.
- Speak at eye level to ensure that the patient can see you as you communicate.
- Locate a hearing aid, eyeglasses, and dentures (if needed).
- Turn on lights.
- Speak slowly, distinctly, and respectfully.
- Use the patient's surname, unless the patient requests otherwise.
- Listen closely.
- Be patient.
- Preserve dignity.
- Use gentleness.

CRITICAL THINKING

Why should you ask geriatric patients to bring all of their medications to the hospital?

Physical Examination

When conducting the physical examination of a geriatric patient, the paramedic should consider the following six points:

1. The patient may tire easily.
2. Geriatric patients often wear many layers of clothing for warmth. This may hamper the examination.
3. Respect the patient's modesty and need for privacy unless it interferes with the care.
4. Explain actions clearly before examining all geriatric patients. This is important with patients with diminished sight.
5. Be aware that the patient may minimize or deny his or her symptoms. Denial may be due to a fear of being bedridden or institutionalized or losing self-sufficiency.
6. Try to distinguish symptoms of chronic disease from acute problems.

If time allows, the paramedic should assess the geriatric patient's immediate surroundings for evidence of alcohol or medication use (e.g., insulin syringes, "vial of life," or MedicAlert information), presence of food, general condition of housing, and signs of adequate personal hygiene. These and other observations help provide information to the physician about the patient's general health and ability for self-care after release from the hospital.

The paramedic should question friends or family members who are present about the patient's appearance and responsiveness *now* versus the patient's normal appearance, responsiveness, and other characteristics. The paramedic also should discreetly ask about advance directives and initiation of care for the patient (described in Chapter 6). If these documents are available, the paramedic should obtain them and convey the information to medical direction. Finally, the paramedic should ensure gentle handling and padding for patient comfort if transport is needed.

SYSTEM PATHOPHYSIOLOGY, ASSESSMENT, AND MANAGEMENT

The pathophysiology, assessment, and management of specific illnesses described in this section include those of the pulmonary system, cardiovascular system, CNS, endocrine system, gastrointestinal system, integumentary system, musculoskeletal system, and problems associated with special senses. Toxicology, environmental considerations, behavioral and psychiatric disorders, trauma, and elder abuse also are discussed in this section. Box 49-2 provides general assessment tools for patient evaluation.

Pulmonary System

Specific illnesses of the pulmonary system that are common in elderly patients include bacterial pneumonia, chronic obstructive pulmonary disease, and pulmonary embolism. These conditions were described in Chapter 24. They are presented here as a review.

BOX 49-2 General Assessment Tools for Patient Evaluation

Thorough neurological examination
Blood pressure
Evaluation of limb lead ECG
Interpretation of 12-lead ECG for signs of ischemia, injury, or anomalies
Auscultation of the heart to detect irregular, muffled, or extra heart sounds
Auscultation of the lungs to detect adventitious breath sounds
Capnography
Oxygen saturation
Evaluation of blood glucose level

BACTERIAL PNEUMONIA

Pneumonia is a leading cause of death in the geriatric age group and often is fatal in frail adults.[14] In addition, geriatric patients are more likely to develop bacteremia. They also are more susceptible to several respiratory pathogens (e.g., gram-negative bacilli). This susceptibility, associated with the presence of chronic disease, impairs respiratory tract clearance. It also allows germs to grow in the throat that then may travel to or be aspirated into the lungs. Because of the decreased lung function, pneumonia often may be associated with respiratory failure. Risk factors for bacterial pneumonia include institutional environments, feeding tubes, chronic diseases, and compromise of the immune system.

Unlike in younger patients with bacterial pneumonia, the usual clinical picture of fever, productive cough, pleurisy, and signs of pulmonary congestion often is absent in the geriatric patient. This atypical presentation is responsible for the common delay in diagnosis. The following are possible signs and symptoms:

- Alterations in mental status
- Cough
- Fever (variable)
- Shortness of breath
- Tachycardia
- Tachypnea

Geriatric patients with pneumonia may be too weak to cough or produce sputum. They also may not be able to breathe deeply. Therefore breath sounds may be misleading because of preexisting emphysema or chronic CHF. Tachycardia and tachypnea often are the most reliable indicators of bacterial pneumonia in the prehospital setting.

Emergency care for geriatric patients with bacterial pneumonia focuses on managing life threats, maintaining oxygenation, and providing transport for physician evaluation. Bacterial pneumonia is linked to a high rate of hospital admission. Pneumonia generally is managed with antibiotics.

CRITICAL THINKING

Why is flu season linked to an increase in pneumonia in the elderly?

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD) in the geriatric patient is a major health problem in the United States. Chronic obstructive pulmonary disease is a common finding in the geriatric patient with a history of smoking. It usually is associated with various diseases that result in reduced expiratory airflow. (Examples of such diseases are asthma, emphysema, and chronic bronchitis.) An exacerbation of COPD often follows an acute respiratory tract infection that causes airway edema, bronchial smooth muscle irritability, and increased mucus secretion. These airway abnormalities may lead to factors associated with acute decompensation, including the following:

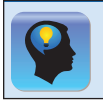
- Limited airflow
- Increased work of breathing
- Dyspnea
- Ventilation-perfusion mismatching
- Hypoxemia
- Respiratory acidosis
- Hemodynamic compromise

Signs and symptoms of COPD in the geriatric patient include extreme anxiety, cyanosis, wheezing, and abnormal or diminished breath sounds associated with marked dyspnea and the use of accessory muscles. Other signs and symptoms include dysrhythmias, paradoxical breathing, jugular vein distention, and decreased oxygen saturation levels (per pulse oximetry). The paramedic should obtain a full history of the event, including any history of intubation or steroid therapy. The paramedic also should be prepared for aggressive airway management. The care for a patient with COPD is aimed at correcting life-threatening hypoxemia and improving airflow. To achieve these goals, the use of airway and ventilatory support with supplemental oxygenation and the administration of bronchodilators by inhalation or injection may be indicated. Failure to begin aggressive treatments to correct the acidosis and hypoxia from COPD can lead to a progressive decline in the patient's condition.

PULMONARY EMBOLISM

Pulmonary embolism is a life-threatening cause of dyspnea. The condition is associated with venous stasis, heart failure, COPD, malignancy, and immobilization. All of these are common in older adults. Most pulmonary emboli in geriatric patients form in the veins of the legs. From there they travel through the femoral veins to the inferior vena cava and the heart. The clinical presentation of pulmonary embolism often is misleading in geriatric patients and frequently is misdiagnosed.[5]

Signs and symptoms of pulmonary embolism can vary greatly. They may range from a presentation of left ventricular failure with sudden tachypnea, unexplained tachycardia (a hallmark sign), and atrial fibrillation to signs and symptoms solely of the underlying venous thrombosis. (These include calf discomfort without tenderness, mild calf or ankle edema, increased warmth, and dilation of superficial veins in one foot or leg.) Pulmonary embolism can precipitate CHF. Pulmonary embolism also may be mistaken for bacterial pneumonia in geriatric patients.



CRITICAL THINKING

What other conditions have similar cardiovascular signs and symptoms?

Emergency care focuses on ensuring adequate airway, ventilatory, and circulatory support; immobilizing and elevating an affected extremity; and rapidly transporting the patient for physician evaluation. In-hospital care may include analgesics, bed rest, hemodynamic stabilization with intravenously administered fluids and vasopressors to support blood pressure, and efforts to prevent further embolization. Thrombolytics are sometimes given to lyse the thrombus. The physician also may treat these patients with anticoagulants to prevent further emboli.

Cardiovascular System

Cardiovascular disorders were described in Chapter 22. Specific disorders reviewed in this section include myocardial infarction, heart failure, dysrhythmias, abdominal and thoracic aneurysm, and hypertension.

MYOCARDIAL INFARCTION

Chest pain as a symptom of myocardial infarction (MI) becomes less frequent by 70 years of age. Only 45% of patients over 85 years of age with MI have this complaint. Lack of typical chest pain can cause MI to be unrecognized in the geriatric patient.[6] The following are six major risk factors that the paramedic should evaluate when assessing a patient for MI:

1. Previous MI
2. Angina
3. Diabetes
4. Hypertension
5. High cholesterol level
6. Smoking

Some geriatric patients have chest pain or discomfort. However, many complain only of vague symptoms. Examples of such include dyspnea (the most common sign in patients over 85 years of age), abdominal or epigastric distress, and fatigue.

In patients older than 85 years, atypical presentation for MI should be anticiapted.[11] For many geriatric patients the event is totally "silent." This may be a result of decreased visceral sensory function or a higher incidence of mental deterioration in this age group. Silent MIs are almost always marked by an atypical complaint. This may include fatigue, breathlessness, nausea, or abdominal pain. Thus the paramedic must maintain a high index of suspicion for MI in elderly patients with unusual warning signs or symptoms. Consider performing a 12-lead electrocardiogram (ECG) if the patient has these complaints.

CRITICAL THINKING

What hormonal change in older women increases their risk for heart disease?

Emergency care includes airway, ventilatory, and circulatory support; oxygen administration and pain management therapy; management of serious dysrhythmias according to advanced life support protocol; and rapid and gentle transportation for physician evaluation.

HEART FAILURE

Heart failure is more frequent in geriatric patients, occurring in about 10% of people over the age of 80. It is also the most common reason for admission to an acute care hospital in patients age 65 and older.[15] Heart failure in this age group also has a larger incidence of noncardiac causes. Heart failure occurs when the ventricular output cannot meet the metabolic demands of the body. Heart failure often is caused by ischemic heart disease, valvular heart disease, cardiomyopathy, dysrhythmias, hyperthyroidism, and anemia. The following are common signs and symptoms of heart failure:

- Dyspnea
- Fatigue (often the first symptom of left-sided heart failure)
- Orthopnea
- Dry, hacking cough progressing to productive cough with frothy sputum
- Dependent edema caused by right-sided heart failure
- Nocturia
- Anorexia, hepatomegaly, ascites

NOTE

Differentiating among the causes of dyspnea is difficult in the prehospital setting. However, such differentiation is important. If the patient has a history of acute episodes of heart failure, the current emergency event also is likely to be heart failure.[16] A thorough patient history is important.

The emergency care is aimed at reversing the conditions associated with heart failure as soon as possible. This will help to prevent cardiac damage. In addition to oxygen administration and electrocardiograph monitoring, management may include intubation, intravenous (IV) therapy, and drug therapy (***nitroglycerin, morphine,*** and perhaps ***furosemide***).

CRITICAL THINKING

How do furosemide, nitroglycerin, and morphine work to relieve the signs and symptoms of heart failure?

DYSRHYTHMIAS

A common cause of dysrhythmias in the geriatric patient is hypertensive heart disease.[17] But any condition that decreases blood flow to the heart can cause rhythm irregularities. When assessing dysrhythmias in the geriatric patient, the paramedic should consider the following:

- Premature ventricular contractions are common in most adults over 80 years of age.

- Atrial fibrillation is the most common dysrhythmia.
- Dysrhythmias may result from electrolyte imbalances.

In addition to the serious implications of some dysrhythmias, associated complications may include traumatic injury from falls that result from cerebral hypoperfusion, transient ischemic attack, and heart failure. The paramedic should focus emergency care on ensuring adequate airway, ventilatory, and circulatory support; administering oxygen; and transporting the patient for physician evaluation. Serious dysrhythmias should be managed as described in Chapter 22.

ABDOMINAL AND THORACIC ANEURYSM

Atherosclerotic disease is a common cause of abdominal and thoracic aneurysm. Abdominal aortic aneurysm affects about 2% to 4% of the U.S. population in men over 50 years of age.[11] Acute dissecting aortic aneurysm is more common than abdominal aneurysm and is associated with a high mortality rate. Signs and symptoms vary according to the site of rupture or extent of dissection (Box 49-3).

The goals of prehospital care are relief of pain and immediate transport to a hospital. Airway, ventilatory, and circulatory support may be required if the patient's condition deteriorates. Other prehospital care measures include the following:

- Gentle handling of the patient
- Allaying anxiety
- High-concentration oxygen administration
- Small-bore IV access to restrict fluids unless severe hypotension is present
- Pain medication per medical direction

HYPERTENSION

Geriatric patients who have atherosclerosis also frequently have hypertension. Associated risk factors for hypertension include advanced age, diabetes, and obesity. Hypertension often is defined as a resting blood pressure consistently greater than 140/90 mm Hg. Chronic hypertension is associated with many medical conditions, including the following:

- Aneurysm formation
- Blindness
- Cardiac hypertrophy and left ventricular failure
- Kidney failure
- Myocardial ischemia and infarction
- Peripheral vascular disease
- Stroke

NOTE

Systolic blood pressure gradually increases with age. However, diastolic pressure often stays normal or slightly decreases. Thus in persons over age 50, systolic pressure is a better indicator of risk for heart disease and stroke.[18] Current guidelines recommend that physicians treat older patients who have systolic hypertension with antihypertensive drugs. The goal of treatment is to achieve a blood pressure less than 140/90 mm Hg or less than 130/80 mm Hg in patients with diabetes or kidney disease. For patients with stage I hypertension (systolic pressure of 140 to 159 mm Hg) and additional cardiovascular risk factors, a sustained reduction in systolic pressure for more than 10 years will decrease mortality rates.[19]

Hypertension in the geriatric patient may manifest only in nonspecific complaints such as headache, forgetfulness, and general malaise. Other signs and symptoms that may indicate chronic hypertension include epistaxis, tremors, and nausea and vomiting. Care is mainly supportive. In severe cases, medical direction may advise the use of antihypertensives (e.g., ***metoprolol***). After physician evaluation, the patient with chronic hypertension often is managed with oral medications, dietary sodium reduction, weight loss, and exercise.

Nervous System

Neurological disorders were described in Chapter 25. Specific disorders described in this section for review include cerebral vascular disease, delirium, dementia, Alzheimer's disease, and Parkinson's disease. Possible assessment findings in patients with neurological disorders are provided in Box 49-4.

BOX 49-3 Signs and Symptoms of Abdominal and Thoracic Aneurysm

Absent or reduced pulses
Acute myocardial infarction
Chest pain
Diminished distal pulses
Heart failure
Hypotension
Low back pain or flank pain
Pericardial tamponade
Pulsatile, tender mass
Stroke
Sudden onset of abdominal or back pain
Syncope
Unexplained hypotension

BOX 49-4 Possible Assessment Findings in Patients with Neurological Disorders

Changes in peripheral, core, and neurovascular perfusion
Changes in response of pupils
Changes in response to motor tests
Dysrhythmias
Adventitious breath sounds

CEREBRAL VASCULAR DISEASE

Stroke is the third leading cause of death in most countries and the leading cause of brain injury in adults.[4] As described in Chapter 22, the neurological impairment is caused by an ischemic or hemorrhagic interruption in the blood supply to the brain. Associated risk factors for cerebral vascular disease in the older adult include smoking, hypertension, diabetes, atherosclerosis, hyperlipidemia, polycythemia, and heart disease. Box 49-5 provides a review of the signs and symptoms of stroke and transient ischemic attack.

Once the paramedic suspects stroke, the paramedic must *minimize time in the field* because there is limited time to initiate therapy. (In many cases, less than 3 hours from onset is recommended for fibrinolytic therapy.) The paramedic should focus on managing the patient's airway, breathing, and circulation and on monitoring vital signs. Aside from supporting vital functions, the most important element of prehospital care for a stroke victim is identification of the patient with stroke and rapid transportation of the patient to a stroke center that can provide treatment within 1 hour after arrival at the emergency department door.[20]

CRITICAL THINKING

What factors can cause a delay between the onset of signs and symptoms of stroke in the geriatric patient and when an emergency telephone call is made?

DELIRIUM

As described in Chapter 35, delirium is an abrupt disorientation to time and place. It usually includes illusions and hallucinations. The patient's mind may "wander;" speech may be incoherent; and the patient may be in a state of mental confusion or excitement. Delirium commonly is a result of physical illness. Signs and symptoms vary according to personality, environment, and severity of the illness. Causes of delirium are associated with organic brain dysfunction: physical versus psychological disorders that affect cognition. Examples of these disorders and risk factors include the following[21]:

BOX 49-5 Signs and Symptoms of Stroke and Transient Ischemic Attack

Ataxia
Diplopia
Facial droop
Language disturbance
Monocular blindness
Numbness
Slurred speech
Unilateral paralysis
Vertigo
Visual disturbance

- Alcohol intoxication or withdrawal
- Anticholinergic medications
- Cardiovascular disease
- Dehydration
- Depression
- Drug reactions
- Environmental emergencies
- Fever
- Hyper/hypoglycemia
- Malnutrition
- Metabolic disorders
- Psychiatric disorders
- Tumor
- Urinary tract infection/bowel obstruction
- Vitamin deficiencies
- Withdrawal from sedatives

Delirium can be life threatening. It requires emergency care. The condition may be reversible if it is diagnosed early. Yet delirium can progress to chronic mental dysfunction. Prehospital care includes the following measures:

1. Ensure adequate airway, breathing, and circulatory support.
   a. Manage hypoxia with oxygen.
   b. Manage hypotension with IV fluids if appropriate.
2. Reduce agitation and anxiety.
3. Avoid patient injury, and ensure personal safety.
   a. Restrain the patient if needed, per protocol.
   b. Sedate the patient as a last resort.
4. Consider hypoglycemia or a narcotic state.
   a. Measure blood glucose level.
   b. Administer ***dextrose 50%*** or ***naloxone*** per protocol.
5. Assess for CNS injury (e.g., trauma or stroke). Perform a careful neurological examination.
6. Look for signs of CNS infection (e.g., encephalitis).
7. Transport the patient for physician evaluation.

DEMENTIA

Dementia is a slow, progressive loss of awareness of time and place. It usually involves an inability to learn new things or recall recent events. Dementia often is a result of brain disease caused by strokes, genetic or viral factors, and Alzheimer's disease. Dementia generally is considered irreversible. It eventually results in full dependence on others as a result of the progressive loss of cognitive functioning. During the course of the disease, patients often try to "cover up" their memory loss by **confabulation** (making up stories to fill gaps in memory). Sudden outbursts or embarrassing conduct may be the first clear signs of dementia. Some patients eventually regress to a "second childhood." At that point, they need full care for feedings, toileting, and physical activity. Dementia is present in about 30% to 50% of persons over 85 years of age.[5] Possible causes of dementia include[21]:

- Alzheimer's disease
- Brain trauma
- Brain tumor
- Drug toxicity

- Huntington's chorea
- Infections
- Major depression
- Parkinson's disease
- Metabolic and endocrine disorders
- Multi-infarct dementia
- Psychiatric disorders

Dementia can be difficult to differentiate from delirium in the prehospital setting. The key difference between the two is that delirium is new with rapid onset, and dementia is progressive (Table 49-2). Thus a history of the event from a reliable witness (e.g., friend or family member) is the best source of information. A history provided by the patient may be unreliable. If a good witness is not available, the paramedic should manage the patient for delirium that may be a life-threatening emergency.

ALZHEIMER'S DISEASE

Alzheimer's disease is a condition in which nerve cells in the cerebral cortex die and the brain substance shrinks. The disease is the single most common cause of dementia and is responsible for the majority of cases in persons over 65 years of age.[22] Alzheimer's disease does not cause death directly; patients ultimately stop eating and become malnourished and immobilized. Then they are prone to intercurrent infections.

The exact cause of Alzheimer's disease is not known. Possible causes include abnormalities in glutamate metabolism, chronic infection, toxic poisoning by metals, reduction in brain chemicals (e.g., acetylcholine), and genetics. Atherosclerosis is *not* a cause of Alzheimer's disease. The primary disorder is in the nerve cells, not the blood vessels.

Early symptoms of Alzheimer's disease mainly are related to memory loss, especially the ability to make and recall new memories (Box 49-6). As the disease progresses, agitation, violence, and impairment of abstract thinking occur. Judgment and cognitive abilities begin to interfere with work and social relations. In the advanced stages of Alzheimer's disease, patients often become bedridden and totally unaware of their surroundings. Once the patient is bedridden, pressure ulcers (bed sores), feeding problems, and pneumonia shorten the patient's life.

No specific treatment exists for Alzheimer's disease. (Some medications such as cholinesterase inhibitors, antipsychotics, and antidepressants may help delay the disease and lessen associated symptoms.) Treatment primarily consists of nursing and social care for the patient and relatives. The paramedic manages Alzheimer's patients the same as dementia patients.

PARKINSON'S DISEASE

As described in Chapter 25, **Parkinson's disease** is a brain disorder caused by degeneration of or damage to nerve cells in the basal ganglia. The disease causes muscle tremor, stiffness, and weakness. Characteristic signs of Parkinson's disease are resting tremors and shaking (usually beginning in one hand, arm, or leg), a rigid posture and muscle stiffness, slow movements, and a shuffling, unbalanced walk. This increases the patient's risk for falls. Other signs and symptoms include:

- Difficulty swallowing and chewing
- Impaired speech
- Impaired cognitive function
- Urinary problems
- Excessive sweating
- Depression
- Sleep difficulties
- Mask-like facial expression

NOTE

Some patients with Parkinson's disease "freeze" when trying to walk or stand up from a sitting position. When assisting a patient to ambulate, the paramedic can have the patient rock from side to side to begin motion or have them count to begin their motor movement.

TABLE 49-2 Differential Diagnosis for Delirium and Dementia

	Delirium	Dementia
Onset	Abrupt	Gradual
Characteristics	Reduced attention span	Impaired recent memory
	Disorganized thinking	Regression
	Hallucinations	Poor judgment

BOX 49-6 The Seven Warning Signs of Alzheimer's Disease

1. Asking the same question over and over again.
2. Repeating the same story, word for word, again and again.
3. Forgetting how to cook, or how to make repairs, or how to play cards—activities that were previously done with ease and regularity.
4. Losing one's ability to pay bills or balance one's checkbook.
5. Getting lost in familiar surroundings, or misplacing household objects.
6. Neglecting to bathe or wearing the same clothes over and over again even as patients insist that they have taken a bath or that their clothes are still clean.
7. Relying on someone else, such as a spouse, to make decisions or answer questions they previously would have handled themselves.

From Alzheimer's Disease Education & Referral Center: *The seven warning signs of Alzheimer's disease,* www.alzheimers.org/pubs/sevensigns.htm, accessed 9-23-03. Reprinted with the permission of the Suncoast Gerontology Center, University of South Florida. Revised 9-1-99.

If left untreated, the disease progresses over 10 to 15 years to severe weakness and incapacity. One in 100 Americans over the age of 60 is afflicted with Parkinson's disease,[23] with 50,000 new cases diagnosed in the United States each year.

The emergency care for these patients mainly is supportive. It includes airway, ventilatory, and circulatory support and transport for physician evaluation. Parkinson's disease has no cure. However, counseling, exercise, special aids in the home, and drug therapy can improve the patient's morale, mobility, and quality of life.

Endocrine System

Two common endocrine disorders often are seen in geriatric patients. These disorders are type 2 diabetes and thyroid disease (described in Chapter 26). The following is a review of these conditions.

TYPE 2 DIABETES

About 20% of older adults have diabetes, and almost 40% have some impaired glucose tolerance.[24] Type 2 (non–insulin-dependent) diabetes is most common in geriatric patients, especially when the person is overweight. The following are associated risk factors in older adults for complications related to diabetes:

- Decreased ability to care for self
- Living alone
- Concurrent illness
- Decline in renal function
- Polydrug use

A combination of dietary measures, weight reduction, and oral hypoglycemic agents can usually keep type 2 diabetes under control. In most cases, insulin injections are not required for type 2 diabetes. However, if not controlled, diabetes can lead to complications. These include **retinopathy** (inflammatory eye disorders), peripheral neuropathy (ulcers on the feet are common), autonomic neuropathy (causes gastrointestinal [GI], genitourinary [GU], cardiovascular [CV] symptoms, and sexual dysfunction), and kidney damage.[25] Diabetic patients also have a higher-than-average risk for atherosclerosis, hypertension, and other cardiovascular disorders and for cataracts. Emergency care for diabetic patients is outlined in Chapter 26 and includes airway, ventilatory, and circulatory support; blood glucose level screening; IV ***dextrose*** (if indicated and in the absence of cerebral damage); and transport for physician evaluation. Possible assessment findings in diabetic patients are provided in Box 49-7.

Hyperglycemic hyperosmolar nonketotic syndrome (HHNS), described in Chapter 26, is a serious complication of elderly type 2 diabetic patients. It carries a mortality rate of 20% to 50%.[5] The paramedic often finds the type 2 diabetic patient comatose. If awake, the patient may complain of profound thirst and frequent urination. Frequent urination results from osmotic diuresis and leads to dehydration and electrolyte loss. Predisposing factors that make the geriatric patients susceptible to hyperglycemic hyperosmolar nonketotic syndrome include infection, noncompliance with medications, polydrug use, pancreatitis, stroke, hypothermia, heat stroke, and MI. If HHNS is suspected, the paramedic should ensure adequate airway, ventilatory, and circulatory support; search vigorously for an underlying cause; initiate IV therapy to manage dehydration; and rapidly transport the patient for physician evaluation.

BOX 49-7 Possible Assessment Findings in Diabetic Patients

Changes in peripheral, core, and neurovascular perfusion
Warm, flushed skin/poor skin turgor
Pale, dry oral mucosa
Furrowed tongue
Hypotension and shock
Tachycardia
Elevated serum glucose level

NOTE

Hyperglycemia is defined as a blood glucose level greater than 200 mg/dL or a fasting level greater than 126 mg/dL.[21]

NOTE

HHNS coma is a complication of type 2 diabetes in elderly patients. Unlike in diabetic ketoacidosis (DKA), the elevated blood glucose level in HHNS coma does not result in ketosis. Instead, it leads to osmotic diuresis and a fluid shift to the intravascular space that result in dehydration.

CRITICAL THINKING

What finding is present in the patient with diabetic ketoacidosis yet is absent in the patient with hyperglycemic hyperosmolar nonketotic coma?

THYROID DISEASE

Thyroid disease is common in geriatric patients. It may be related to the aging process. The classic signs and symptoms of thyroid disorders (e.g., fullness in the neck, goiter, muscle or joint pain) often are not present in the geriatric patient. Thus the paramedic should suspect thyroid dysfunction in any geriatric patient who is ill. Possible

BOX 49-8 Possible Assessment Findings in Patients With Thyroid Disease

Changes in peripheral, core, and neurovascular perfusion
Bradycardia
Respiratory failure or arrest
Hypercarbia
Changes in serum glucose levels
Nonpitting or pitting edema

assessment findings in patients with thyroid disease are provided in Box 49-8.

As described in Chapter 26, **hypothyroidism** results from the destruction of thyroid tissue over time. The disease leads to an insufficient amount of thyroid hormone in the blood. The older patient often attributes the signs and symptoms of hypothyroidism to "growing old." Common complaints include nonspecific musculoskeletal complaints and confusion. More serious conditions associated with this disorder include CHF, anemia, hyponatremia, depression, dementia, seizures, and coma. Other signs and symptoms associated with hypothyroidism include:

- Cold intolerance
- Fatigue
- Weight gain
- Poor cognitive function
- Scaly dry skin and hair loss
- Peripheral and facial edema
- Paranoia

Hyperthyroidism is less common than hypothyroidism in elderly patients. Hyperthyroidism may result from medication errors (e.g., too many doses of a thyroid hormone replacement). Signs and symptoms of hyperthyroidism include weight loss, constipation, mental status changes, CHF, tachydysrhythmias, and lethargy.

LOOK AGAIN
See Chapter 26: Endocrinology, pp. 817-820.

The emergency care mainly is supportive to ensure vital functions. The physician evaluates the patient with thyroid disease and treats the patient with various thyroid drugs, radioactive iodine treatments, and sometimes surgery. Severe complications from thyroid disease include *thyroid storm* and *myxedema coma* (described in Chapter 26). These complications can be made worse in a patient who has coronary artery disease.

Gastrointestinal System

Gastrointestinal emergencies (described in Chapter 29) are common in the elderly. The paramedic should always consider abdominal pain a serious complaint in a geriatric patient. Life-threatening causes of abdominal pain in this age group include abdominal aortic aneurysm, gastrointestinal hemorrhage, ruptured viscus, dead or ischemic bowel, and acute bowel obstruction. Specific disorders discussed in this section are gastrointestinal hemorrhage, bowel obstruction, problems with continence, and problems with elimination. Possible assessment findings in patients with gastrointestinal disorders are provided in Box 49-9.

BOX 49-9 Possible Assessment Findings in Patients With Gastrointestinal Disorders

Changes in peripheral, core, and neurovascular perfusion
Diffuse abdominal tenderness, distention, guarding or masses
Orthostatic blood pressure changes
Hypovolemia
Pale, thin skin
Jaundice
Frail musculoskeletal system
Peripheral, sacral, or periorbital edema
Hypertension
Fever
Tachycardia
Dyspnea

GASTROINTESTINAL HEMORRHAGE

Gastrointestinal bleeding most commonly affects patients between 60 and 90 years of age.[5] Possible causes of GI bleeding include peptic ulcer disease, esophageal varices, stomach and esophageal cancer, diverticulitis, bowel obstruction, and cirrhosis of the liver. GI bleeding in older patients has a mortality rate of about 10%. The older the patient, the higher the risk of death. This higher risk is because of the following[26]:

- Geriatric patients are less able to compensate for acute blood loss.
- They are less likely to feel symptoms and therefore seek treatment at later stages of disease.
- They are more likely to be taking ***aspirin*** or nonsteroidal antiinflammatory drugs (NSAIDs), which places them at higher risk for ulcer disease and bleeding.
- They are at higher risk for colon cancer, intestinal vascular abnormalities, and diverticulitis.
- They are more likely to be taking anticoagulants such as warfarin (Coumadin).

Signs and symptoms of gastrointestinal bleeding include vomiting of blood or coffee-ground emesis; blood-tinged or black, tarry stools; agitation; weakness; syncope; pain; jaundice; and constipation or diarrhea. If the paramedic suspects or confirms bleeding in a patient with signs and symptoms of shock, the paramedic should begin measures to ensure adequate airway, ventilatory, and circulatory support. The paramedic also should transport the patient rapidly for definitive care.

BOWEL OBSTRUCTION

Bowel obstruction generally occurs in patients with prior abdominal surgeries or hernias. Obstruction occurs in those with colonic cancer as well. Most complain of constipation, abdominal cramping, and an inability to pass gas. Other signs and symptoms include protracted vomiting of food or bile and vomiting of fecal material. The patient's heart rate and blood pressure measurements often are in normal ranges. The abdomen also may be mildly distended and tender in all four quadrants. (Abdominal pain is variable.)

The prehospital care mainly is supportive to ensure vital functions. After physician evaluation, patient care may include bowel rest, nasogastric suction, and volume replacement. Some patients may need surgery to lyse the offending adhesions. Surgery may result in a cycle of new scarring and obstruction. Patients also may need surgery for hernia repair (most often in men).

NOTE

Biliary disease refers to disorders of the liver and gallbladder. It describes a wide spectrum of disorders caused by abnormalities in bile composition, biliary anatomy, or function. The disease can result from primary liver disease, congestive heart failure, gallstones, cholecystitis, and medications that adversely affect the liver. Like other GI disorders, biliary disease may be accompanied by jaundice, fever, and vomiting. There often is right upper quadrant abdominal pain that radiates to the upper back and shoulder.

PROBLEMS WITH CONTINENCE

Continence is the ability to control bladder or bowel function. It requires anatomically correct gastrointestinal and genitourinary tracts, competent sphincter mechanisms, cognitive and physical function, and motivation. Some factors associated with continence are affected by age. These factors include a decrease in bladder capacity, involuntary bladder contractions, decreased ability to postpone voiding, and medications that can affect bladder and bowel control. **Incontinence** of urine or bowel is abnormal at any age.

Urinary incontinence can vary in severity. It can be only mild incontinence (the escape of small amounts of urine). Or it can be total incontinence, with complete loss of bladder control. Causes of urinary incontinence include injury or disease of the urinary tract, prolapse of the uterus, a decline in sphincter muscle control surrounding the urethra (common in the elderly), CNS injury or disease, pelvic fracture, prostate cancer, and dementia.

Bowel incontinence in the geriatric patient usually is the result of **fecal impaction.** This occurs when feces lodged in the rectum irritate and inflame the lining. This allows fecal fluid and small feces to pass involuntarily. Other causes of bowel incontinence include severe diarrhea, injury to anal muscles (from childbirth or surgery), CNS injury or disease, and dementia.

BOX 49-10 Possible Causes of Urinary Tract Infection

- Cystocele (fallen bladder in women)
- Diabetes
- Indwelling Foley catheters
- Kidney obstruction
- Medications (immunosuppressive drugs and chemotherapy)
- Prostatitis (inflammation of the prostate gland)
- Urethrocele (urethra prolapse in women)

All forms of incontinence usually are embarrassing for the patient. If incontinence is chronic, it can lead to skin irritation, tissue breakdown, and urinary tract infection (Box 49-10). Some cases are managed with surgery to restore sphincter function. Patients with mild cases often wear absorptive undergarments to relieve discomfort and embarrassment.

CRITICAL THINKING

Consider the incontinent patient. How can you minimize the patient's embarrassment and discomfort?

PROBLEMS WITH ELIMINATION

Causes of difficulty in urination usually result from enlargement of the prostate (in men), urinary tract infection, urethral strictures, and acute or chronic renal failure. Difficulty in bowel elimination often is associated with diverticular disease, constipation, and colorectal cancer. Problems with elimination can cause great pain and anxiety for geriatric patients. The paramedic should take their complaints seriously. These conditions call for physician evaluation to identify the cause and to select appropriate therapy.

NOTE

Chronic renal failure (the inability of the kidneys to excrete waste, concentrate urine, or control electrolyte balance in the body) was described in Chapter 30. Chronic renal failure may be the result of diabetes, congenital disorders, pyelonephritis, hypertension, autoimmune disorders, glomerulonephritis, or medications that have an adverse effect on the kidneys (e.g., antibiotics, NSAIDs, anticancer drugs). The paramedic should refer to Chapter 30 for review.

Integumentary System

As persons age, the skin gradually becomes dry, transparent, and wrinkled. These integumentary changes are associated with a loss of elasticity, uneven pigmentation, and various benign and malignant lesions. In addition, aging results in a gradual decrease in epidermal cellular turnover

and a reduced rate of nail and hair growth. The associated loss of deep, dermal vessels and capillary circulation leads to common complaints such as dry, itchy skin; changes in thermal regulation; and skin-related complications. Some of these complications include the following:

- Slow healing
- Increased risk of secondary infection
- Increased risk of fungal or viral infections
- Increased susceptibility to abrasions and tears

The paramedic should always be gentle with the skin of a geriatric patient. Examples include use of aseptic technique during wound management, gentle placement and removal of electrocardiogram electrodes, and using careful taping procedures when securing IV catheters or tubing.

CRITICAL THINKING
Consider a geriatric patient who has a burn injury. How do these changes influence the patient's recovery?

PRESSURE ULCERS

Pressure ulcers are common in geriatric patients (Figure 49-2). They often develop on the skin of patients who are bedridden or immobile (e.g., **decubitus ulcers**). Most pressure ulcers occur in the lower legs, back, and buttocks, and over bony areas such as the greater trochanter or the sacrum. They often affect victims of brain or spinal cord injury, stroke, or other illnesses that result in a loss or change in the sensation of pain. Skin exposure to moisture (e.g., from incontinence), poor nutrition, and friction or shear also may be factors for developing pressure ulcers. Other causes of pressure ulcers in geriatric patients include vascular and metabolic disorders (e.g., venous stasis and diabetes), trauma, and cancer.

Pressure ulcers result from tissue hypoxia. They generally start as red, painful areas that become purple before the skin breaks down. Then they develop into open sores. Once the integrity of the skin has been breached, the sores often become infected. Then they are slow to heal. Pressure ulcers should be covered with sterile dressing using aseptic technique. The paramedic then should transport the patient for physician evaluation and wound care to facilitate healing.

FIGURE 49-2 Pressure ulcers.

Musculoskeletal System

As described in Chapter 12 and earlier in this chapter, musculoskeletal changes occur as part of the aging process. Two musculoskeletal conditions that are common in elderly patients are osteoarthritis and osteoporosis. (These and other forms of arthritis were described in Chapter 33.)

LOOK AGAIN
See Chapter 33: Nontraumatic Muscle Disorders, pp. 969-972.

OSTEOARTHRITIS

Osteoarthritis is a common form of inflammatory arthritis in geriatric patients. Osteoarthritis is a degenerative condition that results from cartilage loss and wear and tear on the joints (Figure 49-3). The condition leads to pain, stiffness, and sometimes loss of function of the affected joint. Often the affected joint becomes large and distorted from outgrowths of new bone (*osteophytes*) that tend to develop at the margins of the joint surface. Osteoarthritis evolves in the middle years. It occurs to some extent in almost all persons over 60 years of age. However, some persons have no symptoms. After physician evaluation, treatment may

FIGURE 49-3 Osteoarthritis.

include medications (analgesics, nonsteroidal antiinflammatory drugs, corticosteroids), physical therapy, and sometimes joint replacement surgery. Newer drugs (cyclooxygenase-2 inhibitors) relieve the inflammation and pain associated with arthritis. These newer drugs have less risk of causing stomach irritation than traditional medications such as ***aspirin,*** nonsteroidal antiinflammatory drugs, and ibuprofen. An example of these newer drugs is celecoxib (Celebrex).

OSTEOPOROSIS

Osteoporosis is a disease that decreases bone density. It is a natural part of aging and is especially common in older women after menopause. This is because of a decrease in the hormone estrogen, which helps maintain bone mass. Osteoporosis is present in most persons by 70 years of age, by which time the density of the skeleton has diminished by one third. Most persons with osteoporosis have some degree of kyphosis. Risk factors that may affect the progression of the disease include genetics, smoking, exercise habits, and diets poor in calcium and vitamin D.

The loss of bone density causes bones to become brittle. Brittle bones can fracture easily, which often is the first sign of osteoporosis. Typical sites for fractures are just above the wrist, at the head of the femur, and at one of several vertebrae (often a spontaneous fracture). Osteoporosis is treated with preventive measures. These include a diet high in calcium, calcium supplements, exercise, and hormone replacement therapy after menopause (controversial).

Special Problems with Sensations

As persons age, they may experience problems with vision, hearing, and speech.

PROBLEMS WITH VISION

Vision changes begin to occur at around 40 years of age. They gradually increase over time. Vision impairments can severely limit daily activities. They can lead to a loss of independence in geriatric patients. The following are some effects of aging on vision:

- Reading difficulties
- Poor depth perception
- Poor adjustment of the eyes to variations in distance
- Altered color perception
- Sensitivity to light
- Decreased visual acuity

Two common eye conditions that develop with age are cataracts and glaucoma. A **cataract** is a loss of transparency of the lens of the eye. It results from changes in the delicate protein fibers within the lens (Figure 49-4). A cataract never causes full blindness. Yet clarity and detail of an image progressively are lost. Cataracts usually occur in both eyes. In most cases, though, one eye is affected more severely than the other. Almost everyone over 65 years of age has some degree of cataract. Also, most persons over 75 years of age have minor visual deterioration from the disorder.

FIGURE 49-4 Appearance of an eye with a cataract.

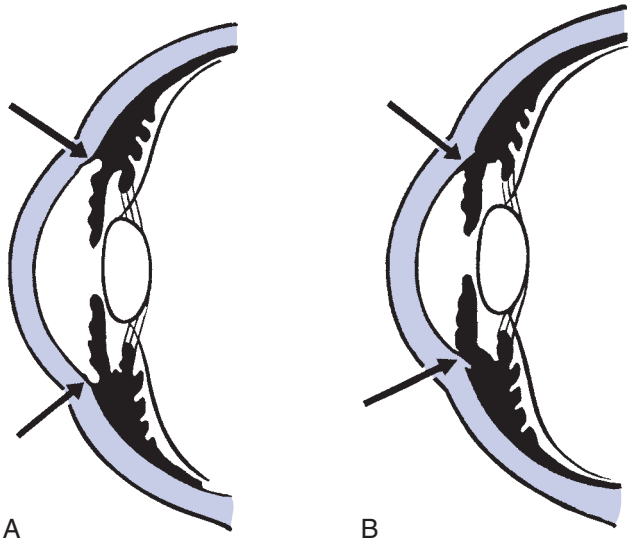


FIGURE 49-5 Glaucoma. **A,** Open-angle glaucoma. The obstruction to aqueous flow lies in the trabecular meshwork. **B,** Closed-angle glaucoma. The trabecular meshwork is covered by the root of the iris. (From Stein HA, Slatt BJ, Stein RM: *The ophthalmic assistant: fundamentals in clinical practice,* St Louis, 1988, Mosby.)

Surgery to remove the cataract is a common procedure in the United States.

Glaucoma is a condition in which intraocular pressure increases. This pressure causes damage to the optic nerve. The result is nerve fiber destruction and partial or full loss of peripheral and central vision (Figure 49-5). Glaucoma may result from aging (rarely seen before 40 years of age), a congenital abnormality, or trauma to the eye. Glaucoma is the most common major eye disorder in persons over 60 years of age and is the leading cause of preventable blindness in the United States.[27] Symptoms of acute glaucoma include dull, severe, aching pain in and above the eye; fogginess of vision; and the perception of "rainbow rings" (halos) around lights at night. Testing for glaucoma is part of most eye examinations in adults. If detected early, the condition can be treated with oral medications and eye drops to relieve pressure.

CRITICAL THINKING
Consider the patient who has glaucoma. What prehospital cardiac medication should not be given to this patient?

PROBLEMS WITH HEARING

Not all geriatric patients have hearing loss. However, overall hearing tends to decrease with age. This results from degeneration of the hearing mechanism (sensorineural deafness). Meniere's disease (increased fluid pressure in the labyrinth), certain drugs, tumors, and some viral infections also can cause hearing problems. Hearing loss can interfere with the ability to perceive speech. Thus it can limit the ability to communicate. Hearing aid devices and surgical implants sometimes can restore or improve hearing.

Tinnitus is the perception of noise in the ear (e.g., ringing, buzzing, or whistling). It can occur as a symptom of many ear disorders. The noise in the ear sometimes may change in nature and intensity. However, in most cases it is present at all times with intermittent awareness by the person. Tinnitus is almost always associated with hearing loss, especially hearing loss that develops from aging.

CRITICAL THINKING
What common analgesic, when taken in excess, can cause tinnitus?

PROBLEMS WITH SPEECH

Speech is the most often used method of communication. Common problems with speech in geriatric patients often are associated with difficulty in word retrieval, decreased fluency of speech, slowed rate of speech, and changes in voice quality. These disorders may occur from damage to the language centers of the brain (usually as a result of stroke, head injury, or brain tumor), degenerative changes in the nervous system, hearing loss, disorders of the larynx, and poor-fitting dentures.

Toxicology

As described in Chapter 13, geriatric patients are at increased risk for adverse drug reactions. This is the result of age-related changes in body composition as well as drug absorption, distribution, metabolism, and excretion.

LOOK AGAIN
See Chapter 13: Principles of Pharmacology and Emergency Medications, pp. 296-297.

Age-related changes that affect absorption include increased gastric pH and decreased gastrointestinal motility. Both of these may increase or decrease the absorption of various drugs (depending on the chemical properties of the drug). Drug distribution may be affected by decreased cardiac output (e.g., as seen in CHF), decreased total body water, changes in the ratio of lean mass to fat, and increased body fat. Metabolic changes may result from decreased liver blood flow; diseases such as thyroid disease, CHF, and cancer; smoking; and drug interactions. (Drug-induced metabolic changes are especially significant in the elderly. This is because they often take several different drugs for multiple diseases and conditions. This further increases their risk for adverse drug reactions.) Renal function decreases with age in the majority of adults. This can lead to an accumulation of drugs that normally are cleared through the renal system. In addition, the action of drugs affecting the CNS (e.g., benzodiazepines, anesthetics, and narcotics) and the cardiovascular system (e.g., beta blockers, calcium channel blockers, and diuretics) often is altered in older adults. Because of these changes, drugs may not produce the desired effect or may cause major drug toxicity in older adults. Drugs that commonly cause toxicity in the geriatric patient include the following:

- Analgesics
- Angiotensin-converting enzyme inhibitors
- Antidepressants
- Antihypertensives
- Beta blockers
- Digitalis
- Diuretics
- Psychotropics

The adverse reactions associated with these and other drugs often result from "accidents" or "mishaps" in the prescribed drug regimen. Other common reasons for drug-induced illness in the geriatric patient include dispensing errors, noncompliance, confusion, forgetfulness, vision impairment, and the self-selection of drugs. In addition, older adults commonly have several prescriptions from more than one physician; improperly resume an old medication in addition to a newly prescribed one; or take prescribed medications along with over-the-counter drugs that may have synergistic or cumulative effects. Finally, changes in habits regarding alcohol intake, diet, and exercise also can affect drug metabolism. These changes can increase the risk for adverse drug reactions. The emergency care for geriatric patients with adverse drug reactions varies. Care may range from transport only to full advanced cardiac life support measures. Box 49-11 lists symptoms of drug toxicity and adverse reactions that can occur in the geriatric patient.

Substance Abuse

As described in Chapter 34, substance abuse involving alcohol and other drugs is common in the elderly population. Up to 17% of U.S. citizens age 60 and older are estimated to be addicted to substances, and this number is expected to rise as the baby boomer population enters older age.[28]

BOX 49-11 Symptoms of Drug Toxicity and Adverse Drug Reactions in the Geriatric Patient

Acute delirium
Akathisia
Altered vision
Bradycardia
Cardiac dysrhythmias
Chorea
Coma
Confusion
Constipation
Fatigue
Glaucoma
Hypokalemia
Orthostatic hypotension
Paresthesias
Psychological disturbances
Pulmonary edema
Severe bleeding
Tardive dyskinesia
Urinary hesitancy

BOX 49-12 Signs of Substance Abuse

Alcohol Abuse
Anorexia
Confusion
Denial
Frequent falling
Hostility
Insomnia
Mood swings
Note: Ingestion of even small amounts of alcohol by the geriatric patient can cause intoxication.

Other Drug Abuse
Altered level of consciousness
Falling
Hallucinations
Memory changes
Orthostatic hypotension
Poor coordination
Restlessness
Weight loss

Note: Individuals often have a history of alcohol and other drug abuse.

Substance abuse in the geriatric patient often is attributed to severe stress as the primary risk factor. This stress may result from life changes such as age-related changes in health or appearance, loss of employment, loss of spouse or life partner, illness, malnutrition, loneliness, loss of independent living arrangements, and others. Box 49-12 lists signs of substance abuse.

If the paramedic suspects substance abuse, friends and family members at the scene should be discreetly interviewed about the patient's alcohol or other drug use. The cornerstones of therapy for these patients are identifying the problem and arranging referral to a physician for treatment. Treatment for the acutely intoxicated patient is described in Chapter 34 and may include resuscitative measures to manage the patient's airway, ventilation, and circulation. In addition, the paramedic should carefully assess the geriatric patient who has signs and symptoms of alcohol or other drug intoxication for occult trauma and any underlying medical conditions. These conditions may include hypoglycemia, cardiomyopathy and dysrhythmias (such as atrial fibrillation), gastrointestinal bleeding, polydrug use (especially barbiturates and tranquilizers), and ethylene glycol or methanol ingestion.

Environmental Considerations

Elderly patients are at risk for developing illness from extremes in the environment. This is a result of the aging process and other factors (see Chapter 45). Two emergencies that relate to the environment are most common in geriatric patients. These are hypothermia and hyperthermia.

HYPOTHERMIA

Patients who are younger often develop hypothermia from extremes in the environment. In contrast, an older patient may develop hypothermia while indoors. This may occur as a result of cold surroundings and/or an illness that alters heat production or conservation. This is due in part to the following characteristics of older adults:

- They are less able to compensate for environmental heat loss.
- They have a decreased ability to sense changes in temperature.
- They have less total body water to store heat.
- They are less likely to develop tachycardia to increase cardiac output in response to cold stress.
- They have a decreased ability to shiver to increase body heat.

In addition to these physical changes, geriatric patients are more prone to develop hypothermia as a result of socioeconomic factors. For instance, a fixed income may inhibit an older person from paying for the cost of properly heating and insulating his or her home. Poor nutrition that results in a decrease in fat stores may contribute to hypothermia in geriatric patients who live alone. The following are other medical causes of hypothermia in geriatric patients:

- Arthritis
- Drug overdose
- Hepatic failure
- Hypoglycemia
- Infection
- Parkinson's disease
- Stroke

- Thyroid disease
- Uremia

The signs and symptoms of hypothermia may be subtle. They may include an altered mental status, slurred speech, ataxia, and dysrhythmias. In severe cases, coma without signs of life may be present. Hypothermia in the geriatric patient carries a high mortality rate. The paramedic should manage these patients as described in Chapter 45. Rapid and gentle transport for in-hospital rewarming and life support measures is crucial for the patient's survival.

HYPERTHERMIA

Hyperthermia in the geriatric patient is less common than hypothermia. Yet hyperthermia carries a significant mortality rate. The condition most likely results from exposure to high temperatures. These temperatures most likely continue for several days (e.g., during a heat wave). As in hypothermia, geriatric patients are unable to control body temperature even in moderate heat. Hyperthermia also may result from medical conditions such as hypothalamic dysfunction and spinal cord injury. Certain medications (e.g., antidysrhythmics, beta blockers, and cyclic antidepressants) can lead to hyperthermia. They do this by inhibiting heat dissipation, increasing motor activity, and impairing cardiovascular function.

As described in Chapter 45, hyperthermic illness may present as heat cramps, heat exhaustion, or heat stroke. Emergency care includes removing the patient from the warm environment, cooling the patient, and ensuring the patient's vital functions through airway, ventilatory, and circulatory support. Rapid transport for physician evaluation is indicated to manage the problems resulting from serious heat-related illness.

Behavioral and Psychiatric Disorders

Fifteen million elderly persons are expected to suffer from some kind of psychiatric illness by the year 2030.[29] In addition to the neurological disorders such as dementia and Alzheimer's disease, depression and suicide are common in geriatric patients.

DEPRESSION

Depression is a serious illness that requires physician evaluation. In the geriatric patient, depression can result from physiological and psychological causes. Examples include cognitive disorders with physical causes (e.g., dementia) and various personality disorders such as schizophrenia (see Chapter 35). Box 49-13 lists other physiological and psychological causes of depression in the geriatric patient. The signs and symptoms of depression vary by individual. They may include the following:

- Decreased libido
- Deep feelings of worthlessness and guilt
- Extreme isolation
- Feelings of hopelessness
- Irritability
- Loss of appetite
- Loss of energy (fatigue)
- Recurrent thoughts of death
- Significant weight loss
- Sleeplessness
- Suicide attempts

BOX 49-13 Common Causes of Depression in the Geriatric Patient

Physiological

Dehydration
Electrolyte imbalance
Fever
Hyponatremia
Hypoxia
Medications
Metabolic disturbances
Organic brain disease
Reduced cardiac output
Thyroid disease

Psychological

Fear of dying
Financial insecurity
Loss of a spouse
Loss of independence
Significant illness

CRITICAL THINKING

What endocrine disorder can produce signs or symptoms that are similar to those of depression?

A major goal of care is to identify the patient who may be depressed. These patients need to be evaluated by a physician. The physician will rule out medical illness—especially thyroid disease, stroke, malignancy, and dementia—or medication use (e.g., beta blockers) that may be responsible for the patient's depression. After determining that there are no physical threats to life, the paramedic should try to establish a rapport with the patient who is depressed. The patient should be encouraged to talk openly about his or her feelings, especially any thoughts of suicide. If possible, the paramedic should interview the family about the patient's mental state and question family members about any history of depression in the patient.

SUICIDE

The rate of completed suicides for geriatric patients is higher than that of the general population, and most of these persons visited their primary care physician in the month before the suicide.[30] Most were suffering from their first episode of major depression, which was only moderately severe, yet the depressive symptoms were unrecognized and untreated. Thus the paramedic should be

aware of the increased risk for suicide when evaluating geriatric patients who are depressed. Clues and indicators for suicide in the geriatric patient that may be obtained through a patient history or observed by friends and family include[31]:

- Talking about or seemingly preoccupied with death and "getting affairs in order"
- Giving away prized possessions (e.g., family heirlooms, photographs, and keepsakes)
- Taking unnecessary risks (e.g., walking alone in unsafe areas or driving without personal restraints)
- Increased use of alcohol or other drugs
- Nonadherence to medical regimen (e.g., failure to take prescribed medications)
- Acquiring a weapon, especially firearms

As described in Chapter 35, there is no evidence that questions about suicidal thoughts and feelings increase the risk of suicide. Many depressed persons are willing to discuss their suicidal thoughts; therefore the paramedic should question the patient about suicidal thoughts if he or she suspects that the patient is at high risk. The following questions are appropriate for the paramedic to ask the patient:

1. Do you have thoughts about killing yourself?
2. Have you ever tried to kill yourself?
3. Have you thought about how you might kill yourself?

Most suicides committed by older adults involve firearms. Therefore, the safety of those at the scene and the emergency medical services crew is a priority when caring for a patient with suicidal tendencies. When indicated, law enforcement personnel should be available at the scene. After assessing the risk for suicidal tendencies, the patient should be transported for physician evaluation. While en route to the hospital, the paramedic should encourage the patient to discuss his or her feelings and reassure the patient that he or she can be helped through the crisis.

Trauma

Trauma (described in detail in Part 9: Trauma) is the fifth leading cause of death for persons over 65 years of age. One third of traumatic deaths in persons 65 to 74 years of age are caused by vehicular trauma, and 25% result from falls. In those older than 72 years of age, falls are the leading cause of unintentional injury or death.[32] Burns also are a major cause of disability and death in geriatric patients. Contributing factors that increase the severity of traumatic injury in geriatric patients include the following:

- Osteoporosis and muscle weakness that increase the likelihood of falls and fractures
- Reduced cardiac reserve that decreases the ability to compensate for blood loss
- Decreased respiratory function that increases the likelihood of adult respiratory distress syndrome
- Impaired renal function that decreases the ability to adapt to fluid shifts

SHOW ME THE EVIDENCE

Researchers in New England performed a retrospective record review of blunt trauma patients ages 17 to 35 years (young) and ages 65 and older (geriatric) seen at one level I trauma center between 2003 and 2008. They sought to correlate blood pressure and heart rate on arrival to the ED with mortality. During this period, 2194 geriatric and 2081 young patients were admitted. Mortality in the geriatric group was 11.4% (251) versus 2.4% (49) in the young group. Bradycardia on arrival was associated with increased mortality in both groups. There was a significant increase in mortality in geriatric patients whose heart rate was greater than 90 beats/min as opposed to 130 beats/min in the young group. Mortality correlated to a systolic blood pressure (SBP) less than 110 mm Hg in geriatric patients but was not significant until SBP declined below 95 mm Hg in the young patients. The authors suggest that new triage set points be considered for geriatric patients with blunt trauma.

From Heffernan DS, Thakkar RK, Monaghan SF, et al: Normal vital signs are unreliable in geriatric blunt trauma victims, *J Trauma* 69(4):813-820, 2010.

VEHICULAR TRAUMA

More than 15 million licensed drivers are over 65 years of age. In 2008 more than 2700 deaths in this age group were attributed to motor vehicle crashes.[32] Most of these vehicle collisions are not related to high speed or use of alcohol. Rather, they are related to errors in perception or judgment or to delayed reaction time. A large number of older adults are injured as drivers or passengers in moving vehicles. In addition, more than 2000 pedestrian fatalities among older adults occur each year in the United States. This accounts for 20% of all pedestrian deaths from trauma.

The risk of death from multiple trauma is estimated to be 3 times greater at 70 years of age than at 20 years of age. This is mainly because the geriatric patient is more susceptible to serious injury from equivalent degrees of trauma. This patient also is less capable of an appropriate, protective physiological response. Prompt identification of injuries and sources of hemorrhage is critical in any trauma patient but is especially important in the geriatric patient. The geriatric patient has much less cardiac reserve. The patient will succumb more quickly to shock.

HEAD TRAUMA

A head injury with loss of consciousness in geriatric patients often has a poor outcome. The brain becomes smaller in size with age (**cerebral atrophy**). This atrophy produces an increase in distance between the surface of the brain and the skull. As veins are stretched across this space, they are more easily torn. This results in subdural hematomata. The extra space within the skull often allows a large amount of bleeding to occur before signs and symptoms of increased intracranial pressure are seen.

Geriatric patients also are at high risk for injuries of the cervical spine because of the arthritic and degenerative changes associated with aging. These structural changes

CRITICAL THINKING
Consider geriatric patients with head trauma. What home medications also can lead to an increased risk of intracerebral bleeding in these patients?

lead to increased stiffening and decreased flexibility of the spine with narrowing of the spinal canal. This makes the spinal cord much more at risk for damage from fairly minor trauma.

CHEST INJURIES

Any mechanism of injury that produces thoracic trauma in a geriatric patient can be potentially lethal. The aged thorax is less elastic. Thus the thorax is more susceptible to injury. The pulmonary system also has marginal reserve because of a reduced alveolar surface area, decreased patency of small airways, and diminished chemoreceptor response.

Injuries to the heart, aorta, and major vessels are a greater risk to geriatric patients than they are to younger patients. Again, this is due to decreased functional reserve in older patients. It also is due to anatomical changes that make injury in these areas of greater significance. Myocardial contusion may be a complication of blunt injury to the chest. If severe, myocardial contusion may result in pump failure or life-threatening dysrhythmias. Rarely, cardiac tamponade occurs after blunt thoracic trauma. Cardiac rupture, valvular injury (e.g., flail valves), and aortic dissection also may occur with significant blunt chest injury. The first two entities are rare but rapidly fatal. When the mechanism of injury produces rapid deceleration, the paramedic should always consider the possibility of dissecting aortic aneurysm. Aortic dissections often are not immediately fatal. Proper evaluation and treatment can be lifesaving (see Chapter 22).

CRITICAL THINKING
Consider the patient who has a dissecting aortic aneurysm. What specific signs and symptoms may the paramedic see in this patient?

In the geriatric patient the heart cannot respond as effectively to increased demand for oxygen as in the younger person. This coupled with a slowed conduction system may cause ischemia and dysrhythmias when the geriatric patient has a significant trauma. These problems may occur even if the heart has not been damaged directly by the trauma. The patient's oxygenation and circulatory status must be closely monitored.

ABDOMINAL INJURIES

Abdominal injuries in geriatric patients have more serious consequences than injuries to any other body area. Abdominal injuries often are less obvious. Thus they require a high degree of suspicion. The geriatric patient is less likely to tolerate abdominal surgery well. This patient is more likely to develop pulmonary complications and infection following surgery.

MUSCULOSKELETAL INJURIES

The osteoporotic bones of geriatric patients are more at risk for fractures, even with mild trauma. Pelvic fractures are highly lethal in this age group. They can cause severe hemorrhage and soft tissue injury. When assessing for skeletal trauma, the paramedic should recall that the geriatric patient may have decreased pain perception. Often these patients have amazingly little tenderness with major fractures. Even with proper care, the mortality rate for geriatric patients with musculoskeletal injury is increased by delayed complications such as adult respiratory distress syndrome, sepsis, renal failure, and pulmonary embolism.

FALLS

Falls are a major cause of morbidity and mortality in older adults, with an overall fatality rate of 7.0%.[32] About one third of older adults living at home fall each year. One in 40 of these persons is hospitalized. A major cause of falls in older adults results from the use of prescribed sedative-hypnotics. These drugs affect balance and postural control. Some examples are alprazolam, ***diazepam,*** chlordiazepoxide, and flurazepam.

CRITICAL THINKING
Consider geriatric patients who have fallen. What common problems may contribute to an increased death rate in these patients?

Fractures are the most common fall-related injuries—the hip being the fracture that most often results in hospitalization. In those who survive hip fracture, most will have significant problems with walking and moving about. They may become more dependent on others for help. Falls that do not result in physical injury may lead to self-imposed immobility from the fear of falling again. When immobility is strict and prolonged, joint contractures, pressure sores, urinary tract infection, muscle atrophy, depression, and functional dependency may result.

The paramedic should assume that any fall indicates an underlying problem until it is proved otherwise. Attempts should be made to uncover any medical, psychological, and environmental factors that may have been responsible for the fall. Thus the patient history should include a full review of all medical problems and medications. It also should include precise details of the fall. (This includes history of falling, time and location of fall, symptoms experienced, activity in which the victim was engaged, use of devices, and presence of witnesses.) The paramedic also should evaluate the patient's cardiovascular, neurological, and musculoskeletal systems.

BURNS

More than 1000 older adults die from fires and burns in the United States each year.[32] The increased risk of morbidity and mortality from burn trauma in older adults is due to preexisting disease, skin changes that result in increased burn depth, impaired nutrition, and decreased ability to fight infection. The initial care and resuscitation of geriatric patients with thermal injury is described in Chapter 39. Geriatric burn patients need special approaches to fluid therapy to prevent damage to the kidneys. The patient's fluid status will need to be assessed in the initial hours after a burn injury by monitoring pulse and blood pressure, and striving to maintain a urine output of at least 50 to 60 mL per hour.

Trauma Management Considerations

The priorities of trauma care for geriatric patients are similar to those for all trauma patients described in Part Nine: Trauma. However, the paramedic should give special consideration to transport strategies and the geriatric patient's cardiovascular, respiratory, and renal systems.

CARDIOVASCULAR SYSTEM

Special considerations for cardiovascular problems include the following:

- Recent or past MI contributes to the risk of dysrhythmias and CHF.
- Adjustment of heart rate and stroke volume may be decreased in response to hypovolemia.
- Geriatric patients may need higher arterial pressures than younger patients for perfusion of vital organs. This is because of atherosclerotic peripheral vascular disease.
- Rapid IV fluid administration to geriatric patients may cause volume overload. The paramedic must take care not to overhydrate these patients. Older adults as a group are more susceptible to CHF. However, hypovolemia and hypotension are also poorly tolerated. The paramedic should consider hypovolemia in any geriatric patient whose systolic blood pressure is less than 120 mm Hg. Tachycardia may not occur if the patient takes beta blockers. The paramedic should monitor lung sounds and vital signs carefully and frequently during fluid administration.

RESPIRATORY SYSTEM

Special considerations for respiratory problems include the following:

- Physical changes decrease chest wall compliance and movement. Thus they diminish vital capacity as well.
- Pa_{O_2} decreases with age.
- Lower P_{O_2} at the same fractional inspired oxygen concentration occurs with each passing decade.
- All organ systems have less tolerance to hypoxia.
- Chronic obstructive pulmonary disease (common in geriatric patients) requires that the paramedic carefully adjust airway management and ventilation support for appropriate oxygenation and carbon dioxide removal. High-concentration oxygen may suppress hypoxic drive in some patients. However, oxygen should never be withheld from a patient with clinical signs of cyanosis. The paramedic may need to remove the patient's dentures for adequate airway and ventilation management.

RENAL SYSTEM

Special considerations for renal problems include the following:

- The kidneys have decreased ability to maintain normal acid-base balance. They have decreased ability to compensate for fluid changes as well.
- Kidney disease may further decrease the ability of the kidneys to compensate.
- Decreased kidney function (along with decreased cardiac reserve) places the injured geriatric patient at risk for fluid overload and pulmonary edema following IV fluid therapy.

TRANSPORTATION STRATEGIES

Special considerations for transportation of geriatric patients include the following:

- Positioning, immobilization, and transport of a geriatric trauma patient may require modifications to accommodate physical deformities (e.g., arthritis or spinal abnormalities).
- Packaging should include bulk and extra padding to support and give comfort to the patient.
- The paramedic can prevent hypothermia by keeping the patient warm.

Elder Abuse

Elder abuse refers to the infliction of physical pain, injury, debilitating mental anguish, unreasonable confinement, or willful deprivation by a caregiver of services that are necessary to maintain mental and physical health of a geriatric person. Elder abuse has become more and more recognized as a growing problem in the United States. Elder abuse is estimated to affect between 1 and 2 million older adults each year.[33]

Elder abuse takes many forms. These include physical abuse, sexual abuse, emotional or psychological abuse, neglect, abandonment, financial or material exploitation, and self-neglect. Box 49-14 lists the signs and symptoms of each type of elder abuse as defined by the National Center on Elder Abuse.

All 50 states have elder abuse statutes. Also, reporting of suspected elder abuse is mandatory under law in most states. If the paramedic suspects abuse or neglect of an older adult, the medical direction should be advised. Moreover, the paramedic should follow the procedures that are established by local protocol. Emergency care is aimed at managing injuries that pose a threat to life and transporting the patient for physician evaluation. Abuse and neglect are discussed further in Chapter 50.

BOX 49-14 Signs and Symptoms of Elder Abuse and Neglect

Physical Abuse

Abandonment

Bruises, black eyes, welts, lacerations, and rope marks
Bone fractures, skull fractures
Open wounds, untreated injuries in various stages of healing
Sprains, dislocations, and internal injuries/bleeding
Broken eyeglasses/frames, physical signs of being subjected to punishment, and signs of being restrained
An elder's report of being hit, slapped, kicked, or mistreated
An elder's sudden change in behavior
The caregiver's refusal to allow examination of an elder without the caregiver being present
The desertion of an elder at a hospital, a nursing facility, or other similar institution
The desertion of an elder at a shopping center or other public location
An elder's own report of being abandoned

Financial or Material Exploitation

Sudden changes in bank account or banking practice, including an unexplained withdrawal of large sums of money by a person accompanying the elder
The inclusion of additional names on an elder's bank signature card
Unauthorized withdrawal of the elder's funds using the elder's automatic teller machine card

Sexual Abuse

Abrupt changes in a will or other financial documents
Bruises around the breasts or genital area
Unexplained venereal disease or genital infections
Unexplained vaginal or anal bleeding
Torn, stained, or bloody underclothing
An elder's report of being sexually assaulted or raped
Unexplained disappearance of funds or valuable possessions
Substandard care being provided or bills unpaid despite the availability of adequate financial resources
Discovery of an elder's signature being forged for financial transactions or for the titles of his or her possessions

Emotional or Psychological Abuse

Sudden appearance of previously uninvolved relatives
Being emotionally upset or agitated
Being extremely withdrawn and noncommunicative or nonresponsive
Unusual behavior usually attributed to dementia (e.g., sucking, biting, or rocking)
An elder's report of being verbally or emotionally mistreated
claiming their rights to an elder's affairs and possessions
Unexplained sudden transfer of assets to a family member or someone outside the family
The provision of services that are not necessary
An elder's report of financial exploitation

Neglect

Self-Neglect

Dehydration, malnutrition, untreated bed sores, and poor personal hygiene
Unattended or untreated health problems
Hazardous or unsafe living conditions/arrangements (e.g., improper wiring and lack of heat or running water)
Unsanitary and unclean living conditions (e.g., dirt, fleas, body lice, soiled bedding, fecal/urine smell, and inadequate clothing)
An elder's report of being mistreated
Dehydration, malnutrition, untreated or improperly attended medical conditions, and poor personal hygiene
Hazardous or unsafe living conditions/arrangements (e.g., improper wiring, no indoor plumbing, and lack of heat or running water)
Unsanitary or unclean living quarters (e.g., animal/insect infestation, no functioning toilet, and fecal/urine smell)
Inappropriate and/or inadequate clothing, lack of the necessary medical aids (e.g., eyeglasses, hearing aids, and dentures)
Grossly inadequate housing or homelessness

Adapted from National Center on Elder Abuse: *The basics: major types of elder abuse,* www.elderabusecenter.org/default.cfm?p=basics.cfm, accessed 10-1-03.

SUMMARY

- The aging process proceeds at different rates in different persons. Respiratory function in the older adult generally is compromised. This is a result of changes in pulmonary physiology that accompany the aging process. Cardiac function also declines with age. This is a result of normal physiological changes and the high incidence of coronary artery disease. Renal blood flow falls an average of 50% between 30 and 80 years of age. A gradual decrease in the number of neurons, decreased cerebral blood flow, and changes in the location and amounts of specific neurotransmitters probably contribute to changes in the CNS. As the body ages, muscles shrink, muscles and ligaments calcify, and the intervertebral disks become thin. Other physiological changes that occur with aging include changes in body mass and total body water, a decreased ability to maintain internal homeostasis, a decrease in the function of immunological mechanisms, an increase in possible nutritional disorders, and decreases in hearing and visual acuity.

Continued

- Normal changes with aging and existing illnesses may make evaluation of an ill or injured geriatric patient a challenge.
- Pneumonia is a leading cause of death in the geriatric age group. It often is fatal in frail adults. Chronic obstructive pulmonary disease (COPD) is a common finding in the geriatric patient who has a history of smoking. The disease usually is associated with various other diseases that result in reduced expiratory airflow. Pulmonary embolism is a life-threatening cause of dyspnea. Pulmonary embolism is associated with venous stasis, heart failure, COPD, malignancy, and immobilization. All of these are common in older adults.
- A lack of typical chest pain can cause an MI to be unrecognized in the geriatric patient. Heart failure is more frequent in geriatric patients and has a larger incidence of noncardiac causes. The most common cause of dysrhythmias in the geriatric patient is hypertensive heart disease. Abdominal aortic aneurysm affects 2% to 4% of the U.S. population over 50 years of age. This aneurysm is most prevalent between 60 and 70 years of age. The incidence of hypertension in the geriatric patient increases when atherosclerosis is present.
- Risk factors for cerebral vascular disease in the older adult include smoking, hypertension, diabetes, atherosclerosis, hyperlipidemia, polycythemia, and heart disease.
- Delirium is an abrupt disorientation to time and place. Delirium is commonly a result of physical illness.
- Dementia is a slow, progressive loss of awareness of time and place. It usually involves an inability to learn new things or remember recent events. This condition often is a result of brain disease. Alzheimer's disease is the most common cause of dementia. Alzheimer's disease is a condition in which nerve cells in the cerebral cortex die and the brain substance shrinks.
- Parkinson's disease is a brain disorder. It causes muscle tremor, stiffness, and weakness.
- About 20% of older adults have diabetes. Almost 40% have some impaired glucose tolerance. Hyperglycemic hyperosmolar nonketotic coma is a serious complication of elderly type 2 diabetic patients. It has a mortality rate of 20% to 50%. Thyroid disease is more common in geriatric patients. It may not present in the classic manner.
- Gastrointestinal bleeding most often affects patients between 60 and 90 years of age. It has a mortality rate of about 10%. Bowel obstruction generally occurs in patients with prior abdominal surgeries or hernias. It also occurs in those with colonic cancer. Some geriatric patients may have problems with continence or with elimination as well.
- Aging results in a gradual decrease in epidermal cellular turnover. It also results in loss of deep and dermal vessels. Alterations in capillary circulation lead to changes in thermal regulation and skin-related complications.
- Osteoarthritis is a common form of arthritis in geriatric patients. It results from cartilage loss and wear and tear on the joints. The loss in bone density from osteoporosis causes bones to become brittle. These bones may fracture easily.
- As persons age, they may experience problems with vision, hearing, and speech.
- Geriatric patients are at an increased risk for adverse drug reactions. This is due to age-related changes in body composition and drug distribution. It also is the result of metabolism and excretion. Moreover, the risk for adverse drug reactions often stems from multiple prescribed drugs. Alcohol abuse is a common problem in geriatric patients.
- The geriatric patient may develop hypothermia while indoors. This may be the result of cold surroundings and/or an illness that alters heat production or conservation. Hyperthermia most likely results from exposure to high temperatures that continue for several days.
- Depression is common in geriatric patients. It can result from physiological and psychological causes. The rate of completed suicides for geriatric patients is higher than that of the general population.
- One third of traumatic deaths in persons 65 to 74 years of age result from vehicular trauma. Twenty-five percent result from falls. In those older than 80 years of age, falls account for 50% of injury-related deaths. The risk of fatality from multiple trauma is estimated to be 3 times greater at 70 years of age than at 20 years of age.
- Elder abuse is classified as physical abuse, psychological abuse, financial or material abuse, and neglect.

CHAPTER

50 Abuse and Neglect

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Define battering.
2. Describe the characteristics of abusive relationships.
3. Outline findings that indicate a battered patient.
4. Describe prehospital considerations when responding to and caring for battered patients.
5. Identify types of elder abuse.
6. Discuss legal considerations related to all forms of abuse.
7. Describe characteristics of abused children and their abusers.
8. Outline the physical examination of the abused child.
9. Describe the characteristics of sexual assault.
10. Outline prehospital patient care considerations for the patient who has been sexually assaulted.

KEY TERMS

battering Repeated physical violence and assault; may include establishing control and fear in a relationship through violence and other forms of abuse.

domestic violence A type of violence that occurs between opposite- and same-sex partners.

economic abuse Making or attempting to make an individual financially dependent by maintaining total control over financial resources, withholding one's access to money, or forbidding one's attendance at school or employment.

elder abuse The infliction of physical pain, injury, debilitating mental anguish, unreasonable confinement, or willful deprivation by a caregiver of services that are necessary to maintain mental and physical health of a geriatric person.

emotional abuse The infliction of anguish, pain, or distress through verbal or nonverbal acts.

financial/material exploitation The illegal or improper use of funds, properties, or assets.

neglect The refusal or failure of the caregiver to fulfill obligations or duties to a person.

patterned injuries Injuries that result from an identifiable object.

physical abuse The use of physical force that may result in bodily injury, physical pain, or impairment.

physical assault An intentional act by one person that creates apprehension in another of an imminent harmful or offensive contact.

self-neglect A type of elder abuse; behaviors of an older adult that intentionally threaten personal health or safety.

sexual abuse Nonconsensual sexual contact of any kind.

shaken baby syndrome A serious form of child abuse that describes injuries to infants that occur after being shaken violently.

stalking A pattern of repeated and unwanted attention, harassment, contact, or any other course of conduct directed at a specific person that would cause a reasonable person to feel fear.

Partner, elder, and child abuse are growing problems in the United States. Paramedics will encounter victims of abuse in their careers. Abuse and neglect can result in mental and physical illness or injury, and even death. Education programs for paramedics must include information about these violent crimes. This information includes identification of victims, special aspects of care, scene safety, and documentation requirements. This chapter addresses the types of abuse and neglect, the personality traits of those who abuse, and legal considerations in providing emergency care.

BATTERING

Battering refers to repeated physical violence and assault. Battering often includes the establishment of control and fear in a relationship through violence and other forms of abuse. The batterer may use acts of violence and series of behaviors to coerce and control the other person. These behaviors include intimidation, threats, psychological abuse, and isolation (Figure 50-1). Battering can include many types of abuse and neglect. Examples include[1]:

- **Physical abuse:** Hitting, slapping, shoving, grabbing, pinching, biting, and hair-pulling, for example. Physical abuse also includes denying a partner medical care or forcing alcohol and/or drug use.
- **Sexual abuse:** Coercing or attempting to coerce any sexual contact or behavior without consent. Sexual abuse includes, but is not limited to, marital rape, attacks on sexual parts of the body, forcing sex after physical violence has occurred, or treating one in a sexually demeaning manner.
- **Emotional abuse:** Undermining an individual's sense of self-worth and/or self-esteem. This may include, but is not limited to, constant criticism, diminishing one's abilities, name-calling, or damaging one's relationship with his or her children.
- **Economic abuse:** Making or attempting to make an individual financially dependent by maintaining total control over financial resources, withholding access to money, or forbidding attendance at school or employment.

NOTE

Although not usually considered a form of abuse, **stalking** can be defined as a pattern of repeated and unwanted attention, harassment, contact, or any other course of conduct directed at a specific person that would cause a reasonable person to feel fear. Like domestic violence, stalking is a crime of power and control. In 2006, 3.4 million people in the United States were victims of stalking.[2] During their lifetimes, 1 in 12 women and 1 in 45 men will be stalked, for an average duration of almost 2 years.[3] During the course of their careers and when assisting law enforcement personnel at emergency scenes, paramedics will likely encounter victims who have been stalked.

The violence associated with battering may not happen often. Yet battering is a hidden and constant terrorizing factor in some relationships. Over time the beatings usually become more severe and more frequent. They often occur without provocation. If children are present in a marriage or relationship, often the violence eventually turns toward them. Persons involved in abusive relationships often fail to see other options and feel powerless to change.

Domestic violence is also known as *intimate partner violence* (IPV). This type of violence occurs between opposite- and same-sex partners. Domestic violence follows a cycle of three phases[2] (Figure 50-2). Phase one involves arguing and verbal abuse; phase two progresses to physical and sexual abuse; and phase three consists of denial and apologies (the "honeymoon phase"). The paramedic best achieves intervention in phase two or three. The cycle repeats itself without intervention and usually increases in frequency and severity. Understanding this cycle of violence will help the paramedic assess the situation and care for the victim.

SHOW ME THE EVIDENCE

Investigators evaluated the accuracy of EMTs as compared to a trained ride-along observer to complete a domestic violence screen on patients transported from their home. They also compared agreement between the Domestic Violence Scene Assessment Screen (DVSAS) and the Abuse Assessment Screen (AAS). Their sample was 43 patients. They found moderate to good agreement between the independent observer and EMT (kappa was 0.56 [0.29-0.83]). When compared to the AAS the DVSAS agreed in 60% of cases (sensitivity 75%; specificity 55%). The authors conclude that EMTs can reliably complete the DVSAS at the end of transport.

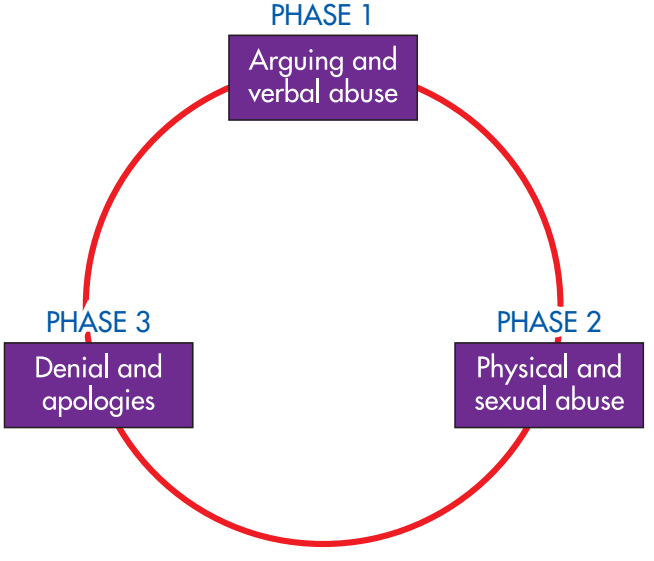

FIGURE 50-2 Cycle of violence.

Battered Women

An estimated 1.3 million women are battered by their husband, boyfriend, or intimate partner each year[4,5] (Box 50-1). Even so, less than 10% of women report battering incidents for reasons that include the following:

1. Personal fear or fear for her children
2. Belief that the offender's behavior will change (abusers often appear charming and loving after the battering incident)
3. Lack of financial and/or emotional support
4. Belief that she is the cause of the violent behavior
5. Belief that battering is "part of the marriage" and must be endured to keep the family together

Women of all cultures, races, occupations, income levels, and ages are battered by their past and present husbands, boyfriends, and intimate partners. Domestic violence is the leading cause of injury to women who are between 15 and 44 years of age in the United States.[6] Women who leave

BOX 50-1 Domestic Violence: Facts and Statistics

- Battered women often are severely injured. At least one third of all emergency department visits by women are due to battering.
- Every year an estimated 4 million to 6 million women are beaten by a spouse or partner. This is more than those who are hurt in auto crashes, rapes, and muggings combined.
- Half of all homeless women and children are homeless as a result of domestic violence.
- About 15% to 25% of pregnant women are battered.
- Battered women are more likely to suffer miscarriages. They also are more likely to give birth to infants with low birth weights.
- Living in suburban and rural areas does not decrease a woman's risk of experiencing an act of violence by a spouse or partner.
- Up to 75% of domestic assaults reported to law enforcement agencies were inflicted after the couples had separated.
- Between 50% and 70% of the men who batter their spouse or partner also abuse their children.
- About 63% of young men between 11 and 20 years of age who are serving time for homicide have killed their mother's abuser.
- Domestic violence is the sixth most dangerous call for law enforcement officers killed in the line of duty.
- The United States has nearly 3 times as many animal shelters as it does shelters for battered women and their children.
- Compared with males, females experience more than 10 times as many incidents of violence by a spouse or partner each year.
- Children are present in 40% to 55% of homes when police intervene in domestic violence calls.
- In 85% to 90% of domestic homicides, the police had been called to the home at least once during the 2 years before the incident. In more than half of these cases the police had been called 5 times or more.
- Almost 6 times as many women victimized by spouses or partners, compared with those victimized by strangers, did not report their violent victimization to police because they feared reprisal from the offender.

From Federal Bureau of Investigation, National Coalition Against Domestic Violence, National Woman Abuse Prevention Project, U.S. Senate, Committee on the Judiciary, U.S. Department of Justice, Bureau of Justice Statistics, May 2005.

their batterers are at 75% greater risk of being killed by the batterer than those who stay in the abusive relationship. These women are also 25 times more likely to be seriously injured by their batterer when they leave than when they stay[7] (Figure 50-3).

NOTE

Intimate partner violence (IPV) in the United States resulted in nearly 2 million injuries and 1510 deaths in 2005. Of these deaths, 78% were women and 22% were men.[8]

FIGURE 50-3 A woman struck in the face.

Battered Men

In about 95% of domestic assaults the batterer is a man.[9] However, women are not the only battering victims. More than 150,000 men in the United States each year are victims of physical violence by a spouse or intimate partner (Figure 50-4).[4] Men report physical violence by a spouse or partner less often than women. This may be the result of humiliation, guilt, and/or fear to admit loss of control. In addition, society may seem to be less empathetic toward battered men than battered women. Communities generally have fewer resources for support.

Characteristics of Persons in Abusive Relationships

Certain personality traits may draw persons into abusive relationships. The following are characteristics of one or both persons in an abusive relationship[10]:

1. Intense need for love and affection
2. Low self-esteem
3. Alcohol or other drug dependence
4. Difficulty in finances, job security, and possible legal issues
5. Background of physical, emotional, or sexual abuse; abusers are often survivors of abuse
6. Belief that abuse is demonstrating discipline
7. Fear of being "out of control"
8. Uncontrolled temper, extreme jealousy, and insecurity
9. Inability to set and enforce personal boundaries
10. Unrealistic expectations of a relationship
11. Difficulty in expressing anger
12. Loyalty to the abuser that takes precedence over emotional or physical safety
13. Repeated attempts to leave the relationship

FIGURE 50-4 Soft tissue injury to the face from blows and to the neck from a firm grip.

14. Clinical depression
15. Suicidal ideation or attempts

Identification of the Battered Patient

The paramedic may have difficulty identifying the battered patient. Often the description of the injuries may be incorrect, inaccurate, and protective of the attacker. Injuries that are unintentional often involve the extremities and the periphery of the body. However, injuries from domestic violence often involve contusions and lacerations of the face, head, neck, breast, and abdomen. Bruises and lacerations may appear to be "old." This is because many victims of abuse do not seek medical help for their injuries. Other clues of domestic violence are the following:

- Excessive delays between injury and seeking treatment
- Repeated requests for emergency medical services assistance
- Injuries during pregnancy
- Substance abuse
- Frequent suicide gestures

Scene Safety

The paramedic must ensure scene and personal safety in domestic violence events. If dispatch reveals that the scene involves domestic violence, the paramedic should summon law enforcement personnel. The EMS crew also should not enter the scene until it has been secured. If domestic violence was not suspected until after arriving at the scene, the victim should be removed from the area as soon as possible. Violence often is directed at EMS personnel. This is especially the case if the abuser feels that the paramedic is giving too much empathy to the victim. Thus the paramedic should not question the victim about possible violence in the presence of the abuser. No display of sympathy should be shown until the victim is in the ambulance or has been separated from the suspected batterer.

Care of the Victim

All injuries should be managed according to standard protocols. The paramedic should direct special attention to the emotional needs of the victim. The abuser often is unwilling to allow the victim to give a history or allow the victim to be alone with EMS personnel. Therefore, the paramedic should question the patient privately about the incident when possible.

CRITICAL THINKING
If you suspect abuse, what can you say to encourage the victim to talk about it?

History of the events that led to physical injury should be obtained by using direct questions. Often the patient will avoid eye contact and be hesitant or evasive about details of an injury. Some may offer clues by saying, "Things haven't been going well lately," or "There have been problems at home" (Box 50-2). The paramedic should convey to the patient his or her suspicions of battering. The patient may be relieved to know that someone else is aware of the abuse.

During the patient interview, it is important to be nonjudgmental and to avoid comments such as "How awful" or "Why don't you leave?" The paramedic should listen carefully to the victim and offer emotional support. The patient should be encouraged to gain control of his or her life and to consider the best interests and needs of any children who may be involved in the abusive relationship. Access to community resources should be provided to the victim. These resources include battered spouse programs, victim-witness assistance programs, and other support agencies for abused victims and their families. Finally, the paramedic should discuss safety measures with the victim who elects not to be transported for evaluation. This may include helping the patient identify a quick way out of a dangerous situation (e.g., where to go and whom to call). It also may include giving the victim an approved written list

BOX 50-2 Lies Abusers Tell

- "I just need to be understood."
- "I had a bad childhood."
- "I can't control it."
- "I get angry."
- "She fights too."
- "She pushes my buttons."
- "If I don't control her, she will control me."
- "My smashing things isn't abusive, it's venting."
- "I have a lot of stress in my life."
- "I just have an anger management problem."
- "I just have a problem when I drink or use drugs."

BOX 50-3 National Domestic Violence Hotline

In 1996 the U.S. government established a nationwide 24-hour toll-free domestic violence hotline through the Violence Against Women Act of 1994. The voice number for the hotline is 1-800-799-SAFE. The TDD number for the hearing impaired is 1-800-787-3224. The hotline is available 365 days a year. It operates throughout the United States, Puerto Rico, and the Virgin Islands. The hotline is staffed by trained advocates. These advocates offer crisis intervention, support, and referrals to local services in the caller's community.

Other components of the act include allocating funds for training prosecutors and police, maintaining shelters, and providing educational programs in schools and communities. These programs work with the hotline to treat domestic violence as a serious crime. They also help to prevent domestic violence before it starts.

or a small card (that can be hidden easily from the abuser) of community resources, shelters, and hotline numbers (Box 50-3).

CRITICAL THINKING
How would you feel if you respond to a call in which a woman has been injured by a batterer but chooses not to leave?

Some patients who have suffered abuse eventually leave the abusive relationship. This often is made possible by health care providers and support agency personnel who do the following:

- Treat the victim in a sensitive and sympathetic manner.
- Confirm that the victim is not at fault and does not deserve to be abused.
- Ensure the victim's safety.
- Become "agents of change" in helping provide the support needed for the victim to leave the abusive environment.

Legal Considerations

Physical assault is an intentional act by one person that creates apprehension in another of an imminent harmful or offensive contact. Physical assault is a crime that may be a misdemeanor or a felony, depending on state law, the amount of injury inflicted, and devices that the attacker uses during the assault. Often the attacker is arrested but is released from custody within hours on his or her own recognizance. If early release from custody is likely, the patient must be made aware of this and encouraged to take personal safety precautions.

Most states do not have mandatory reporting requirements for acts of domestic violence.[11] Paramedics should be aware of the requirements in their state. Emergency medical services personnel are bound professionally to advise medical direction of their suspicions and observations about acts of violence.

Any act of physical abuse against a spouse, partner, elder, or child is a crime. Therefore, the scene must be treated as a crime scene. Paramedics should be careful not to disturb the scene or destroy possible evidence. Documentation is key. It should include a precise account of injuries, a description of the reported mechanisms of injuries, and a depiction of the behavior of the victim and alleged abuser. Using body diagrams in the patient care report may be helpful. The paramedic should record the victim's own words in the narrative when possible and record the names of police officers and witnesses at the scene. These details are important in cases of litigation (see Chapter 4).

LOOK AGAIN
See Chapter 4: Documentation, pp. 67-68.

ELDER ABUSE

Elder abuse (abuse, neglect, exploitation of the elderly) was described in Chapter 49. Elder abuse is a prevalent medical and social problem in the United States. Although it is difficult to estimate how many older Americans are abused, neglected, or exploited, studies suggest that there may be as many as 5 million victims every year.[12] Factors that contribute to elder abuse include the following:

- Increased life expectancy
- Physical and mental impairment
- Decreased productivity
- Increased dependence
- Limited resources for care of the elderly
- Economic factors
- Stress of the middle-age caregiver responsible for two generations

CRITICAL THINKING
Do you think that the problem of elder abuse will increase or decrease during your career in emergency medical services? Why?

Types of Elder Abuse

According to the National Center on Elder Abuse[13] elder abuse may be classified as *physical abuse* (Figure 50-5), *sexual abuse, emotional/psychological abuse, neglect, abandonment, financial or material exploitation,* and *self-neglect* (Box 50-4). (**Self-neglect** refers to behaviors of an older adult that intentionally threaten personal health or safety. Examples include poor nutrition and noncompliance with prescribed drugs.) Elder abuse also is classified by where it occurs. It occurs in domestic settings or in institutions.

FIGURE 50-5 Injuries from facial blows to an older adult.

DOMESTIC SETTINGS

The average victim of elder abuse in domestic settings is about 78 years of age. The National Aging Resource Center on Elder Abuse provides data regarding types of elder abuse in domestic settings.[14] The abused elder usually has multiple, chronic health conditions that make him or her dependent on others for care. Widows over 75 years of age carry the greatest risk of elder abuse. Neglect is the most common form of elder abuse in domestic settings; unexplained trauma is the most common finding. Evidence suggests that elder abuse is associated more with the personality of the abuser than with the burden of caring for a sick, dependent person (Box 50-5).

Four major theories of causes of domestic elder abuse are as follows:

1. Elder abuse occurs in settings where the caregiver is under a great amount of stress. This stress is a result of personal problems and/or a lack of knowledge about how to provide care to an older adult.
2. Mental and/or physical impairments common in many older adults make them more likely to be abused than older adults who are in good health.
3. A "cycle of violence" often occurs in elder abuse. The cycle begins with ongoing tension. This tension escalates in a crisis in which abuse occurs. The abuse generally is followed by a period of calm, reconciliation, and denial, after which the cycle repeats.
4. Abusers of older adults often have more personal problems than nonabusers. (For example, they may have job insecurity and/or financial troubles.)

Older adults often are repeatedly abused by family members. The abusers most often are the children of the abused. Because of this familial relationship, many older adults do not report the abuse. Many also do not seek medical care for their injuries.

INSTITUTIONAL SETTINGS

About 5% of the U.S. population 65 years of age and older live in nursing homes, elder care facilities, assisted-living facilities, and board-and-care homes. Almost 50% of American who are 95 years of age and older reside in nursing homes. Based on Census Bureau projections, by 2030 it is estimated that 70% of patients 85 years of age and older will require some form of residential care.[15] These individuals are at risk for intentional harm, physical violence, verbal aggression, or neglect from other residents and paid caregivers, staff, and professionals. Clues that may indicate institutional abuse include the following:

- Burns caused by cigarettes, caustics, or acids
- Caregiver who cannot explain the victim's condition adequately
- Dehydration, malnutrition, or pressure sores
- Emotional abuse
- Loss of weight
- Neglect
- Open wounds, cuts, bruises, welts, or discoloration
- Physical abuse
- Unsanitary and unclean conditions (dirt, soiled bed, or fecal or urine odor)
- Unusual behavior by the victim (sucking, biting, or rocking)
- Victim who is begging for food
- Victim who is emotionally upset or agitated
- Victim who is extremely withdrawn and noncommunicative
- Victim with poor personal hygiene
- Victim's sudden change in behavior

Legal Considerations

All 50 states have elder abuse statutes. Reporting of suspected elder abuse is mandatory under law in most states. If the paramedic suspects any form of elder abuse, all findings should be carefully documented. Medical direction should be advised and procedures established by local protocol should be followed.

CHILD ABUSE

In 2007 child protective service agencies investigated more than 3 million reports alleging maltreatment of children. These agencies determined that an estimated 794,000 of these children were victims of substantiated or indicated abuse or neglect.[16] That same year, an estimated 1760 children died from child abuse.[17] As described in Chapter 48, various forms of child abuse—including physical injury, sexual exploitation, infliction of emotional pain, and neglect—can result in physical or emotional impairment.

Neglect is the most common form of child abuse. However, many children suffer more than one type of abuse. Neglect is the failure to provide physical care (e.g., medical care, nutrition, shelter, and clothing) or the failure to provide emotional care (i.e., indifference and disregard). Most substantiated reports of child abuse or neglect come from professional sources (educators, social services, law

BOX 50-4 Signs and Symptoms of Elder Abuse

Physical Abuse
- Bruises, black eyes, welts, lacerations, and rope marks
- Bone fractures, broken bones, and skull fractures
- Open wounds, cuts, punctures, untreated injuries in various stages of healing
- Sprains, dislocations, and internal injuries/bleeding
- Broken eyeglasses/frames, physical signs of being subjected to punishment, and signs of being restrained
- Laboratory findings of medication overdose or underutilization of prescribed drugs
- An elder's report of being hit, slapped, kicked, or mistreated
- An elder's sudden change in behavior
- The caregiver's refusal to allow visitors to see an elder alone

Sexual Abuse
- Bruises around the breasts or genital area
- Unexplained venereal disease or genital infections
- Unexplained vaginal or anal bleeding
- Torn, stained, or bloody underclothing
- An elder's report of being sexually assaulted or raped

Emotional/Psychological Abuse
- Being emotionally upset or agitated
- Being extremely withdrawn and noncommunicative or nonresponsive
- Unusual behavior usually attributed to dementia (e.g., sucking, biting, rocking)
- An elder's report of being verbally or emotionally mistreated

Neglect
- Dehydration, malnutrition, untreated bed sores, and poor personal hygiene
- Unattended or untreated health problems
- Hazardous or unsafe living conditions/arrangements (e.g., improper wiring, no heat, or no running water)
- Unsanitary and unclean living conditions (e.g., dirt, fleas, lice on person, soiled bedding, fecal/urine smell, inadequate clothing)
- An elder's report of being mistreated

Abandonment
- The desertion of an elder at a hospital, a nursing facility, or other similar institution
- The desertion of an elder at a shopping center or other public location
- An elder's own report of being abandoned

Financial or Material Exploitation
- Sudden changes in bank account or banking practice, including an unexplained withdrawal of large sums of money by a person accompanying the elder
- The inclusion of additional names on an elder's bank signature card
- Unauthorized withdrawal of the elder's funds using the elder's ATM card
- Abrupt changes in a will or other financial documents
- Unexplained disappearance of funds or valuable possessions
- Substandard care being provided or bills unpaid despite the availability of adequate financial resources
- Discovery of an elder's signature being forged for financial transactions or for the titles of his/her possessions
- Sudden appearance of previously uninvolved relatives claiming their rights to an elder's affairs and possessions
- Unexplained sudden transfer of assets to a family member or someone outside the family
- The provision of services that are not necessary
- An elder's report of financial exploitation

Self-Neglect
- Dehydration, malnutrition, untreated or improperly attended medical conditions, and poor personal hygiene
- Hazardous or unsafe living conditions/arrangements (e.g., improper wiring, no indoor plumbing, no heat, no running water)
- Unsanitary or unclean living quarters (e.g., animal/insect infestation, no functioning toilet, fecal/urine smell)
- Inappropriate and/or inadequate clothing, lack of the necessary medical aids (e.g., eyeglasses, hearing aids, dentures)
- Grossly inadequate housing or homelessness

From National Center on Elder Abuse: Major Types of Elder Abuse, U.S. Administration on Aging. http://www.ncea.aoa.gov/ncearoot/main_site/FAQ/Basics/Types_Of_Abuse.aspx, accessed July 21, 2011

BOX 50-5 Percentage of Those Who Abuse Elders

Adult children: 32.5%
Grandchildren: 4.2%
Intimate partners: 14.4%
Sibling: 2.5%
Other relative: 12.5%
Friend or neighbor: 7.5%
All others: 18.2%
Unknown: 2.0%

From The AGS Foundation for Health and Aging: *Preventing elder abuse and neglect in older adults,* New York, 2009, American Geriatric Society.

enforcement, and medical personnel). Persons in the family of the victim report only 18% of child abuse cases.[17]

Characteristics of Abusers

The characteristics of abusers are not related to social class, income, or level of education. Most child abusers are the child's parents (77%). Eleven percent are other relatives of the victim. Most abusers are under 40 years of age. Two thirds are female (usually the child's mother). Persons who are in other caregiving relationships to the victim (e.g., childcare providers, foster parents, and facility staff) account for only 2% of perpetrators. About 10% of all abusers are noncaregivers or unknown. Neglect often is

BOX 50-6 Characteristics of Child Abusers

- Demonstrate immature behavior
- Show personal preoccupation (self-centeredness)
- Have little perception of how a child feels (physically or emotionally)
- Are critical of the child
- Seldom touch or look at the child
- Are unconcerned about the child's injury, treatment, or prognosis
- Show no feeling of guilt or remorse
- Blame the child for the injury or illness

BOX 50-7 Who Are the Child Victims of Abuse?

- Nearly 50% are 7 years of age or younger.
- Thirty-three percent are younger than 4 years of age.
- Nearly 20% are 8 to 11 years of age.
- Twenty-one percent are 12 to 18 years of age.
- Fifty-one percent are female.
- Forty-eight percent of sexual abuse victims are boys.
- Children younger than 4 years of age account for 76% of fatalities from abuse.

From Child Maltreatment 2008, Administration for Children & Families, U.S. Department of Health and Human Services, Washington, DC.

attributed to female perpetrators, whereas sexual abuse most often is attributed to males.[17] Box 50-6 provides other characteristics of child abusers.

CRITICAL THINKING

How does it make you feel when you hear a story about child abuse on the news? Think about how you will manage those feelings when you are at a scene with such a child.

A family history of rigorous discipline accounts for the cyclical nature of child abuse. Because many abusers were severely punished and beaten as children by their parents, they often prefer to use other forms of discipline for their children. But the stresses of child rearing eventually culminate in some parents regressing to the earliest patterns of discipline that they experienced as a child. The abusive adult sometimes is aware of this cyclical nature. The adult may even try to seek help to prevent abusive behavior toward his or her children. During this pre-abuse state, the following pattern often occurs:

1. The adult makes several calls for help within a 24-hour period to 9-1-1 or support agencies.
2. The adult frequently calls EMS for inconsequential symptoms.
3. The adult begins to exhibit behavior of being unable to handle an impending crisis.

The pre-abuse state is important in identifying the potential for abuse. The pattern is often repetitive and results in frequent calls for EMS to visit the patient's home. The paramedic should remember that this behavior indicates the adult's awareness that child abuse is likely to occur. It also means that the adult is actively seeking help to prevent the abuse.

Characteristics of the Abused Child

Abused children often display behavior that provides important clues about abuse and neglect (Box 50-7). Although this behavior may be age-related, the paramedic should observe carefully the child under 6 years of age who is excessively passive, the child over 6 years of age who is excessively aggressive, and the child of any age with the following characteristics:

- Does not mind if his or her parents leave the room
- Cries hopelessly during treatment or cries very little
- Does not look at parents for reassurance
- Is wary of physical contact
- Is extremely apprehensive
- Appears constantly on the alert for danger
- Constantly seeks favors, food, or comfort items (e.g., blankets and toys)

Physical Examination

Injuries during childhood are common. Most injuries are unintentional and not the result of abuse. Distinguishing between an intentional and unintentional injury can be challenging for the paramedic. The most important clues can be obtained by observing the child and his or her relationship with the parent or caregiver and by matching the history of the event to the injury. If the child volunteers the history of the event without hesitation and matches the history that the parent provides (and the history is suitable for the injury), child abuse is unlikely.

LEGAL CONSIDERATIONS

When possible, the paramedic should partner with another colleague when performing the examination of a child who is a suspected victim of abuse. This will help verify that the note-taking is objective. The exam also will help ensure that assumptions and personal perceptions do not taint findings. The report must be succinct and legible. The paramedic should document all relevant findings and observations. Child abuse is a crime that is reportable under law in all 50 states. Paramedics should follow local protocol in reporting suspected child abuse. In addition, they should discuss any suspicions of child abuse or neglect with medical direction.

COMMON TYPES OF INJURIES

Common types of injuries associated with child abuse include the following:

Soft tissue injuries: Soft tissue injuries are the most common injury seen in cases of child abuse. They are often found in early abuse. They may present in various forms such as multiple bruises and ecchymosis, especially if bruises

are extensive and are a mixture of old and new bruises. Defense wounds may be found on multiple body planes. They often are **patterned injuries** that result from an identifiable object. (For example, they might be bites, loop marks from a cord or belt [Figure 50-6], cigarette burns, or bristle marks from a hairbrush.) In addition, scalds are a common form of abuse in the young and old (Figure 50-7).

Fractures: Fractures are the second most common injury in cases of child abuse. They often are caused by twisting and jerking forces and may be different ages (new and healed), indicating repeated injury. Rib fractures and multiple fractures are common findings.

Head injuries: Head injury is the most common cause of death in cases of child abuse, and children who survive head injury often have permanent disability (Figure 50-8). Often there is a visible progression of injury that begins at the child's trunk and extremities and moves toward the head. Associated injuries include scalp wounds, skull fractures, subdural or subgaleal hematomata, and repeated concussions.

Abdominal injuries: Abdominal injuries in cases of child abuse are less common than those injuries just described. However, they often are serious. Blunt trauma to the abdomen may lead to rupture of the liver as well as injuries to the intestines and mesentery.

FIGURE 50-6 Patterned injury from being struck with a belt.

FIGURE 50-7 "Bath dipping" typically produces scalds on the buttocks and feet.

Children Who Die From Abuse and Neglect

As stated earlier in this chapter, more than 1700 children die from child abuse and neglect in the United States each year. Fatal injuries from maltreatment result from many different acts, including the following:

- Severe head trauma
- Shaken baby syndrome
- Trauma to the abdomen and thorax

NOTE

Shaken baby syndrome (SBS) is a serious form of child abuse. It describes injuries to infants that occur after being violently shaken for as little as 5 seconds.[18] These rapid shakes can cause cerebral hemorrhage, brain damage, blindness, paralysis, and death. Shaken baby syndrome most often occurs before 2 years of age but may be seen up to age 5. The shaking episode usually results from inconsolable crying. It is estimated that as many as 1000 to 1400 babies are severely injured or killed by shaking each year in the United States.[19]

- Scalding
- Drowning
- Suffocation
- Poisoning

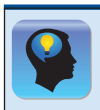
FIGURE 50-8 Multiple bruises on an infant's head from finger pressure.

Types of neglect that can result in death include the following:

1. *Supervision neglect* includes death that involves a critical moment in which the parent or caregiver is absent and the child is killed by a suddenly arising danger (e.g., leaving a child unattended in a bathtub).
2. *Chronic neglect* includes death that is caused by slowly building problems (e.g., malnutrition).
3. Deaths that result from *child physical abuse* involve fatal parental assaults on infants and children. These assaults are triggered by events such as inconsolable crying, feeding difficulties (Figure 50-9), failed toilet training, and the parent's exaggerated perceptions of acts of "disobedience." Parents may have unrealistic expectations for the child's behavior for the child's age group.

Another factor that increases a child's risk of death is living in a home where spouse or partner abuse occurs. Acts of domestic violence often are transferred to children living in the household. Studies have shown that frequently the following characteristics identify an abusive parent who kills a child[17]:

- Is a young male in his mid-twenties
- Lives near or below poverty level
- Has not finished high school
- Is depressed and unable to cope with stress
- Has experienced violence firsthand



CRITICAL THINKING

How can you calm yourself after caring for a child killed by abuse before writing a patient care report that likely will be called to account?

SEXUAL ASSAULT

Sexual assault is a serious crime. The number of sexual assaults has fallen by more than 60% in recent years. Even so, 248,300 victims age 12 years or older reported a sexual assault in 2007. (It is estimated that every 2 minutes someone in the United States is sexually assaulted.) Approximately 60% of all assaults are not reported to law enforcement personnel.[20] Sexual assault can result in mental or physical injury and death.[21]

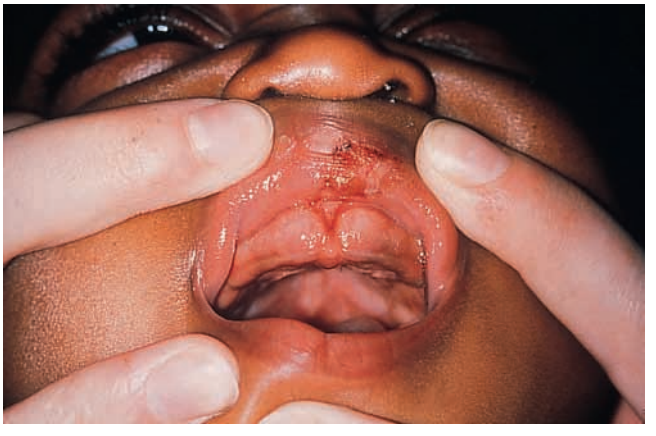


FIGURE 50-9 A torn frenulum that may have been caused by forced bottle-feeding.

DID YOU KNOW?

Who Are The Victims of Sexual Assault?

Women

1 out of every 6 American women has been the victim of an attempted or completed rape in her lifetime (14.8% completed rape; 2.8% attempted rape).

17.7 million American women have been victims of attempted or completed rape.

9 of every 10 rape victims were female in 2003.

Although about 80% of all victims are Caucasian, minorities are somewhat more likely to be attacked.

Lifetime rate of rape/attempted rape for women by race:

- Allwom en:1 7.6%
- Caucasianwom en:1 7.7%
- African-Americanwom en:1 8.8%
- AsianP acific Islander women: 6.8%
- AmericanI ndian/Alaskanwom en:3 4.1%
- Mixedr acewom en:2 4.4%

Men

About 3% of American men—or 1 in 33—have experienced an attempted or completed rape in their lifetime.

- In 2003, 1 in every 10 rape victims was male.
- 2.78 million men in the United States have been victims of sexual assault or rape.

Children

15% of sexual assault and rape victims are under age 12.

- 29%ar eag es1 2-17.
- 44%ar eu nderag e1 8.
- Ages1 2-34ar et heh ighestr isky ears.
- Girls ages 16-19 are 4 times more likely than the general population to be victims of rape, attempted rape, or sexual assault.
- 7% of girls in grades 5-8 and 12% of girls in grades 9-12 said they had been sexually abused.
- 3% of boys in grades 5-8 and 5% of boys in grades 9-12 said they had been sexually abused.

In 1995 local child protection service agencies identified 126,000 children who were victims of either substantiated or indicated sexual abuse.

- Oft hese,7 5%we reg irls.
- Nearly 30% of child victims were between the ages of 4 and7 .

93% of juvenile sexual assault victims know their attacker.

- 34.2%of at tackerswe ref amilym embers.
- 58.7%we reac quaintances.

Effects of Rape

Victimsof s exualas saultar e:

- 3 times more likely to suffer from depression.
- 6 times more likely to suffer from posttraumatic stress disorder.
- 13t imesm orelik elyt oabu sealc ohol.
- 26t imesm orelik elyt oabu sedr ugs.
- 4t imesm orelik elyt oc ontemplates uicide.

Adapted from Who Are the Victims of Rape, Abuse, and Incest National Network (RAINN), http://www.rainn.org.

Legal Aspects of Sexual Assault

Each state has different interpretations of sexual assault. The term generally refers to any genital, anal, oral, or manual penetration of the victim's body by way of force and without the victim's consent. Lack of consent includes the inability to give consent. This inability may be a result of impaired mental function caused by alcohol and other drugs (Rohypnol, gamma-hydroxybutyrate [GHB], ketamine), sleep, or unconsciousness. If a victim reports a sexual assault, the paramedic should accept the victim's story as accurate. The victim should be encouraged to seek medical care. Ideally the patient should be transported to a hospital with specialized personnel (sexual assault nurse examiner [SANE]) so that evidence of the assault can be collected. In addition, the patient should be accompanied by a local support advocacy group representative, if available.

In many cases, sexual assault is a felony crime that must be proved by evidence. Legal considerations for providing care to a patient who has been sexually assaulted include the following:

1. Take steps to preserve evidence.
2. Discourage the patient from urinating or defecating, douching, or bathing.
3. Do not remove evidence from any part of the body that was subjected to sexual contact unless necessary to provide urgent medical care.
4. Notify law enforcement personnel as soon as possible, if the victim consents.
5. Be aware that there will be a "chain of evidence" with specific requirements of proof.
6. Follow local and state requirements in reporting these cases. Consult with medical direction and follow established protocols.

NOTE

In most states, it is the prerogative of the patient whether to report a sexual assault (unless a firearm is involved). If the victim does not want police involved and the paramedic summons law enforcement, the patient's HIPAA rights may be violated (see Chapter 6).

Characteristics of Sexual Assault

Anyone can be a victim of sexual assault at any age. The victim often knows the assailant. Sometimes the victim feels shame and personal responsibility for the attack. The methods that the assailant uses to gain control over male and female victims include entrapment, intimidation, and physical force. The assailant commonly uses threats of harm and a weapon to gain submission. Male victims are more likely to suffer significant physical trauma from sexual assault by other men than are female victims (Box 50-8). The following are common injuries that result from sexual assault:

- Abrasions and bruises on the upper limbs, head, and neck
- Forcible signs of restraint (e.g., rope burns and mouth injuries)
- Petechiae of the face and conjunctiva caused by choking
- Human bites
- Broken teeth, swollen jaw or cheekbone, and eye injuries from being punched or slapped in the face
- Anogenital trauma (bruises, abrasions, lacerations)
- Muscle soreness or stiffness in the shoulder, neck, knee, hip, or back from restraint in postures that allow sexual penetration

BOX 50-8 Five Myths and Misconceptions About Sexual Assault

Myth: All victims of sexual assault are women, and all perpetrators are men.
Fact: Most sexual assaults are perpetrated by men. However, men can be assaulted by other men. Sometimes women perpetrate sexual assaults against men and other women.
Myth: Rape is an impulsive act.
Fact: About 58% to 71% of rapes clearly are planned.
Myth: Rape is motivated by sexual desire.
Fact: Rape is a crime of violence, motivated by anger and the desire for power and control.
Myth: Most women are raped by strangers.
Fact: Most women are victims of "acquaintance rape" by a known, trusted assailant.
Myth: According to the law, a husband cannot be charged with rape against his wife.
Fact: The law stipulates circumstances in which the husband can be charged with rape against his wife.

CRITICAL THINKING

How do you feel when you hear others say, "That rape victim brought it on herself"?

Psychosocial Aspects of Care

The trauma of sexual assault creates physical and psychological distress. Victims may behave in various ways. Some may be surprisingly calm and seem in control of their emotions. In contrast, others may be agitated, apprehensive, distraught, or tearful. After managing all threats to life, the paramedic should proceed with care by providing emotional support to the victim. As described in Chapter 31 , the paramedic should not question victims of sexual assault in detail about the incident in the prehospital setting. The paramedic should limit the patient history to only what is required to provide care. The initial contact with the victim should include the following:

- Nonjudgmental and supportive attitude
- Empathetic and sensitive comments
- Quiet speech
- Slow movements

- Considerate gestures (ensure privacy and respect modesty)
- Avoid "why" questions, such as "Why were you alone in that part of town?"

The paramedic should move the patient to a safe and quiet environment. This will help to avoid further exposure and embarrassment. When possible, a paramedic of the same gender should provide care. If this is not possible, a chaperone should be present. The patient should not be left unattended. The paramedic should ask for permission to call a friend, family member, or sexual assault crisis advocate. Concerns of the victim about pregnancy and contracting human immunodeficiency virus and other sexually transmitted diseases should be relayed to medical direction. After the patient recovers from physical injury, the goal of treatment is for the patient to regain control of his or her life. Often this takes long-term counseling and support.

Child Victims

Children are particularly vulnerable to sexual assault and usually have frequent contact with the assailant. Often the assault occurs in a trusted person's home. Most sexual assaults involve a male assailant and female victim. About 30% of acquaintance sexual assaults occur when the victim is between 11 and 17 years of age. Many young victims do not think of their experience as a sexual assault because they often are fondled or physically explored without intercourse. As a result, they rarely report the attack and often assume that they are to blame. (Many times, children will conceal sexual assault out of fear of punishment.) Victims involved in a same-sex assault also are unlikely to report the incident because of confusion or embarrassment. For these reasons, most victimized children do not receive proper treatment, including prophylaxis and counseling.

ASSESSMENT AND PATIENT CARE CONSIDERATIONS

Assessment for children of sexual assault should proceed as described before for other victims. The assessment should include age-related considerations that are appropriate for all children. The paramedic should be aware of the following symptoms when caring for any child. These symptoms may indicate behavior or physical manifestations as a result of sexual assault:

- Abrupt behavior changes
- Sleep difficulties, sleep disorders, and nightmares
- Withdrawal from and avoidance of friends and family
- Low self-esteem or desire to be invisible
- Phobias related to the offender
- Hostility
- Self-destructive behaviors
- Mood swings, depression, and anxiety
- Regression (e.g., bed-wetting)
- Truancy
- Eating disorders
- Alcohol or other drug use

The attitude and behavior of adults, including health care providers, greatly influence a child's impression of the assault. The paramedic should try to lessen the emotional influence of the assault by reassuring the child that he or she is not responsible for the attack. The child should also be assured that he or she did nothing wrong. The paramedic should encourage the child to talk openly about the assault and any concerns that he or she may have.

LEGAL CONSIDERATIONS

If sexual assault is suspected or confirmed, the paramedic must follow laws that apply to the crime. Local and state laws affect the confidentiality of children. Paramedics should be aware of the regulations in their community and consult with medical direction.

SUMMARY

- Battering is the establishment of control and fear in a relationship through violence and other forms of abuse.
- Domestic violence follows a cycle of three phases. Phase one involves arguing and verbal abuse. Phase two progresses to physical and sexual abuse. Phase three consists of denial and apologies. Certain personality traits may predispose a person to abusive relationships.
- The paramedic may have a hard time identifying the battered patient. Injuries from domestic violence often involve contusions and lacerations of the face, neck, head, breast, and abdomen.
- The paramedic must ensure scene and personal safety in domestic violence events. The paramedic should manage physical injuries according to standard protocols. The paramedic should direct special attention toward the emotional needs of the victim as well. Assault is a crime. The perpetrator is often released soon after arrest. This is a dangerous time for the victim.
- Elder abuse is classified into four categories: physical abuse, psychological abuse, financial or material abuse, and neglect.
- All 50 states have elder abuse statutes. Reporting of suspected elder abuse also is mandatory under law in most states.
- Most child abusers are the child's parents (77%). Eleven percent are other relatives of the victim. Abused children often exhibit behavior that provides key clues about abuse and neglect. The paramedic should observe carefully the child under 6 years of age who is passive or the child over 6 years of age who is aggressive.

Continued

- If the child volunteers the history of the event without hesitation and matches the history that the parent provides (and the history is suitable for the injury), child abuse is unlikely.
- Injuries may include soft tissue injuries, fractures, head injuries, and abdominal injuries.
- Sexual assault generally refers to any genital, anal, oral, or manual penetration of the victim's body by way of force and without the victim's consent.
- After managing all threats to life, the paramedic should provide emotional support to the victim. The paramedic should deliver care in a way that preserves evidence.

CHAPTER

51 Patients with Special Challenges

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Identify considerations in prehospital management related to physical challenges such as hearing, visual, and speech impairments; obesity; and patients with paraplegia or quadriplegia.
2. Identify considerations in prehospital management of patients who have mental illness, are developmentally disabled, or are emotionally or mentally impaired.
3. Describe special considerations for prehospital management of patients with selected pathological challenges.
4. Outline considerations in management of culturally diverse patients.
5. Describe special considerations in the prehospital management of terminally ill patients.
6. Identify special considerations in management of patients with communicable diseases.
7. Describe special considerations in the prehospital management of patients with financial challenges.

KEY TERMS

amblyopia The loss of one eye's ability to see details; the most common cause of eye vision problems in children; also known as "lazy eye."

astigmatism A vision condition that causes blurred vision attributable either to the irregular shape of the cornea (the clear front cover of the eye) or sometimes to the curvature of the lens inside the eye.

ataxia Failure of muscle coordination; a type of cerebral palsy.

athetosis A neuromuscular condition characterized by slow, continuous, and involuntary movement of the extremities; a type of cerebral palsy.

bariatrics The field of medicine that focuses on the treatment and control of obesity and diseases associated with obesity.

cataract A cloudy or opaque area in the normally clear lens of the eye; most common in people over age 55.

cerebral palsy A general term for nonprogressive disorders of movement and posture.

conductive deafness Refers to the faulty transportation of sound from the outer to the inner ear. This type of deafness often is curable.

cortical vision impairment A temporary or permanent visual impairment caused by the disturbance of the posterior visual pathways and/or the occipital lobes of the brain; the most common cause of permanent visual impairment in children.

cystic fibrosis An inherited metabolic disease of the lungs and digestive system that manifests in childhood; also known as *mucoviscidosis*.

deafness A complete or partial inability to hear.

diversity Differences of any kind: race, class, religion, gender, sexual preference, personal habitat, and physical ability.

Down syndrome A congenital condition characterized by varying degrees of mental retardation and multiple defects; also known as *trisomy 21*.

emotional/mental impairment Impaired intellectual functioning that results in an inability to cope with normal responsibilities of life.

glaucoma An eye disease in which the internal pressure in the eyes increases enough to damage the nerve fibers in the optic nerve, causing vision loss.

hyperopia A vision condition in which distant objects are seen clearly but close ones do not come into proper focus; also known as "farsightedness."

mental illness Any form of psychiatric disorder.

mental retardation A disorder characterized by below-average intellectual function with deficits or impairments in the ability to learn and adapt socially.

multiple sclerosis A progressive disease of the central nervous system in which scattered patches of myelin in the brain and spinal cord are destroyed.

muscular dystrophy An inherited muscle disorder of unknown cause marked by a slow but progressive degeneration of muscle fibers.

myasthenia gravis An autoimmune disorder in which muscles become weak and tire easily.

myopia A vision condition in which near objects are seen clearly, but distant objects do not come into proper focus; also known as "nearsightedness."

obesity A condition in which a person is 30% above ideal body weight.

optic nerve atrophy A permanent visual impairment caused by damage to the optic nerve.

optic nerve hypoplasia A congenital condition in which the optic nerve has not developed properly; it is too small.

paraplegia A weakness or paralysis of both legs and sometimes part of the trunk.

quadriplegia A weakness or paralysis of all four extremities and the trunk.

retinopathy A general term that refers to some form of noninflammatory damage to the retina of the eye; one of many retinal diseases.

sensorineural deafness A type of deafness in which sounds that reach the inner ear fail to be transmitted to the brain because of damage to the structures within the ear or to the acoustic nerve; often incurable.

spastic paralysis A type of cerebral palsy that produces abnormal stiffness and contraction of groups of muscles.

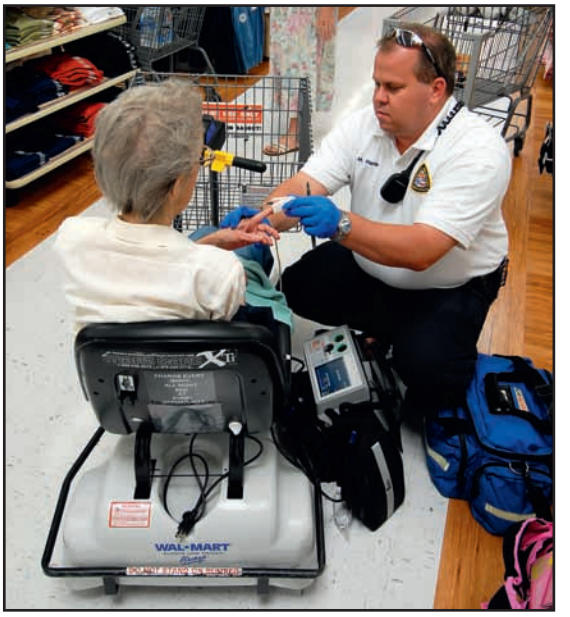
spina bifida A congenital defect in which part of one or more vertebrae fail to develop completely, leaving a portion of the spinal cord exposed.

strabismus A condition that occurs when one or both eyes turn in, out, up, or down; usually caused by poor eye muscle control; also known as "crossed eye."

terminally ill patients Patients with advanced stage of disease with an unfavorable prognosis and no known cure.

trisomy 21 A genetic failure where there is a triplet of chromosomes 21 rather than the usual pair; the cause of Down syndrome.

Paramedics often provide care to patients with special challenges. The patient groups to be discussed in this chapter include those who have physical, emotional, or pathological challenges; patients who are culturally diverse, have terminal illness, and communicable diseases; and those with financial challenges that may hinder access to health care.



(Courtesy Ray Kemp. St. Charles, Mo.)

PHYSICAL CHALLENGES

Patients who are physically challenged may require special considerations in patient assessment and management. The physical challenges presented in this chapter include hearing, visual, and speech impairments; obesity; and patients with paraplegia or quadriplegia.

Hearing Impairments

Deafness is a complete or partial inability to hear. Total deafness is rare and usually congenital. Partial deafness may range from mild to severe. It most commonly results from an ear disease, injury, or degeneration of the hearing mechanism that occurs with age. All deafness is conductive or sensorineural and may be a combination of both (*mixed hearing loss*).

Conductive deafness refers to the faulty transportation of sound from the outer to the inner ear. This type of deafness often is curable. In adults, conductive deafness commonly results from the buildup of earwax that blocks the outer ear canal. Conductive deafness also may result from infection (e.g., otitis media) and from injury to the eardrum or middle ear (e.g., from barotrauma).

Sensorineural deafness often is incurable. In this type of deafness, sounds that reach the inner ear fail to be transmitted to the brain. This is because of damage to the structures within the inner ear or to the acoustic nerve, which connects the inner ear to the brain. Sensorineural deafness that is present in early life may be congenital. It also can result from a birth injury or from damage to the developing fetus (e.g., from premature birth or a mother who has syphilis during pregnancy). Sensorineural deafness that occurs in later life may be caused by prolonged exposure to loud noise, disease (e.g., Meniere's disease), tumors, medications, viral infections, or natural degeneration of the cochlea or labyrinth in old age.

NOTE

Auditory neuropathy/auditory dyssynchrony (AN/AD) describes a diagnosis that affects a small group of patients with hearing loss and speech difficulties that are out of proportion with their hearing loss. The exact cause(s) of the disease is (are) unknown. Theories include axonal damage to the auditory nerve, abnormalities within the auditory brainstem, viral disease, seizure disorders, high fever, and others.[1] AN/AD is most common in children, but is also diagnosed in adults. In children, AN/AD may lead to developmental speech and language delays (*auditory processing deficit*) that can affect all levels of learning.

Special Considerations

The paramedic can use several helpful techniques for recognizing a patient who has a hearing impairment. One of these is noting the presence of hearing aids. Another is observing the patient for poor diction or the inability to respond to verbal communication in the absence of direct eye contact. Some accommodations may be needed. One includes retrieving the patient's hearing aid or other amplified listening device. Another is providing paper and pen to aid in communication.

When providing care to these patients, the paramedic should not shout or exaggerate lip movement. Rather, the paramedic should speak softly and directly into the patient's ear canal, using a low-pitched voice. (About 80% of hearing loss is related to the inability to hear high-pitched sounds.) Another method to aid in communication includes asking family members to assist. The paramedic also can use pictures to illustrate basic needs and routine medical procedures. Other communication assistance devices include American Sign Language, pictographs (laminated cards that show drawings of common activities), speech amplifiers, and wireless text communications.

Finally, the paramedic must notify the hospital as soon as possible if the patient has severe deafness. Some patients with severe hearing impairments will speak with unusual syntax. Some may use American Sign Language. Personnel with special training (e.g., an interpreter) may need to be summoned to assist with patient care.

Visual Impairments

Estimates indicate that more than 1 million Americans are blind and that 3 million are visually impaired, even with the best correction.[2] Normal vision depends on the uninterrupted passage of light from the front of the eye to the light-sensitive retina at the back. Any condition that obstructs the passage of light from the retina can cause vision loss. Vision impairment may be present at birth from a congenital disorder. It also may result from a number of other causes. These causes include the following:

- Cataracts
- Degeneration of the eyeball, optic nerve, or nerve pathways
- Diseases such as diabetes and hypertension
- Eye or brain injury (e.g., trauma, chemical burns, and stroke)
- Infections such as those that are caused by cytomegalovirus, herpes simplex virus, and bacterial ulcers
- Vitamin A deficiency in children living in developing countries

Patients with visual impairments may be totally blind or have a partial loss of vision that affects central vision, peripheral vision, or both (Box 51-1). A patient who has central loss of vision is usually aware of the condition. Those who have a loss of peripheral vision may be more difficult to identify. This is because the loss often remains unnoticed by the person until it is well advanced.

BOX 51-1 Types of Visual Impairments[3]

Amblyopia ("lazy eye"): The loss of one eye's ability to see details; the most common cause of eye vision problems in children.

Astigmatism: A vision condition that causes blurred vision attributable either to the irregular shape of the cornea (the clear front cover of the eye) or sometimes to the curvature of the lens inside the eye.

Cataract: A cloudy or opaque area in the normally clear lens of the eye; most common in people over age 55.

Cortical vision impairment: A temporary or permanent visual impairment caused by the disturbance of the posterior visual pathways and/or the occipital lobes of the brain; the most common cause of permanent visual impairment in children.

Glaucoma: An eye disease in which the internal pressure in the eyes increases enough to damage the nerve fibers in the optic nerve, causing vision loss.

Hyperopia (farsightedness): A vision condition in which distant objects are seen clearly but close ones do not come into proper focus.

Myopia (nearsightedness): A vision condition in which near objects are seen clearly but distant objects do not come into proper focus.

Optic nerve atrophy: A permanent visual impairment caused by damage to the optic nerve.

Optic nerve hypoplasia: A congenital condition in which the optic nerve has not developed properly; it is too small.

Retinopathy: A general term that refers to some form of noninflammatory damage to the retina of the eye; one of many retinal diseases.

Strabismus (crossed eye): A condition that occurs when one or both eyes turn in, out, up, or down; usually caused by poor eye muscle control.

SPECIAL CONSIDERATIONS

Techniques in assessing and managing patients with vision loss are described in Chapter 17. To review, accommodations that may be necessary for these patients include retrieving visual aids, describing all procedures before performing them, and providing sensory information (e.g., location of obstacles) as needed. The paramedic should guide ambulatory patients by "leading," not by "pushing." If possible and appropriate, a patient's guide dog should be permitted to accompany the patient to the hospital. The paramedic should advise medical direction of the patient's special needs. That way, the appropriate personnel can be made available.

LOOK AGAIN

See Chapter 17: Therapeutic Communications, pp. 486-488.

Speech Impairments

Speech impairments include disorders of language, articulation, voice production, or fluency (blockage of speech). All of these can lead to an inability to communicate well (Box 51-2).

Language disorders result from damage to the language centers of the brain. (They usually result from stroke, head injury, or brain tumor.) These patients often exhibit **aphasia** (loss of power of speech) with a slowness to understand speech and problems with vocabulary and sentence structure. Aphasia can affect children and adults. It may affect their ability to speak and to comprehend written or spoken words. Delayed development of language in a child may result from hearing loss, lack of stimulation, or emotional disturbance. It also may result from *pragmatic language impairment,* a developmental disorder related to autism and Asperger's syndrome (described in Chapter 35).

An articulation disorder is an inability to produce speech sounds. The disorder sometimes is referred to as *dysarthria* or *motor speech disorder.* These disorders result from damage to nerve pathways passing from the brain to the muscles of the larynx, mouth, or lips. Often the patient's speech will be slurred, indistinct, slow, or nasal. Disorders of articulation may result from brain injury. They also may result from diseases such as multiple sclerosis and Parkinson's disease. In children, articulation disorders commonly result from delayed development from hearing problems. *Phonological process disorder* is a type of articulation disorder in which there are difficulties with "rules of language," such as combinations of words and syllables. Examples include "top" for "stop," "daw" for "dog," and "tee" for "three."

BOX 51-2 Types of Speech Impairments

Language Disorders
Brain tumor
Delayed development
Emotional disturbance
Head injury
Hearing loss
Lack of stimulation
Stroke

Articulation Disorders
Damage to nerve pathways passing from the brain to muscles in the larynx, mouth, or lips
Delayed development from hearing problems
Slow maturation of nervous system

Voice Production Disorders
Disorders affecting closure of vocal cords
Hormonal or psychiatric disturbance
Severe hearing loss

Fluency Disorders
Stuttering (for example)
Patient is not fully understood

CRITICAL THINKING
What may cause a paramedic to become impatient when caring for a patient with this type of disorder?

Voice production disorders are characterized by hoarseness, harshness, inappropriate pitch, and abnormal nasal resonance. They often result from disorders that affect closure of the vocal cords. Some disorders are caused by hormonal or psychiatric disturbances and by severe hearing loss.

Fluency disorders are not well understood. They are marked by repetitions of single sounds or whole words and by the blocking of speech. An example of a fluency disorder is stuttering.

SPECIAL CONSIDERATIONS

Once speech impairment has been identified, history taking and assessment need to be modified. Methods include allowing extra time for the patient to respond to questions, clarifying what the patient says or asking the patient to repeat an answer if it was not clearly understood, and offering appropriate aids (e.g., pen and paper) to assist in communications. If the patient lip-reads, the paramedic should face the patient at eye level and speak slowly and clearly. (Gum chewing should be avoided.) The hospital also should be advised if a patient has a severe speech impairment, so that appropriate personnel (e.g., audiologist or speech specialist) can be made available.

Obesity

Obesity is defined as being 30% above ideal body weight. The disease affects nearly one third of the adult American population and is responsible for at least 300,000 deaths in the United States each year.[4] In addition, obesity in U.S. children and teens ranges from about 10% in infants and toddlers, to about 18% in adolescents and teenagers.[5] As discussed in Chapter 2, the body mass index (BMI) is used to define ideal body weight, overweight, and obesity ranges. An adult who has a BMI between 25 and 29.9 is considered overweight; a BMI of 30 or higher is considered obese.[6]

Obesity is an abnormal increase in the proportion of fat and cells. The increase is mainly in the viscera and the subcutaneous tissues of the body. Although reasons for obesity in some persons are unclear, known causes for the condition include the following:

- Caloric intake that exceeds calories expended
- Low basal metabolic rate
- Genetic disposition for obesity

The complications of obesity are many (Box 51-3). Obesity increases a person's chance of becoming seriously ill. For example, obesity is associated with an increased risk for hypertension, stroke, heart disease, diabetes, and some cancers. Osteoarthritis also is aggravated by increased body weight. The condition is treated with weight loss programs, exercise, counseling, medications, and sometimes surgery.

BOX 51-3 Medical Complications of Obesity[7]

- Blood lipid (fat) abnormalities
- Cancer, including cancer of the uterus, cervix, ovaries, breast, colon, rectum, and prostate
- Depression
- Gallbladder disease
- Gynecological problems, such as infertility and irregular periods
- Heart disease
- High blood pressure
- Metabolic syndrome
- Nonalcoholic fatty liver disease
- Osteoarthritis
- Skin problems, such as intertrigo and impaired wound healing
- Sleep apnea
- Stroke
- Type 2 diabetes

The goal of treatment is lasting weight loss. The field of medicine that focuses on the treatment and control of obesity and diseases associated with it is known as **bariatrics.**

CRITICAL THINKING

Consider this situation. A crew member makes an insensitive remark about a patient's obesity within hearing range of the patient or the patient's family. How will you respond?

SPECIAL CONSIDERATIONS

The paramedic needs to give special considerations to caring for an obese patient. These include the need to obtain a thorough history. The history often will be extensive because of associated health problems. The paramedic should be aware that symptoms the patient may credit to obesity (e.g., fatigue, shortness of breath at rest or on exertion) may be a sign of an acute illness. (For example, the illness may be congestive heart failure or myocardial infarction.)

The examination of an obese person also may require some modifications. These may include using large blood pressure cuffs, positioning the patient to better allow for hearing lung sounds, and placing electrocardiogram leads on areas of the body with less fat (e.g., the arms and thighs versus the chest wall). In addition, more personnel and special equipment may be needed to assist with moving the patient for transport (Figure 51-1). (For example, stretchers that can accommodate excessive weight and wide girth, ambulances equipped with a winch system, and ramps to load and offload the patient safely.) Obese patients often are self-conscious about their weight. They may worry about the hardships they place on the EMS crew and other rescuers. Paramedics must maintain professionalism during these patient care encounters.

FIGURE 51-1 Device to move bariatric patient.

NOTE

One should note that weight limits vary widely for helicopters. When requesting an emergency rotary aircraft flight, the paramedic should inform the dispatcher if the patient is obese. This will help to determine whether the patient can be transported safely by air.

Patients With Paraplegia/Quadriplegia

Paraplegia is weakness or paralysis of both legs and sometimes part of the trunk; **quadriplegia** is weakness or paralysis of all four extremities and the trunk. The conditions result from nerve damage in the brain and spinal cord. These conditions usually are caused by a crash, sports injury, fall, or gunshot wound. (Medical illnesses such as lupus, multiple sclerosis, and stroke also can result in weakness and paralysis.) Paraplegia and quadriplegia are accompanied by a loss of sensation and loss of urinary control. Priapism may be present in some male patients.

NOTE

When performing the physical assessment, the application of pressure that would be appreciated by patients with normal sensation may not be recognized in patients who have weakness or paralysis.

SPECIAL CONSIDERATIONS

Patients with extremity and trunk paralysis may require accommodations in patient care. For example, the patient may have a halo traction device to stabilize the spine (Figure 51-2). Or the patient may rely on a home ventilator to assist with breathing. Both of these situations can complicate airway management. They also can make patient transport more difficult. Some patients who are paralyzed will have special equipment (e.g., walkers or wheelchairs); ostomies for the trachea, bladder, or colon; and medical devices that rely on electricity or a battery supply.

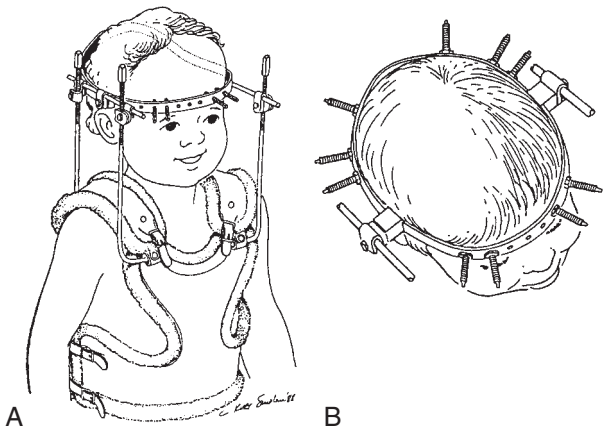


FIGURE 51-2 **A,** Custom halo vest and light superstructure. **B,** Ten pin placement sites for infant halo ring attachment using multiple-pin, low-torque technique. Usually, four pins are placed anteriorly, avoiding the temporal area, and the remaining six pins are placed in the occipital area.

(Technology-assisted devices will be presented in Chapter 52.) Additional personnel may be required to assist with moving special equipment and to prepare the patient for ambulance transport.

MENTAL CHALLENGES

Persons who have developmental, emotional, behavioral, or psychological and psychiatric problems are considered mentally challenged. The specific patient groups presented in this section include those with mental illness, developmental disabilities, emotional impairments, and emotional/mental impairments.

Mental Illness

Mental illness refers to any form of psychiatric disorder. As described in Chapter 35, most forms of mental illness result from biological, psychosocial, or sociocultural causes. A person's mental illness may result from more than one of these factors. To review, examples of biological causes of mental illness are schizophrenia and depression that result from biochemical imbalance; and organic causes such as trauma, illness, and dementia. Psychosocial causes of mental illness can result from childhood trauma, child abuse or neglect, a dysfunctional family structure, or other issues that cause an inability to resolve situational conflicts in a person's life. Sociocultural causes of mental illness may be related to personal relationships, family stability, economic status, and other factors that result in situational stress.

SPECIAL CONSIDERATIONS

Recognizing a patient with mental illness may be difficult, especially if the patient has only mild symptoms of the disease. Other patients with more serious disorders may have signs and symptoms that are consistent with mental illness. (An example is paranoid behavior in patients with schizophrenia.) When obtaining the patient history, the paramedic should not hesitate to ask about the following:

- History of mental illness
- Prescribed medications
- Compliance with prescribed medications
- Use of over-the-counter herbal products (e.g., St. John's wort)
- Concomitant use of alcohol or other drugs

If the patient is anxious, the paramedic should ask the patient's permission before performing any assessment or any procedure. This will help to establish rapport and trust during the care. Unless the call is related specifically to the mental illness, care should proceed in the same manner as for any other patient. Patients with mental illness experience medical illness and injury like all other patient groups. If the patient acts aggressively or combatively, the paramedic should retreat from the scene and request law enforcement personnel to secure the scene.

Developmentally Disabled

A person who is developmentally disabled has impaired or insufficient development of the brain. This causes an inability to learn at the usual rate (*developmental delay*). Developmental delay has many causes, including the following:

- Lack of stimulation (as seen with child abuse or neglect)
- Severe vision or hearing impairment
- Mental retardation
- Brain damage before, during, or after birth
- Severe diseases of body organs and systems

Persons who are developmentally disabled often function well with daily activities, hold jobs, and live independently (or with their family or in residential group homes). However, some development delays may be severe and may affect any or all of the major areas of human achievement: walking upright; fine eye-hand coordination; listening, language, and speech; and social interaction.

The accommodations that may be needed when caring for these patients will vary depending on the severity of disability. The paramedic should allow extra time for obtaining a history and performing an examination. Additional time should also be allotted for preparing the patient for transport. When possible, a member of the patient's family or a caregiver should remain with the patient during the care.

CRITICAL THINKING

Do you think a patient with developmental delays should have any input into their care? Why?

Down Syndrome

Down syndrome results from an abnormal chromosome. This abnormality causes mild to severe mental retardation and a characteristic physical appearance (Figure 51-3). The child with Down syndrome has features that typically include the following:

- Eyes that slope upward at the outer corners
- Folds of skin on either side of the nose that cover the inner corners of the eyes
- A small face and small facial features
- A large and protruding tongue

FIGURE 51-3 Child with Down syndrome.

- Flattening on the back of the head
- Hands that are short and broad

In most cases, Down syndrome occurs from the failure of the two chromosomes numbered 21 in a parent cell to go into separate daughter cells during the first stage of sperm or egg cell formation. This results in a triplet of chromosomes 21 **(trisomy 21)** rather than the usual pair. The extra number 21 chromosome is passed on to the child and leads to Down syndrome. The incidence of affected fetuses increases with increased maternal age (mothers over age 35). It also increases in those with a family history of Down syndrome.

NOTE
In the general population, trisomy 21 occurs in only 1 of about 600 live births. After age 35, a mother's chances of having a Down syndrome child increase dramatically to as high as 1 in 100 by age 40.[8] Because of this increased risk, pregnant mothers over age 35 usually are tested to assess for the abnormality.

Patients with Down syndrome usually do not survive past middle age. Many are cared for at home, and others live in long-term nursing care facilities. About 25% of children born with Down syndrome have a heart defect at birth. Many have congenital intestinal disorders, hearing defects, and other illnesses. The degree of mental disability varies with an intelligence quotient (IQ) that ranges from 30 to 80. (An IQ of 80 to 120 is considered average.) Persons with Down syndrome are capable of limited learning and often are affectionate and friendly. Extra time must be allowed for obtaining a history and for performing assessment and patient care procedures.

Emotionally Impaired

Persons with emotional problems often suffer from anxiety disorders. These disorders were described in Chapter 35. They can result in a wide range of physical or mental symptoms attributed to mental stress.

LOOK AGAIN
See Chapter 35: Behavioral and Psychiatric Disorders, pp. 1036-1038.

SPECIAL CONSIDERATIONS

Distinguishing between symptoms produced by stress and those that indicate serious medical illness may be difficult. Thus management should always focus on the presenting complaint. The paramedic also should assume the most serious cause. As described in Chapter 35, signs and symptoms that may result from emotional impairment include somatic complaints such as chest discomfort, tachycardia, dyspnea, choking, and syncope. Hence the paramedic must gather a full history from the patient. A thorough examination also is essential to rule out serious illness. The prehospital care for these patients (in the absence of serious illness) mainly is supportive. It includes calming measures and transport for physician evaluation.

Emotionally/Mentally Impaired

Emotional/mental impairment (EMI) refers to persons who have impaired intellectual functioning **(mental retardation).** This impairment results in an inability to cope with the normal responsibilities of life. Mental retardation can be classified further with IQ assessment as mild (IQ 55 to 70), moderate (IQ 40 to 54), severe (IQ 25 to 39), and profound (IQ less than 25).[9] The more severe grades of emotional/mental impairment usually have a specific physical cause (e.g., brain damage or Down syndrome). In contrast, mild emotional/mental impairment often has no specific cause. However, poverty, malnutrition, and heredity may play a role (Box 51-4). Mild mental retardation is the most common form of emotional/mental impairment. It accounts for about 85% of the retarded population.

SPECIAL CONSIDERATIONS

Changes to normal patient care vary based on the patient's level of retardation. Many with mild retardation show no symptoms other than slowness in carrying out mental tasks. Others with moderate to severe retardation may have limited to absent speech. Neurological problems are common. These patients may require extra time and care in patient assessment, management, and transportation.

PATHOLOGICAL CHALLENGES

Certain pathological conditions may require special assessment and management skills. Specific pathological conditions presented in this section include arthritis, cancer, cerebral palsy, cystic fibrosis, multiple sclerosis, muscular dystrophy, poliomyelitis, previous head injury, spina bifida, and myasthenia gravis. These conditions have been presented elsewhere in this text by subject matter. The following discussion will provide a brief review.

BOX 51-4 Causes of Mental Retardation

Genetic Conditions
Phenylketonuria (a single-gene disorder causing an enzyme deficiency)
Chromosomal disorder (e.g., Down syndrome)
Fragile X syndrome (a single-gene disorder on the Y chromosome; the leading inherited cause of mental retardation)

Problems During Pregnancy
Use of alcohol or other drugs by the mother
Use of tobacco
Illness and infection (toxoplasmosis, cytomegalovirus, rubella, syphilis, human immunodeficiency virus)

Problems at Birth
Brain injury
Prematurity
Low birth weight

Problems After Birth
Childhood diseases (whooping cough, chickenpox, measles, Hib disease)
Injury (e.g., head injury or near drowning)
Exposure to lead, mercury, and other environmental toxins

Poverty and Cultural
Deprivation
Malnutrition
Disease-producing conditions
Inadequate medical care
Environmental health hazards
Lack of stimulation

From Arc National Headquarters: *Introduction to mental retardation,* Arlington, Tex, 2004, The Association.

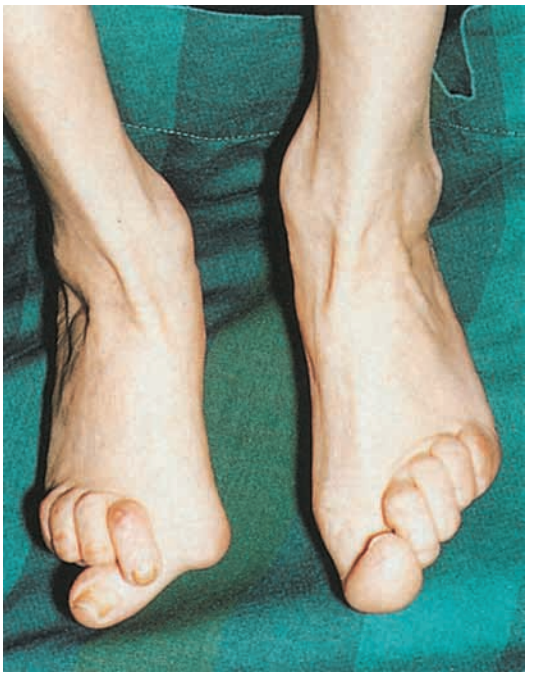

FIGURE 51-4 Rheumatoid arthritis of the feet.

Arthritis

As described in Chapter 26 and Chapter 49, arthritis is the inflammation of a joint, characterized by pain, stiffness, swelling, and redness. The disease has many forms and varies widely in its effects. Two forms of arthritis are common. One is osteoarthritis that results from cartilage loss and wear and tear of the joints (common in elderly patients). The other is rheumatoid arthritis (an autoimmune disorder that damages joints and surrounding tissues) (Figure 51-4).

SPECIAL CONSIDERATIONS

Patients with arthritis often have decreased range of motion and mobility. This may limit the physical exam. (It is important to ensure patient comfort whenever possible.) The paramedic also should determine current medication use (e.g., analgesics) before administering drugs to these patients. Transport strategies must take into account the patient's limited mobility. The paramedic also must adjust the equipment (e.g., backboards and splints) to fit the patient (not vice versa). This can be achieved by supplying adequate padding to fill all voids.

Cancer

Cancer is a group of diseases that allow for an unrestrained growth of cells in one or more of the body organs or tissues (see Chapter 32). The malignant tumors most often develop in major organs. These include the lungs, breasts, intestine, skin, stomach, and pancreas. However, they also may occur in cell-forming tissues of the bone marrow and in the lymphatic system, muscle, or bone.

SPECIAL CONSIDERATIONS

Patients with cancer often are very ill. The signs and symptoms of their disease depend on the site of origin of the cancer (Box 51-5). Often no signs of the disease are visible. However, medical treatment (e.g., chemotherapy or radiation) for many of the cancers can produce obvious signs and symptoms and various illnesses that may initiate an EMS response. (Patients with cancer are also at increased risk for pulmonary embolism.) Signs and symptoms associated with chemotherapy and radiation include the following:

- Anorexia
- Depression
- Fatigue
- Gastrointestinal upset
- General malaise
- Loss of appetite
- Loss of hair (alopecia)
- Pain

BOX 51-5 Common Examples of Site of Origin Classifications for Cancer

Adenocarcinoma: Originates in glandular tissue
Blastoma: Originates in embryonic tissue of organs
Carcinoma: Originates in epithelial tissue (i.e., tissue that lines organs and tubes)
Leukemia: Originates in tissues that form blood cells
Lymphoma: Originates in lymphatic tissue
Myeloma: Originates in bone marrow
Sarcoma: Originates in connective or supportive tissue (e.g., bone, cartilage, muscle)

Requests for emergency services for patients with advanced cancer often are related to the patient's pain medication. An example is patients whose pain is no longer relieved by the medicine. Another example is patients who have taken an accidental overdose of pain medicine. This may result in an altered level of consciousness or respiratory depression. If the patient's pain is not being managed, the paramedic should consult with medical direction. (Larger than normal doses may need to be given to provide pain relief.) If an overdose is suspected, the paramedic should initiate the standard care for narcotic overdose.

A full patient history should be obtained, including a list of all medications. Many cancer patients take anticancer drugs and pain medications through transdermal skin patches that contain analgesic agents and through surgically implanted devices (e.g., MediPorts). If intravenous therapy is necessary, additional time should be allotted to access the patient's peripheral veins or medication port. (Strict aseptic technique is especially important in these patients. They often are immunocompromised as a result of the treatment for their disease.) As described in Chapter 14, paramedics should consult with medical direction and follow protocols before using a surgically implanted port for fluid or drug therapy. Special techniques are required to access these devices.

The course of the disease and the medical regimen of care for cancer patients can be devastating for the patient, family, and loved ones. The paramedic must provide emotional support for all involved. Also essential is to ensure the patient's comfort. Finally, patients should be transported to the hospital where they are being treated for their cancer, when possible.

Cerebral Palsy

Cerebral palsy (CP) is a general term for nonprogressive disorders of movement and posture. The disease results from damage to the fetal brain during later months of pregnancy, during birth, during the newborn period, or in early childhood (Box 51-6). The most common cause of cerebral palsy is cerebral dysgenesis (abnormal cerebral development) or cerebral malformations.[10] Other less common causes include fetal hypoxia, birth trauma, maternal infection, kernicterus (excessive fetal bilirubin, associated with hemolytic disease), and postpartum encephalitis, meningitis, or head injury. Cerebral palsy often is diagnosed during the child's first year of life when parents notice unusual muscle tone during holding. Sometimes they notice feeding difficulties. No cure exists for the disease. But those persons with moderate disability may live with relative independence and have a near-normal life expectancy.

BOX 51-6 Causes of Cerebral Palsy

Disorders During Pregnancy That May Cause Cerebral Palsy[11]

1. Multiple births (e.g., twins, triplets)
2. A damaged placenta that may interfere with fetal growth
3. Sexually transmitted infectious diseases (e.g., AIDS, herpes, syphilis, gonorrhea)
4. Poor nutrition
5. Exposure to toxic substances, including nicotine, alcohol, and drugs
6. Rh or ABO blood type incompatibility between mother and infant
7. Chromosome abnormalities
8. Biochemical genetic disorders
9. Chance malformations of the baby's brain
10. A labor that is too long or too abrupt; poor oxygen supply may destroy brain tissue
11. German measles during pregnancy
12. Small pelvic structure
13. Premature delivery
14. Cesarean or breech delivery
15. Effects of anesthetics, analgesics

Disorders During Early Childhood That May Cause Cerebral Palsy as a Result of Brain Injury

1. Infections such as meningitis
2. Brain hemorrhages
3. Head injury following falls, car accidents, or abuse
4. Drowning accidents
5. Poisoning

TYPES OF CEREBRAL PALSY

Three distinct types of cerebral palsy exist. They are spastic paralysis, athetosis, and ataxia. **Spastic paralysis** produces abnormal stiffness and contraction of groups of muscles. With this type of cerebral palsy, the child may be categorized as *diplegic, hemiplegic,* or *quadriplegic*. With diplegic, all four limbs are affected. The legs are affected more severely than the arms. With hemiplegic, the limbs on only one side of the body are affected. The arm is usually more severe than the leg. With quadriplegic, all four limbs are severely affected, not necessarily symmetrically.

Athetosis produces involuntary writhing movements and a loss of coordination and balance. Hearing defects, epilepsy, and other central nervous system disorders are often present with the disease. Although some with athetosis and diplegia are highly intelligent, 30% to 50% of all

persons with cerebral palsy have mental retardation.[12] Most persons with quadriplegia are severely retarded.

Ataxia is the least common form of cerebral palsy. People with ataxic CP have a disturbed sense of balance and depth perception. They usually have poor muscle tone (hypotonic), a staggering walk, and unsteady hands. Ataxia results from damage to the cerebellum, the brain's major center for balance and coordination.

CRITICAL THINKING

How can you determine the patient's normal level of functioning?

SPECIAL CONSIDERATIONS

Weakness, paralysis, and developmental delay vary by the type and severity of disease. For example, some children with mild cerebral palsy attend regular schools. Others with more severe forms of the disease never learn to walk or communicate well. They may require lifelong skilled nursing care. Accommodations that may be needed while providing care include allowing extra scene time for the physical examination and extra resources and personnel to aid transport.

Cystic Fibrosis

Cystic fibrosis (CF) (*mucoviscidosis*) is an inherited metabolic disease of the lungs and digestive system that manifests in childhood. The disease is caused by a defective, recessive gene that is inherited from each parent. The defective gene causes the glands in the lining of the bronchi to produce excessive amounts of thick mucus. This predisposes the person to chronic lung infections. In addition, the pancreas of a patient with cystic fibrosis fails to produce the enzymes required for the breakdown of fats and their absorption from the intestine. These alterations in metabolism cause classic symptoms of cystic fibrosis that include pale, greasy-looking, foul-smelling stools (often noticeable soon after birth); persistent cough and breathlessness; and lung infections that often develop into pneumonia, bronchiectasis, and bronchitis. Other features of the disease include stunted growth and sweat glands that produce abnormally salty sweat. In some cases the child with cystic fibrosis may fail to thrive; many patients survive into adulthood, although poor health is common.

NOTE

If only one defective gene is inherited, that person will be a carrier of the disease. However, the person will have no symptoms. Often, these persons are unaware that they carry the defective gene. Genetic counseling and testing are appropriate for persons who have a family history of cystic fibrosis.

SPECIAL CONSIDERATIONS

Older patients (and parents of children) with cystic fibrosis generally are aware of their disease. Some may be oxygen dependent. They may need respiratory support and suctioning to clear the airway of mucus and secretions. Many will use inhalants. The paramedic should expect a lengthy history and physical exam because of the nature of the disease and associated medical problems. Some patients will have received heart and lung transplants. They may require transfer to specialized medical facilities for treatment. If parents are unaware of the possibility of cystic fibrosis in the presence of signs and symptoms described previously, the paramedic should advise the physician at the hospital of his or her suspicions.

Multiple Sclerosis

Multiple sclerosis is a progressive and incurable autoimmune disease of the central nervous system that destroys patches of myelin in the brain and spinal cord. Scarring and destruction of the tissues cause symptoms that range from numbness and tingling to paralysis and incontinence. The cause of multiple sclerosis is unknown; however, it may have a heritable or viral component. (Many persons with multiple sclerosis lead active, normal lives between exacerbations of their illness.) The disease usually begins early in adult life, becomes active for a brief time, and then resumes years later. As described in Chapter 25, the symptoms of multiple sclerosis vary with the affected areas of the central nervous system. The symptoms may include the following:

Brain Involvement

- Ataxia
- Blurred or double vision
- Clumsiness
- Fatigue
- Muscle weakness
- Numbness, weakness, or pain in the face
- Slurred speech
- Vertigo

Spinal Cord Involvement

- Extremities that feel heavy and become weak
- Spasticity
- Tingling, numbness, or feeling of constriction in any part of the body

The symptoms of multiple sclerosis may occur singly or in combination. They may last from several weeks to several months. Attacks vary in intensity and may be precipitated by injury, infection, or physical or emotional stress. Some patients become disabled, bedridden, and incontinent early in middle life. Disabled patients also often suffer from painful muscle spasms, constipation, urinary tract infections, skin ulcerations, and mood swings. The disease is managed with medications, physical therapy, and counseling.

SPECIAL CONSIDERATIONS

Some patients with multiple sclerosis may be difficult to examine. They may be unable to provide a complete medical history because of the nature of their illness. The paramedic should allow extra time for patient assessment and to prepare the patient for transport. (The patient should not

be expected to ambulate.) In severe cases, respiratory support may be indicated.

Muscular Dystrophy

Muscular dystrophy (described in Chapter 25) is an inherited muscle disorder that results in a slow but progressive degeneration of muscle fibers. The disease is classified according to the age that symptoms first appear, the rate at which the disease progresses, and the way in which the disease is inherited. Muscular dystrophy is incurable. Genetic counseling and testing is appropriate for persons with a family history of muscular dystrophy.

The most common form of the disease is *Duchenne's muscular dystrophy,* caused by a sex-linked recessive gene that affects only males. Duchenne's muscular dystrophy rarely is diagnosed before age 3. Signs and symptoms of the disease include a child who is slow in learning to sit up and walk; an unusual gait; curvature of the spine; and muscles that become bulky as they are replaced by fat. Eventually, most children will be unable to walk. Many do not live past their teenage years as a result of chronic lung infections and congestive heart failure. With other less common forms of muscular dystrophy, patients may live well into their middle years with varying degrees of muscle weakness.

SPECIAL CONSIDERATIONS

Accommodations that may be required during emergency care depend on the person's age, weight, and severity of disease. For example, young children may be fairly easy to examine and prepare for transport. When caring for older patients, extra personnel may be needed to move the patient to the ambulance. In severe cases the patient may need respiratory support.

Poliomyelitis

Poliomyelitis (polio) is an infectious disease caused by *Poliovirus hominis.* The virus is spread through direct and indirect contact with infected feces and by airborne transmission. Poliovirus attacks with variable severity. The severity can range from asymptomatic infection to a febrile illness without neurological complications to aseptic meningitis and finally to paralytic disease (including respiratory paralysis) and possible death.

As described in Chapter 25, the incidence of polio cases has declined since the Salk and Sabin vaccines were made available in the 1950s. The disease, however, may affect nonimmune adults and indigent children. Signs and symptoms of polio in the nonparalytic and paralytic forms include fever, malaise, headache, and intestinal upset. In the majority of cases, persons with the nonparalytic form of polio recover fully. In the paralytic form, extensive paralysis of muscles of the legs and lower trunk can occur.

SPECIAL CONSIDERATIONS

Caring for a patient with paralytic polio who has respiratory paralysis may necessitate advanced airway support to ensure adequate ventilation. (Patients on home ventilators typically have a tracheostomy.) If the lower body is paralyzed, catheterization of the bladder may be needed (see Appendix, Advanced Practice Procedures in Critical Care). Extra resources and personnel may be needed to prepare the patient for transport.

Previously Head-Injured Patients

Traumatic brain injury can result from many types of trauma (see Chapter 40). These injuries can affect many cognitive, physical, and psychological skills. Physical deficit can include ambulation, balance and coordination, fine motor skills, strength, and endurance. Cognitive deficits of language and communication, information processing, memory, and perceptual skills are common. Psychological status also often is altered (Table 51-1).

TABLE 51-1 Brain Injury Deficits

Injury	Injury Deficits
Cerebral Cortex	
Frontal lobe	Paralysis of various body parts
	Inability to plan a sequence of complex movements
	Inability to focus on tasks
	Mood changes
	Personality changes
	Inability to express language
Parietal lobe	Inability to name an object
	Problems with reading and writing
	Difficulty in distinguishing right from left
	Difficulty with math skills
	Difficulty with eye and hand coordination
Occipital lobe	Defects in vision
	Production of hallucinations
	Visual illusions
	Inability to recognize words
	Difficulties in reading and writing
Temporal lobe	Difficulty in recognizing faces
	Difficulty in understanding spoken words
	Short-term memory loss
	Interference with long-term memory
	Persistent talking
	Aggressive behavior
Brainstem	Decreased vital capacity in breathing
	Difficulty in swallowing food and water
	Difficulty with organization
	Problems with balance and movement
	Dizziness and nausea
	Sleeping difficulties
Cerebellum	Loss of ability to coordinate fine movements
	Loss of ability to walk
	Tremors
	Dizziness
	Slurred speech

SPECIAL CONSIDERATIONS

Depending on the patient's area of brain injury, obtaining a history and performing assessment and care may be difficult. Some patients may need restraint. Family and other caregivers should be involved in managing the patient (when appropriate). The paramedic also should interview them to determine whether the patient's actions and responses are "normal" or "baseline" for the patient. Additional time should be allotted at the scene to provide care to these patients.

CRITICAL THINKING
Why is this group of patients at high risk for injury?

Spina Bifida

Spina bifida (see Chapter 25) is a congenital defect. With this condition, part of one or more vertebrae fails to develop. This leaves a portion of the spinal cord exposed. The condition ranges in severity from that of minimal evidence of a defect to a child who is severely disabled. In severe cases the legs of some children may be deformed with partial or full paralysis and loss of sensation in all areas below the level of the defect. Associated abnormalities may include hydrocephalus with or without brain damage (Figure 51-5), cerebral palsy, epilepsy, and mental retardation.

SPECIAL CONSIDERATIONS

Because of the varying degrees of spina bifida, care must be tailored to the patient's specific needs. Some patients require no special accommodations. Others need extra on-scene time for assessment and management. Additional resources and personnel to prepare the patient for transport may be needed as well.

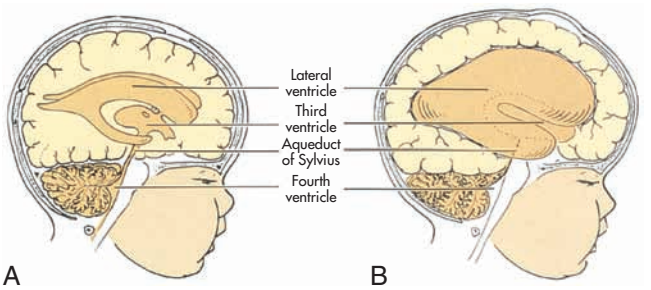

FIGURE 51-5 Hydrocephalus: a block in flow of cerebrospinal fluid. **A,** Patent cerebrospinal fluid circulation. **B,** Enlarged lateral and third ventricles caused by obstruction of circulation—stenosis of aqueduct of Sylvius.

NOTE
Between 18% and 73% of children and adolescents with spina bifida are estimated to be sensitive to latex.[13] Thus all patients with spina bifida should be considered at high risk for having an allergic reaction to rubber. These persons should avoid contact with rubber products, especially during medical procedures. The paramedic should use only nonlatex gloves. Alternative products can be substituted safely. These other products usually are made of silicone, plastic, or vinyl. Other common medical equipment that may contain latex includes:

- Oral and nasal airways
- Endotracheal tubes
- IV tubing
- Surgical masks
- Rubber aprons
- Catheters
- Injection ports
- Needle sheaths on medicines
- Wound drains
- Blood pressure cuffs
- Syringes
- Stethoscopes
- Tourniquets
- Electrode pads

Myasthenia Gravis

Myasthenia gravis is an autoimmune disorder in which muscles become weak and tire easily. The damage occurs to muscle receptors that are responsible for transmitting nerve impulses. The disease commonly affects muscles of the eyes, face, throat, and extremities (Figure 51-6). Myasthenia gravis is a rare disease that can begin suddenly or gradually. It can occur at any age but usually appears in

FIGURE 51-6 A patient with myasthenia gravis.

women between ages 20 and 30 and in men after 50 years of age.[14] Classic signs and symptoms include the following:

- Drooping eyelids, double vision
- Difficulty speaking
- Difficulty in chewing and swallowing
- Difficult extremity movement
- Weakened respiratory muscles

The affected muscles become fatigued with use. However, they may recover completely with rest. The condition may be worsened by infection, stress, medications, and menstruation. Myasthenia gravis often can be controlled with drug therapy to enhance the transmission of nerve impulses in the muscles. (Removal of the thymus gland may improve the condition.) In a small number of patients the disease will progress to paralysis of the throat and respiratory muscles and may lead to death.

SPECIAL CONSIDERATIONS

Accommodations required for care will vary based on the patient's presentation. In most cases, supportive care and transport will be all that is required. In the presence of respiratory distress, the paramedic should take measures to ensure adequate airway and ventilatory support.

CULTURALLY DIVERSE PATIENTS

As described in Chapter 17, individuals vary in many ways, and huge diversity exists in populations of all cultures. **Diversity** is a term that once was used mainly to describe "racial awareness." Now it refers to differences of any kind. These differences include age, race, class, religion, gender, sexual preference, personal habitat, and physical ability. Good health care depends on sensitivity toward these differences.

CRITICAL THINKING

What kinds of diversity are there in your classroom? How do you feel about that diversity?

Experiences of health and illness vary widely as a result of different beliefs, behaviors, and past experiences. These experiences may conflict with learned medical practice of the paramedic. By revealing awareness of cultural issues, the paramedic conveys interest, concern, and respect. When dealing with patients from different cultures, the paramedic should remember the following eight key points:

1. The individual is the "foreground" and the culture is the "background."
2. Different generations and individuals within the same family may have different sets of beliefs.
3. Not all persons identify with their ethnic cultural background.
4. All persons share common problems or situations.
5. Respect the integrity of cultural beliefs.
6. Realize that persons may not share your explanations of the causes of their ill health but may accept conventional treatments. (You do not have to "convert" a patient to your way of thinking to get the desired result.)
7. You do not have to agree with every aspect of another's culture, nor does the person have to accept everything about yours for effective and culturally sensitive health care to occur.
8. Recognize your personal cultural assumptions, prejudices, and belief systems. Do not let them interfere with patient care.

Special Considerations

Regardless of the patient's cultural background, education, occupation, or ability to speak English, most patients will be anxious during an emergency event. If the paramedic does not speak the patient's language, communication should begin using English first. The patient may understand or speak some English words or phrases. (Bystanders, co-workers, or family members may be available to assist.) In some areas, special translator devices (e.g., a telephone language line, a computer-generated Internet or cell phone application) for non–English-speaking patients are available. If the patient does not speak or understand English, the paramedic should try to communicate with signs or gestures. The hospital should be notified as soon as possible so that arrangements for an interpreter can be made.

If time allows, the paramedic should perform all assessment procedures slowly and with the patient's permission. The paramedic should be aware that "private space" is culturally defined (see Chapter 17). Therefore the best approach is to point to the area of the body to be examined before touching the patient. The paramedic must respect the patient's need for modesty and privacy at the scene and during transport. Women and men of some cultures have very strict religious beliefs regarding personal modesty and the appropriateness of being touched, especially by strangers. When possible, every effort should be made to honor their wishes, protect their privacy, and ensure their comfort.

TERMINALLY ILL PATIENTS

As health care professionals, paramedics will care for **terminally ill patients.** (These are patients with advanced stage of disease with an unfavorable prognosis and no known cure.) Often, these calls will be emotionally charged events. They will require a great deal of empathy and compassion for the patient and his or her loved ones. If emotions at the scene are out of control, the paramedic must take control and try to calm the persons involved.

If EMS has been called during the late stages of a patient's terminal illness or for a change in the patient's condition, a full history should be obtained. The patient or family should be asked about advance directives and the appropriateness of resuscitation procedures (see Chapter 6). The paramedic should review carefully any documentation made available concerning advance directives (e.g., a do not resuscitate order). Advance directives should be discussed with medical direction so that care decisions can be made.

NOTE
Not all patients receiving hospice care will have advance directives. Although advance directives are encouraged and sometimes required by hospice, there are variations between hospice programs and their requirements to participate.

LOOK AGAIN
See Chapter 6: Medical and Legal Issues, pp. 102-103.

Special Considerations

Care of a terminally ill patient often is mainly supportive and limited to calming and comfort measures. Care may include transport for physician evaluation. Many terminally ill patients and their families will be involved in hospice care (described in Chapter 2) to help them deal with death and dying. Pain assessment and the management of pain are important aspects of caring for these patients. The paramedic should try to gather a full pain medication history and examine the patient for the presence of transdermal drug patches or other pain-relief devices. Following an assessment of the patient's vital signs, level of consciousness, and medication history, medical direction may advise the use of analgesics or sedatives to ensure the patient's comfort.

PATIENTS WITH COMMUNICABLE DISEASES

As described in Chapter 28, exposure to some infectious diseases can be a significant health risk to paramedics. Thus it is crucial to ensure personal protection on *every* response. The required precautions depend on the mode of transmission and on the ability of the pathogen to cause disease. For example, in some cases gloves provide the required protection. In other cases, respiratory barriers also are needed. Although paramedics cannot be provided with a totally risk-free environment, simple measures of protection greatly reduce exposure to pathogens.

Special Considerations

Some infectious diseases (e.g., acquired immunodeficiency syndrome [AIDS]) are detrimental to the emotional well-being of affected patients, their families, and loved ones. The psychological aspects of providing care to these patients include an emphasis on recognizing each patient as an individual with unique health care needs, respecting each person's personal dignity, and providing considerate, respectful care focused upon the person's individual needs.

CRITICAL THINKING
How do you think you will feel when called to care for a patient who is positive for human immunodeficiency virus or has acquired immunodeficiency syndrome?

FINANCIAL CHALLENGES

More than 45.7 million Americans and one third of persons living in poverty are estimated to have no health insurance.[15] In addition, the insurance coverage held by many others would not carry them through a catastrophic illness. Financial challenges for health care can quickly result from loss of a job and depletion of savings. Financial challenges that are combined with medical conditions that require uninterrupted treatment (e.g., cancer, tuberculosis, HIV/AIDS, diabetes, hypertension, and mental disorders) or that occur in the presence of unexpected illness or injury can deprive the patient of basic health care. Most medical personnel and health care facilities recognize their ethical duty to provide services immediately, without regard to payment, in emergencies.

Poor health also is associated closely with homelessness. Many homeless persons have multiple health problems. In addition to chronic illness, frostbite, leg ulcers, and respiratory tract infections are common. These often are the direct result of homelessness. Homeless persons also are at greater risk for trauma from muggings, beatings, and rape. Homelessness precludes good nutrition, good personal hygiene, and basic first aid. In addition, some homeless persons with mental disorders may use alcohol or other drugs to self-medicate. Those with addictive disorders often are at risk of human immunodeficiency virus and other communicable diseases. Paramedics should be familiar with services in their community for the homeless. They should know where to refer the homeless for food and shelter.

NOTE
It is estimated that approximately 3.5 million people in the United States, 1.35 million of them children, are likely to experience homelessness in a given year.[16] In addition, in 2007, 12.5% of the U.S. population, or 37.3 million people, lived in poverty.[17]

CRITICAL THINKING
Consider patients with chronic illness and no insurance. How do you think that financial pressures influence medication compliance in these patients?

Special Considerations

Persons with financial challenges often are anxious about seeking medical care. Fortunately, the ability to pay for emergency care generally is not a concern for EMS personnel (see Chapter 7). According to *Emergency Medical Services: Agenda for the Future,* "the focus of public access is the ability to secure prompt and appropriate EMS care regardless of socioeconomic status, age, or special need. For all those who contact EMS with a perceived requirement for care, the subsequent response and level of care provided must be commensurate with the situation."[18] When caring for a

patient with financial challenges who is concerned about the cost of receiving needed health care, the paramedic should explain the following:

1. The patient's ability to pay should never be a factor in obtaining emergency care.
2. Federal law requires that care be provided, regardless of the patient's ability to pay.
3. Payment programs for health care services are available in most hospitals.
4. Government services are available to help patients in paying for health care.
5. Free (or near-free) health care services are available through local, state, and federally funded organizations.

In cases in which no life-threatening condition exists, the paramedic should ask the patient which hospital is covered through the patient's health plan or insurance policy. When the patient does not have insurance coverage, the paramedic should tell the patient about alternative facilities for health care for the patient's present condition. The patent also should be counseled about future situations that do not require transport for emergency department evaluation. As an example, the paramedic should provide an approved list of alternative health care sites (e.g., a minor-emergency center or health clinic) that can provide medical care at costs that are much less than those charged by emergency departments.

SHOW ME THE EVIDENCE

From July 2006 to March 2007 researchers in San Francisco gathered data on adult patients who made a decision to come to the ED for care and met selected inclusion criteria. They asked homeless patients and a control group of patients who were not homeless a series of questions about their ED visit. Homeless patients were more likely to say they came to the ED because of hunger, fear for safety, or lack of shelter. Over half of the homeless patients reported being assaulted. Homeless patients interviewed spent an average of 3.5 nights per week sleeping on the street and only one third of the homeless patients felt they had adequate clothing. Although there were a number of limitations to this study, the authors conclude that nonmedical needs constitute a significant number of ED visits in homeless persons.

From Rodriguez RM, Fortman J, Chee C et al: Food, shelter and safety needs motivating homeless persons' visits to an urban emergency department, *Ann Emerg Med* 53(5):598-602, e591, 2008, doi: 10.1016/j.annemergmed.2008.07.046.

SUMMARY

- Certain accommodations may be needed for a hearing-impaired patient. These include helping with a patient's hearing aid, providing paper and pen to aid in communication, speaking softly into the patient's ear, and speaking in clear view of the patient.
- When caring for the visually impaired patient, the paramedic should help the patient use his or her glasses or other visual aids. The paramedic also should describe all procedures before performing them.
- Allow extra time for the history of a patient with speech impairment. If appropriate, provide aids such as a pen and paper to assist in communication.
- When caring for an obese patient, use the proper-sized diagnostic devices. Also, secure extra personnel if needed to move the patient for transport.
- When transporting patients with paraplegia or quadriplegia, extra personnel may be needed to move special equipment.
- Once rapport and trust have been established with a patient who has mental illness, the paramedic should proceed with care in the standard manner.
- When caring for a patient with developmental delays, the paramedic should allow enough time to obtain a history, perform an assessment, deliver care, and prepare for transport.
- The challenge in assessing patients with emotional impairments is distinguishing between symptoms produced by stress and those caused by serious medical illness.
- Pathological conditions may require special assessment and management skills. The paramedic should ask about current medications and the patient's normal level of functioning.
- Diversity refers to differences of any kind. These include race, class, religion, gender, sexual preference, personal habitat, and physical ability. Good health care depends on sensitivity toward these differences.
- Often, calls involving the care of a terminally ill patient will be emotionally charged. They require a great deal of empathy and compassion for the patient and his or her loved ones.
- Some infectious diseases will take a toll on the emotional well-being of affected patients, their families, and loved ones. Paramedics should be sensitive to the psychological needs of the patient and his or her family.
- Financial challenges can deprive a patient of basic health care services. These patients may be reluctant to seek care for illness or injury.

CHAPTER

52 Acute Interventions for Home Care

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Discuss general issues related to the home health care patient.
2. Outline general principles of assessment and management of the home health care patient.
3. Describe medical equipment, assessment, and management of the home health care patient with inadequate respiratory support.
4. Identify assessment findings and acute interventions for problems related to vascular access devices in the home health care setting.
5. Describe medical equipment, assessment, and management of the patient with a gastrointestinal or genitourinary crisis in the home health care setting.
6. Identify key assessments and principles of wound care management in the home health care patient.
7. Outline maternal/child problems that may be encountered early in the postpartum period in the home health care setting.
8. Describe medical therapy associated with hospice and comfort care in the home health care setting.

KEY TERMS

bladder catheterization Drainage of the bladder using a urinary catheter.

bronchopulmonary dysplasia A chronic respiratory disorder characterized by scarring of lung tissue, thickened pulmonary arterial walls, and ventilation-perfusion mismatch; often occurs in infants who have long-term dependence on artificial ventilation.

colostomy A surgical opening into the large intestine.

failure to thrive The abnormal retardation of the growth and development of an infant resulting from conditions that interfere with normal metabolism, appetite, and activity.

gastric tube A device that is inserted into the stomach or intestines; used to remove fluids and gas by suction or gravity, to instill irrigation solutions or medications, and to administer enteral feedings.

hospice A type of care and philosophy of care that includes supportive social, emotional, and spiritual services for the terminally ill and their family.

ileostomy A surgical opening into the small intestine.

infantile apnea An unexplained episode of cessation of breathing for 20 seconds or longer, or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, and/or marked hypotonia (diminished tone).

obstructive apnea A form of sleep apnea involving a physical obstruction of the upper airways that can lead to pulmonary failure, chronic fatigue, and cardiac abnormalities.

ostomy An artificial opening into the urinary tract, gastrointestinal tract, or trachea; any surgical procedure in which an opening is created between two hollow organs or between a hollow viscus and the abdominal wall.

palliative care A unique form of health care primarily directed at providing relief to terminally ill persons through symptom management and pain management; also known as comfort care.

sleep apnea A disorder characterized by abnormal pauses in breathing or episodes of abnormally slow breathing during sleep.

urosepsis Septic poisoning caused by retention and absorption of urinary products in the tissues.

vascular access device A device used to provide nutritional support and to administer medications in patients who need long-term vascular access.

The cost-driven allocation of health care resources and advances in technology have led to shortened hospital stays. This also has allowed many patients to be treated in the home setting. An estimated 7.6 million persons in the United States require home health care services because of acute illness, long-term health conditions, personal preference, permanent disability, or terminal illness.[1] Paramedics likely will play a key role in providing acute interventions to these patients.

(Courtesy Monroe Yancie, St. Louis, Mo.)

OVERVIEW OF HOME HEALTH CARE

Home health care began in the United States in the late 1800s as a direct result of escalating city growth and an increase in the number of immigrants moving into large cities.[2] The emphasis of home health care at that time was personal hygiene and preventive care. The health services were provided by visiting nurses. These nurses worked in tenements to assist the poor. They also cared for wealthy and middle-class families after births or discharges from hospitals. At first, few physicians were associated with most of these home health care groups.

Until the mid-1960s, home health care continued to focus on the poor. The remainder of the population received care in hospitals and physicians' offices. With the passage of the Social Security Act Amendments (commonly known as Medicare) in 1965, home health care became a benefit to older adult patients receiving Medicare. This greatly accelerated growth of the industry. (In 1973 these services were extended to certain disabled younger Americans; hospice benefits were added in 1983.) By 1997 an estimated 38.5 million older adult and disabled Americans were enrolled in Medicare programs. In 2008, 7.6 million Medicare recipients received formal home care services.[3] Medicare is the single largest payer of home care services in the United States.[4] Other funding sources include Medicaid, the Older Americans Act, Title XX Social Services Block Grants, the Veterans Administration, TRICARE/CHAMPUS for military personnel, private insurance, and managed care organizations.

In recent years, federal health care reform has led to the development of managed care services that are provided to members by managed care organizations (see Chapter 1). These plans now cover about 95% of the U.S. population.[4] They have greatly influenced methods of health care delivery (including home health care services).

Today, home health care incorporates a wide variety of health and social services. These services are provided at home to recovering, disabled, or chronically ill and terminally ill persons in need of medical, nursing, social, or therapeutic treatment and help with the essential activities of daily living. The following is a sampling of services provided to home health care patients:

- Skilled nursing services
- Physical, speech, and occupational therapy
- Medical social services
- Home health aides
- Nutritional counseling

Advanced Life Support Response to Home Health Care Patients

About 21% of home health care patients have conditions related to diseases of the circulatory system as their primary diagnosis.[3] (Persons with heart disease, including congestive heart failure, constitute about half of this group.) Other common diagnoses of home health care patients include cancer, diabetes, chronic lung disease, renal failure/dialysis, and hypertension. Thus emergency responses for home health care patients likely will be more common for emergency medical services (EMS) agencies. Typical emergencies may include respiratory failure, cardiac decompensation, septic complications, equipment malfunction, and other conditions that worsen in the home health care setting (Box 52-1).

BOX 52-1 Examples of Home Health Care Problems

Home Care Services Requiring Intervention by a Home Health Care Practitioner or Physician

Acquired immunodeficiency syndrome
Cardiopulmonary care
Catheter management/intravenous therapy infusion
Chemotherapy
Dermatological and wound care
Gastroenterological and ostomy care
Hospice care
Organ transplantation
Orthopedic care
Pain management
Rehabilitative care
Specimen collection
Urological and renal care

Home Health Care Problems Requiring Acute Intervention

Acute cardiac events
Acute infections
Acute respiratory events
Gastrointestinal/genitourinary crisis
Hospice/comfort care
Inadequate respiratory support
Maternal/child conditions
Vascular access complications

Injury Control and Prevention in the Home Health Care Setting

The scientific approach to illness and injury prevention as a means to minimize morbidity and mortality is discussed in Chapter 3. Readers should refer to that chapter to review primary prevention, acute care, and rehabilitation (tertiary prevention); their concepts; and their strategies.

INFECTION CONTROL

As with all other patient encounters, the paramedic should practice infection control in the home health care setting. Infection control includes using universal precautions and body substance isolation (or transmission-based precautions) when indicated. This practice, along with treating all patients as though they have an infectious disease, forms the basis for infection control guidelines recommended by the Centers for Disease Control and Prevention. The Occupational Safety and Health Administration, Centers for Disease Control and Prevention, and Environmental Protection Agency (EPA) recommend the same infection control standards for the treatment of home health care patients as for acute care patients. Equipment proposed by these agencies for infection control in the home setting includes the following:

CRITICAL THINKING
What factors decrease the risks of spreading infection within a home health care setting versus a hospital?

- Mask
- Gown
- Goggles, glasses, or face shield
- Resuscitation mask
- Specimen bags
- EPA-approved disinfectant effective against hepatitis B virus, human immunodeficiency virus, and tuberculosis
- Soap and water/hand sanitizers
- Disposable paper towels
- Impervious trash bags and labels

This text assumes that the proper personal protection will be used by paramedics. The nature of the emergency and the patient's condition will dictate what protection to use.

Types of Home Care Patients

The need to reduce the costs of health care and the technological advances in medicine have allowed many types of patients to receive home care. Many EMS agencies ask their communities to notify them when someone is part of a complex home health care program. Many of these agencies will visit the home before the onset of an emergency. This allows them to become familiar with the patient's condition and special equipment. There are many classifications of home health care patients. Examples include those with the following conditions:

- Pathological conditions of the airway causing inadequate pulmonary toilet or inadequate alveolar ventilation and/or oxygenation
- Circulatory pathological conditions causing alterations in central circulation (e.g., heart failure) or peripheral circulation (e.g., pressure ulcers, delayed healing, or infection)
- Neurological conditions such as stroke, traumatic brain injury, spinal cord injury
- Orthopedic trauma or surgery that requires rehabilitation (e.g., fractured hip, hip or knee replacement)
- Gastrointestinal/genitourinary conditions requiring special devices such as ostomies, feeding catheters, and special equipment needed for home dialysis
- Infection from cellulitis or systemic illness (e.g., sepsis)
- Wounds that require care (e.g., surgical wound closure, decubitus wounds, and surgical drains)

Other patient groups the paramedic may encounter in the home health care setting include patients receiving hospice care, expectant or new mothers, patients with dementia or other conditions that require psychological support for the patient or family, patients receiving

chemotherapy or home care for chronic pain, and patients with organ transplants or those who are waiting for organ transplantation (*transplant candidate*).

GENERAL PRINCIPLES AND MANAGEMENT

Scene Size-Up

When paramedics arrive at the scene of a home health care patient, the scene size-up should include universal precautions, elements of scene safety, and an assessment of the patient's environment (environmental setting).

UNIVERSAL PRECAUTIONS

As described in Chapter 13 and Chapter 28, paramedics should use universal precautions to guard against communicable disease when caring for any patient. Equipment that may be found in the home health care setting includes containers of medical waste, ostomy collection bags, tracheostomy tubes, sharps, soiled dressings, and other equipment (e.g., emesis basins, walkers, and wheelchairs) that may be contaminated with the patient's body fluids. In addition to personal precautions, the EMS crew should ensure that any infectious waste found in the home is contained properly. The waste should be disposed according to protocol.

LOOK AGAIN

See Chapter 14: Venous Access and Medication Administration, pp. 380-381.

SCENE SAFETY

Whenever an EMS response is made to a person's home, the paramedic should evaluate the scene for the presence of dangerous pets, firearms and other home protection devices, and for any home hazards (e.g., inadequate lighting, icy sidewalks, or steep stairwells). For the safety of the EMS crew, the patient, and others at the scene, all potential hazards found in a home must be contained or remedied. For example, it may be necessary to request law enforcement personnel to help with unruly or hostile bystanders. In addition, extra personnel and equipment may be needed to help move a patient down a flight of steps for transport or to manage technology-assisted patient care devices.

ENVIRONMENTAL SETTING

The paramedic should assess the setting for the patient's ability to maintain a healthy environment. Examples include cleanliness of the home; evidence of basic nutritional support; and needs of heat, water, shelter, and electricity. The EMS crew also should note any signs of abuse or neglect. Other factors to note are the cleanliness and condition of any medical devices. (For example, this includes clean oxygen and ventilation equipment and wheelchairs and hospital beds that are in good repair.)

Patient Assessment

The primary survey should focus on life-threatening illness or injury, and appropriate measures should be taken as indicated (see Chapter 19). After the primary survey, a focused history should be obtained and secondary assessment performed. The paramedic should make use of any medical documents found in the home (e.g., patient records kept by home health care providers and do not resuscitate orders). In addition, information should be gathered from family and health care professionals (e.g., a home care nurse or physical or respiratory therapist) who may be present at the scene. Critical findings should alert the paramedic to forgo a detailed assessment and proceed with resuscitation measures and rapid transport for physician evaluation. If there are no critical findings, the paramedic should perform a physical examination that considers the possibility of medication interactions, compliance with the treatment regimen, and the possibility of dementia or a metabolic disturbance in a patient with an altered mental status.

A comprehensive assessment may include a physical examination using inspection, palpation, auscultation, and percussion (as indicated by the patient's condition and chief complaint). The reassessment (ongoing assessment) should evaluate any changes in the patient's status while at the scene or en route to the hospital. These assessment strategies can aid in differential diagnosis, treatment, and direction of patient management.

Management and Treatment Plan

Depending on the patient's condition, the home health care treatment may need to be replaced with advanced life support measures. These measures may include airway, ventilatory, and circulatory support and pharmacological and nonpharmacological therapy (e.g., electrical therapy).

Some patients with acute illness or injury need to be transported to the hospital for evaluation. When transport is needed, the paramedic must give special consideration for patient packaging and for moving the patient's equipment. Examples include properly securing intravenous (IV) catheters, urinary catheters, and feeding tubes; and ensuring available personnel to assist with moving patient care devices such as ventilation equipment. Family members at the scene often are well versed on the patient's medical devices. They usually will be eager to help when asked by the EMS crew. If there is no family at the scene, the paramedic should attempt to contact a family member or caregiver and advise this person of the patient's condition and hospital destination.

Other patients need only home care follow-up by home health care practitioners, or they may need a referral to other public service agencies. The paramedic should follow protocol and consult with medical direction about referrals and the need for notifying private physicians or home health care agencies. Regardless of the need for EMS transport, the paramedic should thoroughly document all findings and any care provided on the patient care report.

CRITICAL THINKING
What feelings may a patient's family member (or caregiver) in the home setting have if there is a problem and the patient's condition worsens?

SPECIFIC ACUTE HOME HEALTH CARE INTERVENTIONS

Acute home health care emergencies may occur from equipment failure or malfunction, drug reactions, complications related to home treatment, and worsening medical conditions. This section discusses acute interventions for respiratory support, cardiovascular support, vascular access devices, gastrointestinal/genitourinary crisis, acute infections, maternal/child conditions, and hospice/palliative care.

Respiratory Support

More than 630,000 patients are discharged to home health care with diseases of the respiratory system each year.[1] These patients are at increased risk for airway infections. The progression of some respiratory diseases also may lead to an increased respiratory demand, making current support inadequate. Examples of chronic pathological conditions that require home respiratory support include the following:

- Asthma
- Awaiting lung transplantation
- Bronchopulmonary dysplasia
- Chronic lung disease
- Cystic fibrosis
- Infection causing exacerbation of condition
- Sleep apnea

Acute interventions may be required for these patients. Any patient with respiratory distress should receive high-concentration oxygen, pulse oximetry monitoring, and ventilatory support as priorities in care. Problems that may lead to a request for EMS assistance include increased respiratory demand, increased bronchospasm, increased secretions, obstructed or malfunctioning respiratory devices, or improper application of medical devices to support respirations.

OXYGEN THERAPY IN THE HOME SETTING

Three common ways to provide oxygen therapy in the home are compressed gas, liquid oxygen, and oxygen concentrators. Compressed gas is oxygen stored under pressure in oxygen cylinders equipped with a regulator that controls flow rate. Liquid oxygen is cold and is stored in a container similar to a thermos. When released, the liquid converts to gas and is used like compressed gas. An oxygen concentrator is an electrically powered device that separates oxygen from air, concentrates it, and stores it (Figure 52-1). This system does not have to be resupplied and is not as costly as liquid oxygen. A cylinder of oxygen must be available as a backup, however, in case of power failure.

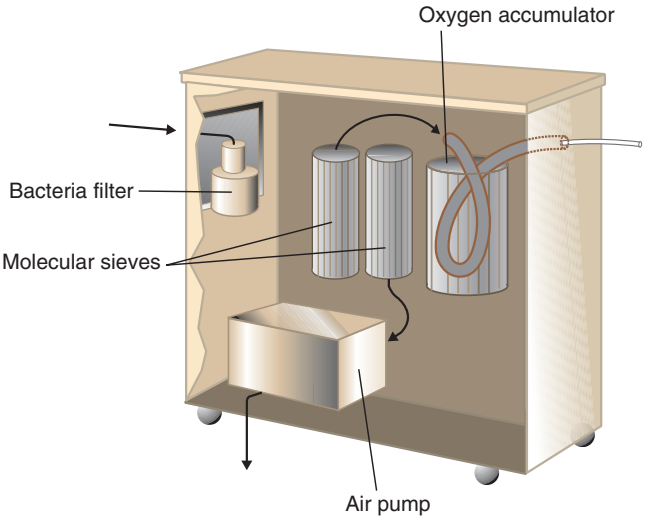

FIGURE 52-1 Oxygen concentrator.

CRITICAL THINKING
What safety precautions for administering oxygen should be in place in the home setting?

Oxygen is delivered to patients via nasal cannulae, oxygen masks, tracheostomy collars (devices that deliver high humidity and oxygen to patients with surgical airways), and ventilators. Some patients may require continuous positive airway pressure (CPAP) delivered by ventilatory support systems through mask CPAP, nasal CPAP, or biphasic positive airway pressure (BiPAP). As described in Chapter 24, the BiPAP ventilatory support system (designed for mask-applied ventilation in the home) delivers two different levels of positive airway pressure. The system cycles spontaneously between a preset level of inspiratory positive airway pressure and expiratory positive airway pressure. The BiPAP ventilatory support system is intended only to augment the patient's breathing; it does not provide for total ventilatory requirements. The BiPAP system is used by some patients with sleep apnea or chronic obstructive pulmonary disease.

Supportive ventilator management may be indicated to achieve the following:

- Prevent nocturnal hypoxemia caused by sleep hypoventilation in patients with neuromuscular disorders (e.g., muscular dystrophy or myasthenia gravis).
- Prevent respiratory fatigue in patients with chronic obstructive pulmonary disease.
- Improve ventilation and oxygen saturation in patients with **obstructive apnea,** a form of **sleep apnea** involving a physical obstruction of the upper airways that can lead to pulmonary failure, chronic fatigue, and cardiac abnormalities.

DID YOU KNOW?

Sleep Apnea

Sleep apnea is a disorder characterized by abnormal pauses in breathing or episodes of abnormally slow breathing during sleep. The pauses often occur 5 to 30 times or more each hour. The condition is common, affecting about 12 million Americans.[5] Untreated, sleep apnea can increase the risk of hypertension, stroke, myocardial infarction, worsening heart failure, and dysrhythmias. It also is related to obesity and diabetes. Once diagnosed, the most common treatment in adults is application of continuous positive airway pressure (CPAP) during sleep. Other treatment therapies include lifestyle changes (weight loss, smoking cessation, limited alcohol use), alterations in sleep positioning, and the use of mouthpieces designed to maintain an open airway during sleep. Surgical alteration of the soft tissues of the airway may be indicated for some patients.

Home Ventilators. Home ventilators can be classified as *volume ventilators, pressure ventilators,* and *negative-pressure ventilators.* Most ventilators have a number of controls and ventilator settings. Box 52-2 describes some of these settings.

Volume ventilators (volume-preset) deliver a predetermined volume of gas with each cycle, after which inspiration is terminated. These types of ventilators deliver a constant tidal volume regardless of changes in airway resistance or compliance of the lungs and thorax. The volume remains the same unless very high peak airway pressures are reached. In that case, safety release valves stop the flow (Box 52-3 and Table 52-1).

Pressure ventilators (pressure-preset) are pressure-cycled devices that terminate inspiration when a preset pressure is achieved. When the preset pressure is reached, the gas flow stops, and the patient passively exhales. These ventilators most often are used for patients whose ventilatory resistance is not likely to change.

Negative-pressure ventilators have settings for the respiratory rate and pressure of the negative force exerted. These devices use negative pressure to raise the rib cage and lower the diaphragm. This creates negative pressure within the lungs so that air flows into the lungs. Negative-pressure ventilators often are used for patients with healthy lungs who have a muscular inability to inhale. (For example, this may include patients with spinal cord injury or neuromuscular disease.) Examples of this type of ventilator are the "iron lung" and plastic wrap, or poncho ventilators (Figure 52-2).

BOX 52-2 Standard Initial Ventilator Settings

FIO_2 (fraction of inspired oxygen)	100%
Tidal volume	10 to 15 mL/kg body mass
Respiratory rate	10 to 15 breaths/min
Inspiratory flow rate	40 to 60 L/sec
Sensitivity	12 cm H_2O
Sigh rate (optional)	1 to 2/min

BOX 52-3 Ventilator Alarms

Ventilators are equipped with alarms. These alarms signal that there are problems with ventilator function. There are alarms for loss of power, frequency alarms (indicating changes in respiratory rate), volume alarms (indicating low exhaled volume or low/high minute ventilation), and high-pressure alarms. If alarms are sounding, the paramedic should check for the following possible causes:

- Kinks in endotracheal tube
- Disconnected ventilator tubing or poor connections
- Water in ventilator tubing
- Excessive secretions
- Pneumothorax
- Patient anxiety

After consulting with medical direction, acute interventions may include providing temporary ventilation assistance with a bag-mask device, repositioning the endotracheal tube, correcting poor ventilator tube connections, emptying water from tube or water traps, suctioning the airway, decompressing the thorax, and possibly sedating the patient.

TABLE 52-1 Ventilator Alarms*

Alarm Type	Causes	Interventions
High pressure	Increased secretions	Suction secretions from patient.
High pressure	Kinked tubing	Unkink tubing.
High pressure	Water in tubing	Disconnect tubing and allow it to drain.
High pressure	Anxiety	Decrease anxiety by providing a calm environment.
Low pressure	Disconnected tubing	Reconnect tubing.
Low pressure	Cuff leak	Add 1 mL of air at a time to pilot balloon of tracheostomy tube.
Low pressure	Tracheostomy tube out	Reinsert new tracheostomy tube.
Oxygen	Insufficient oxygen supply	Manually ventilate patient's lungs and prepare for transport.
Ventilator not operating	Power failure	Manually ventilate patient's lungs and prepare for transport.

*Note: A memory aid useful for identifying possible causes of ventilator malfunction is DOPE. This stands for **d**isplacement of the tube, **o**bstruction of the tube, **p**neumothorax, and **e**quipment failure.

ASSESSMENT FINDINGS

When caring for a patient who requires oxygen therapy, the paramedic should evaluate the patient's work of breathing, tidal volume, peak flow, oxygen saturation, and quality of breath sounds. This assessment can be performed with visual inspection (chest rise and fall), peak flow meters, pulse oximetry, and auscultation (described in Chapter 15 and Chapter 24). The paramedic should be alert for signs and symptoms of hypoxia, including the following:

- Confusion and mental status changes
- Increased work of breathing
- Cyanosis
- Dyspnea
- Headache
- Hypertension
- Hyperventilation
- Restlessness
- Tachycardia

FIGURE 52-2 Home negative pressure ventilator.

MANAGEMENT

Management goals for a patient receiving oxygen therapy who requires acute intervention are to improve airway patency, ventilation, and oxygenation.

Improving Airway Patency. To improve airway patency, the paramedic first should reposition airway devices (e.g., face masks and nasal cannulae) to ensure they are applied properly and are well fitted. Any secretions that obstruct airflow from the airway should be cleared with suction and sterile water should be used to clean airway devices. If needed, the home airway device should be replaced with a new device. A tracheostomy tube that has become blocked and cannot be cleared may need to be replaced with another tracheostomy tube to ensure adequate ventilation (Figure 52-3) or the tube can be replaced temporarily with an endotracheal tube (see Chapter 15).

NOTE

The paramedic should always ensure that powered airway equipment is working properly; that oxygen is flowing; and that the equipment is connected to the power source (battery or electrical current). Equipment that is connected properly and still not working may result from power outage in the home (e.g., failed fuse or circuit breaker).

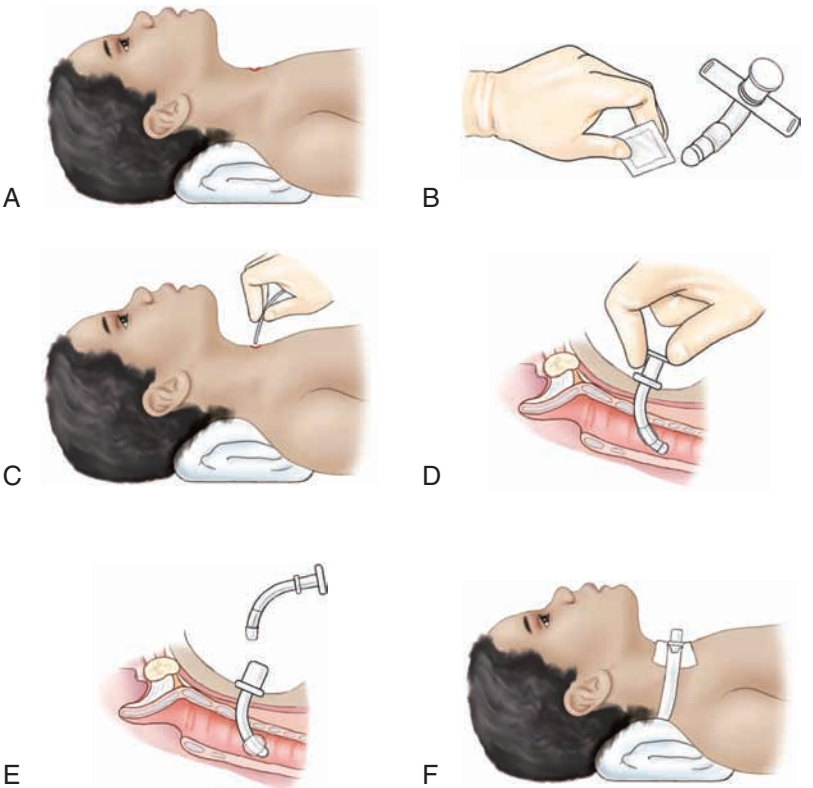

FIGURE 52-3 Replacement of a tracheostomy tube. **A,** Position the child with padding under the shoulders. **B,** Select a tube the same size or one size smaller than the one removed and moisten it with sterile, water-soluble lubricant. **C,** Suction the stoma and trachea before insertion of the new tube. **D,** Insert the tube gently into the trachea with the curve pointing downward. **E,** If the tube has an obturator, remove it; if it is a cuffed tube, inflate the cuff. **F,** Assess for correct tube placement and secure the tube.

LOOK AGAIN
See Chapter 15: Airway Management, Respiration, and Artificial Ventilation, pp. 426-427.

Improving Ventilation and Oxygenation. If ventilation does not improve after providing a patent airway, the paramedic should remove the home ventilator care device. The patient's ventilations should then be assisted with positive-pressure ventilation via a bag-valve-mask device and supplemental oxygen. Oxygen saturation should be monitored with pulse oximetry. The paramedic also should administer supplemental oxygen as needed to maintain oxygen saturation at 90% or higher. Medical direction may advise adjusting the settings of a home care device or changing the flow rate of an oxygen delivery device to improve ventilation and oxygenation. Extra personnel may be needed to assist in moving the patient who has a ventilator device to the ambulance for transport.

On some ventilators the inspiratory flow rate is determined by tidal volume, respiratory rate, and the inspiratory/expiratory ratio. (This ratio is generally 1 : 2. This allows for complete exhalation and prevents air trapping.) On other ventilators the flow rate is set independently. This allows for adjustment of airflow to the flow wave pattern that is most comfortable for the patient. If the patient is having difficulty with spontaneous breathing, an increase in the flow rate may be indicated. However, a higher flow rate means a shorter inspiratory time and usually a higher respiratory pressure because of increased resistance. A lower flow rate requires a longer inspiratory time with a decreased inspiratory pressure. The paramedic should always consult with medical direction before changing the flow rate on any ventilator.

PSYCHOLOGICAL SUPPORT AND COMMUNICATION STRATEGIES

Difficulty breathing can be a horrifying experience for the patient, especially for a patient who depends on a ventilator. The paramedic crew should try to calm the patient and family. They should be assured that respirations will be supported adequately by other means while at the scene and during transport.

Some patients with tracheostomies have special valves attached to the tracheostomy tube ("talking trachs"). These valves redirect exhaled air around the tracheostomy tube, through the vocal cords, and out of the mouth and nose to allow for normal speech. Loss of verbal communication is a major source of anxiety in patients who have tracheostomies. The ability to communicate with these patients will be based on the patient's cognition, level of consciousness, language, and fine and gross motor skills. Methods of communication may include signing and writing on notepads. The paramedic should enlist the help of family and other caregivers in communicating with the patient.

Cardiovascular Support

As described in Chapter 22, it is likely that paramedics will encounter patients who have a left ventricular assist device (LVAD). The most common patient groups who use LVADs are heart transplant candidates, heart surgery patients during recovery, and patients with severe congestive heart failure. To review, an LVAD is a battery-operated, mechanical pump-type device that is surgically implanted. It helps maintain the pumping ability of a heart that cannot effectively function on its own. It essentially assumes or augments the pumping function of the left ventricle. LVADs can operate in fixed mode—the pump beats at a set rate, regardless of other conditions—and auto mode—the pump fills at a variable rate depending on the patient's activity and volume status. With either mode, there is no relationship to the rate or rhythm of the heart. Families and caregivers generally are advised to contact EMS if the patient:

- Is unconscious
- Is awake but nonresponsive
- Falls or suddenly collapses
- Has a severe sensory or motor deficit
- Experiences a severe dysrhythmia or cardiac arrest

TYPES OF LVADS

The two most common LVADs used today are pulsatile pumps and nonpulsatile pumps. A pulsatile LVAD pumps blood in a cycle similar to the normal heart (cycles of contraction-relaxation). Nonpulsatile pumps move blood continuously through the body. Both types of LVADs are controlled by battery packs and an electronic pump and system controller. (These are usually carried on a belt around the patient's waist or on a shoulder strap.) Both types of LVADs can malfunction, triggering an advisory or alarm. Therefore, home care patients and their families are trained to troubleshoot the device. Examples of malfunctions include a failure in the pumping device or system controller, and loss of power. Most malfunctions of an LVAD can be remedied by the patient or family member by checking cables, changing the power source, and changing the system controller. Some devices have emergency "hand pumps" in the event there is a system failure. Manufacturer recommendations for managing advisories and alarms should be closely followed. An LVAD that fails to provide the pumping action of the left ventricle can result in heart failure and cardiac arrest.

NOTE
There are a number of LVADs in use. Some models will produce a palpable pulse and blood pressure; other models do not (depending on the device). In addition, some patients with end-stage heart failure will also have a pacer or implanted defibrillation device in place.

MANAGEMENT

If the patient experiences pulseless ventricular tachycardia, ventricular fibrillation, or asystole, normal care protocols should be applied. Manufacturer guidelines regarding chest compressions and defibrillation must be followed. For example, performing chest compressions over some LVADs may damage the heart and cause severe bleeding. Some LVADs will need to have the power source disconnected before administering electrical therapy. The paramedic should consult with knowledgeable family members or caregivers and with medical direction (Figure 52-4).

Vascular Access Devices

Many patients in the home care setting have an indwelling **vascular access device** (VAD). Vascular access devices are used to provide nutritional support. They also are used to administer medications. In addition, VADs are used for patients who need long-term vascular access. (For example, this includes patients receiving dialysis or chemotherapy.) Those with indwelling vascular devices may experience problems, including the following:

- Anticoagulation associated with percutaneous or implanted devices
- Embolus formation associated with indwelling devices, stasis, and inactivity
- Air embolus associated with central venous access devices
- Obstructed or malfunctioning VADs
- Infection at the access site ("line sepsis")
- Infiltration and extravasation
- Obstructed dialysis shunts
- Bleeding if catheter is torn

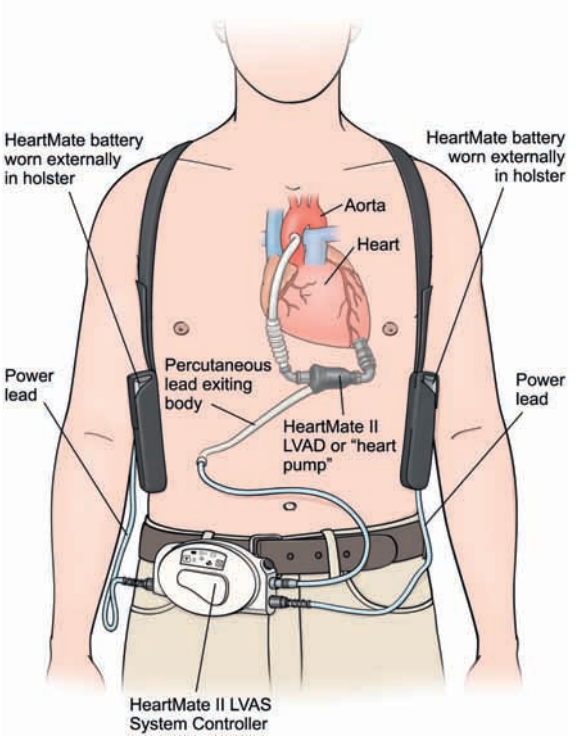

FIGURE 52-4 Ventricular assist device.

> **NOTE**
> Congestive heart failure is a common reason for hospitalization. Attempts often are made to manage these patients at home when possible. Thus paramedics may find patients with congestive heart failure receiving medications (e.g., ***dobutamine***) intravenously through a VAD in the home setting.

TYPES

As described in Chapter 14, there are a variety of vascular access devices. These include surgically implanted subcutaneous VADs, medication delivery devices (e.g., MediPorts), peripheral VADs (e.g., peripherally inserted central catheters [PICCs] and midline catheters), central venous tunneled catheters (e.g., Hickman, Groshong, or Broviac), and dialysis shunts (Figure 52-5).

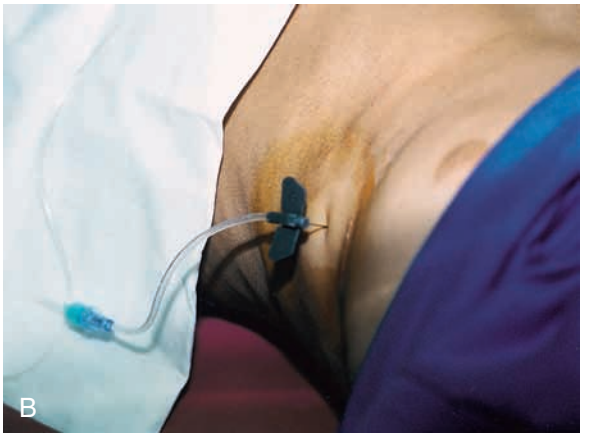

FIGURE 52-5 Vascular access devices. **A,** External venous catheter (note redness from dressing site). **B,** Implanted venous access device with Huber needle placement.

LOOK AGAIN
See Chapter 14: Venous Access and Medication Administration, pp. 367-368.

ASSESSMENT FINDINGS AND ACUTE INTERVENTIONS

Certain assessment findings may require acute interventions in patients with VADs. These findings include infection, hemorrhage, hemodynamic compromise from circulatory overload or embolus, obstruction of the vascular device, catheter breakage, and leakage of medication (e.g., chemotherapeutic agents) (Table 52-2).

Infection. Home health care patients who have VADs generally are instructed to regularly examine the area for infection. They also are instructed to change the dressings around their device often. As a rule, this is done by family members and home health care practitioners. All types of dressings must be changed immediately if they become wet, soiled, contaminated, or unocclusive. A common problem of VADs is infection near the exit site, tunnel, or port. Signs and symptoms of localized site infection include pain, redness, warmth, and purulence. Signs and symptoms of systemic infection (which may result from a site infection) include fever, tachycardia, general weakness, malaise, mental status changes, body aches, and possibly septicemia. If the patient has any evidence of systemic signs of infection, he or she should be transported to the hospital. General principles in managing the site of infection are as follows:

1. Wash your hands.
2. Put on nonsterile gloves and remove the old dressing.
3. Discard dressing and gloves.
4. Open the dressing change kit and don sterile gloves.
5. Inspect site for signs of swelling, redness, or other complications.
6. Clean the site vigorously.
   a. Chlorhexidine is gaining acceptance as the antiseptic of choice. Use a side-to-side cleaning motion.
   b. If using alcohol and povidone-iodine (in this order or iodine will be inactivated):
      i. Use the alcohol first to kill *Staphylococcus epidermidis* (organism most likely to cause catheter sepsis).
      ii. Then vigorously clean with povidone-iodine and let skin dry completely.

TABLE 52-2 Correcting Common Problems With Venous Access Devices

Complication	Signs and Symptoms	Prehospital Interventions
Mechanical Problems		
Clotted intravenous catheter	Interrupted flow rate, resistance to flushing and blood withdrawal	Attempt to aspirate clot. If unsuccessful, contact medical direction.
Cracked or broken tubing	Fluid leaking from tubing	Apply padded hemostat above break to prevent air from entering line and change tubing (with orders from medical direction).
Dislodged catheter	Catheter out of vein	Apply pressure to site with a sterile gauze pad.
Too-rapid infusion	Nausea, headache, lethargy, dyspnea	Adjust infusion rate, and if applicable, check infusion pump. Contact medical direction about need to transport.
Other Problems		
Air embolism	Apprehension, chest pain, tachycardia, hypotension, cyanosis, seizures, loss of consciousness, and cardiac arrest	Clamp catheter. Place patient in a steep, left lateral Trendelenburg position. Give oxygen as ordered. If cardiac arrest occurs, begin cardiopulmonary resuscitation.
Extravasation	Swelling and pain around insertion site	Stop infusion. Assess patient for cardiopulmonary abnormalities. Notify medical direction for further advice.
Phlebitis	Pain, tenderness, redness, and warmth	Apply gentle heat to area; elevate insertion site if possible.
Pneumothorax and hydrothorax	Dyspnea, chest pain, cyanosis, and decreased breath sounds	If signs and symptoms of tension pneumothorax are present, consider needle decompression after consulting with medical direction. Rapid transport is indicated.
Septicemia	Red and swollen catheter site, chills, fever	Transport for physician evaluation.
Thrombosis	Erythema and edema at insertion site; ipsilateral swelling of arm, neck, face, and upper chest; pain at insertion site and along vein; malaise; fever; tachycardia	Apply warm compresses to insertion site; elevate affected extremity. Transport patient.
Hemorrhage	Bleeding at site of venous access device or from broken device	Apply pressure to site. Clamp venous access device and treat for shock.

7. Do not apply ointment unless you are removing the catheter.
8. Cover with a gauze or transparent dressing (according to local medical direction protocol).

CRITICAL THINKING

Will it always be possible to identify the catheter as the source of sepsis while on the scene?

Hemorrhage. Bleeding at the site of a VAD should be controlled by applying gentle, direct pressure with aseptic technique. These patients need to be transported for physician evaluation. Blood loss from a broken or dislodged VAD can be significant. (Medical direction may recommend that the damaged catheter be clamped.) If blood loss is severe, the patient should be treated for hemorrhagic shock.

Hemodynamic Compromise. Hemodynamic compromise may result from circulatory overload or embolus. Circulatory overload can develop from too much IV fluid being delivered too fast. Signs and symptoms of circulatory overload include a rise in blood pressure, distended neck veins, pulmonary congestion (crackles and wheezes), and dyspnea. If circulatory overload is suspected, the paramedic should do the following:

1. Slow the infusion to a keep-open rate.
2. Provide high-concentration oxygen and monitor oxygen saturation.
3. Elevate the patient's head.
4. Maintain body warmth. This will promote peripheral circulation. It also will ease the stress on the central veins.
5. Monitor vital signs.
6. Consult with medical direction for patient management and disposition.

CRITICAL THINKING

What drug(s) may the physician order if this happens?

Displacement of a surgically implanted catheter or port is rare. However, an embolus that occurs from air, thrombus, or plastic or catheter tip entering the circulation can develop (Box 52-4). Signs and symptoms of an embolus include hypotension; cyanosis; weak, rapid pulse; and loss of consciousness. A patient suspected of having an embolism should be managed as follows (described in Chapter 14):

1. Stop the IV infusion.
2. Position the patient on the left side with the head down (in an attempt to keep the embolus in the right side of the heart).
3. Administer high-concentration oxygen and monitor oxygen saturation.
4. Notify medical direction.

BOX 52-4 Causes of Embolus Formation

Intravenous fluid containers that run dry
Air in intravenous tubing
Loose connections in catheter tubing
Catheter tears and breakage

Thrombus

Clot formation from inactivity or stasis

Plastic or Catheter Tip Migration

Plastic or catheter fragment from tugging or shearing forces
Wire from central line placement

If a plastic or catheter tip embolism is suspected, medical direction may advise that a constricting band be applied above the VAD site. This should stop the embolus from further movement.

Obstruction of the Vascular Device. An indwelling vascular device may become obstructed and disrupt the flow of fluids and medications. When this occurs, immediate intervention is needed. The device must be cleared by irrigation or the administration of fibrinolytic agents. The paramedic should always consult with medical direction before attempting to clear an obstruction from a VAD.

NOTE

Accessing a VAD requires special needles and adapters. Only paramedics with special training and authorization from medical direction should attempt to access these devices.

Flushing and Irrigation. Vascular access devices and medication ports need regular irrigation with normal saline and/or ***heparin.*** The solution used depends on the type of VAD (Table 52-3). The frequency of irrigation depends on the specific device and on the frequency of medication administration. If a VAD is obstructed, the paramedic should consult with medical direction and follow these steps[6]:

1. Explain the procedure to the patient.
2. Establish a sterile field and use strict aseptic technique.
3. Prepare prescribed irrigation solutions (normal saline or normal saline and ***heparin***).
4. Clean the injection cap(s) with an antiseptic and alcohol wipe (per protocol) and allow to air-dry.
5. Release the clamp from the catheter (if present).
6. Irrigate the lumen with an appropriate volume of solution using a 10-mL syringe (no faster than 0.5 mL/sec). If resistance is persistent, stop the irrigation, or the catheter may rupture. *Note:* The paramedic must never try to force or dislodge a clot or other obstruction. Fibrinolytic agents may be required. The application of force could dislodge the obstruction and cause it to enter the circulatory system.

TABLE 52-3 Irrigation for Vascular Access Devices

Device	Syringe Size (mL)	Solution	Amount (mL)
Peripheral access devices	3	Heparin flush solution 10 units/mL	2.5-3.0
Central Venous Access Devices			
Groshong	10	0.9% sodium chloride (normal saline)	5; 10-20 following blood draws
MediPorts	10	Sodium chloride 0.9% (normal saline)	10
		Heparin 100 units/mL	5

From Terry J: *Intravenous therapy: clinical principles and practice,* Philadelphia, 1995, Saunders.

7. Aspirate blood back into the syringe; this removes clots or fibrin sheaths.
8. Flush with normal saline (10 to 20 mL) to clear the system.
9. Use a heparin lock if necessary (e.g., Broviac, Hickman, or peripherally inserted central catheter).
10. Clamp catheter if needed.
11. Loop the catheter with the cap pointing upward on the dressing. Secure with tape.
12. Properly dispose of all equipment.

Anticoagulant Therapy. At times, a medication port or other vascular device may require declotting with fibrinolytic agents (e.g., tissue plasminogen activator [t-PA]). Flushing with fibrinolytic agents should be performed by specialized personnel. An x-ray may be needed before administration of these agents.

Other Complications. If you are unable to aspirate blood from the central VAD, or the patient or family reports that the length of the catheter that was visible has changed, do not administer fluid or drugs through it. The patient will need transport for further evaluation.

A decrease in the length of catheter coupled with a sudden onset of tachycardia can mean that the catheter has moved into the right atrium. If the patient hears bubbling in the ear when the catheter is flushed, or has a sudden earache on the side of the body where the catheter is inserted, the catheter may have advanced into the jugular vein. In all of these situations, an x-ray will be needed to determine the location of the catheter.

Catheter Damage. A damaged (e.g., cracked or torn) catheter can allow fluids or medications to infiltrate into the surrounding tissues and lead to an air embolism. Signs and symptoms of a damaged catheter include leaking fluid, complaint of a burning sensation, or swollen and tender skin near the insertion site. If catheter damage is suspected, the infusion should be stopped immediately. The catheter should be clamped between the crack or tear in the catheter and the patient. These patients are managed with high-concentration oxygen and pulse oximetry, IV access through a peripheral vein, and transport for physician evaluation. A patient who develops an altered level of consciousness (indicating a possible air embolism) should be positioned on the left side. The head should be slightly lowered. This positioning will help to prevent the embolism from traveling to the brain.[7]

Gastrointestinal/Genitourinary Crisis

More than 500,000 patients with diseases of the digestive or genitourinary system are discharged to home health care each year.[1] Some of these patients have medical devices such as urinary catheters or urostomies, indwelling nutritional support devices (e.g., percutaneous endoscopic gastrostomy tube or gastrostomy tube), colostomies, and nasogastric tubes (Box 52-5). Acute interventions that may be required for these patients can result from urinary tract infection (UTI), **urosepsis,** urinary retention, and problems with gastric emptying or feeding.

URINARY TRACT INFECTION, UROSEPSIS, AND URINARY RETENTION

Urinary tract infection is common. It occurs in all age groups and both genders (see Chapter 30). The organisms most often associated with UTI are gram-negative organisms normally found in the gastrointestinal tract. These include *Escherichia coli, Klebsiella, Proteus, Enterobacter,* and *Pseudomonas.* These frequently are introduced from the hands of health care personnel at the time of bladder catheterization.[7] (About 75% of UTIs are the result of urological instrumentation. Sterile technique during these procedures

BOX 52-5 Medical Therapy Found in the Home Setting for Patients With Gastrointestinal/Genitourinary Disease

Devices for Gastric/Intestinal Emptying or Feeding
- Colostomy
- Feeding tube
- Nasogastric tube
- Percutaneous endoscopic gastrostomy tubes, jejunostomy tubes, gastrostomy tubes

Devices for the Urinary Tract
- External urinary catheters (e.g., condom catheter or Texas catheter)
- Indwelling urinary catheter (e.g., Foley catheter or coudé catheter)
- Surgical urinary catheters (e.g., suprapubic catheters)
- Urostomy

is crucial.) Other factors that increase the risk of UTI include the following:

- Obstructions (e.g., urethral strictures, calculi, tumors, or blood clots)
- Trauma (e.g., abdominal injury, ruptured bladder, or local trauma related to sexual activity)
- Congenital anomalies (e.g., polycystic kidneys, horseshoe kidney, or spina bifida)
- Abdominal or gynecological surgery
- Acute or chronic renal failure
- Immunocompromised state (e.g., patients with human immunodeficiency virus or older adults)
- Postpartum state
- Aging changes, particularly in women

If UTI is allowed to progress, it may lead to septic complications (urosepsis). This disease is managed with antibiotics.

Urinary Retention. Urinary retention may result from urethral stricture, inflammation, enlarged prostate, central nervous system dysfunction, foreign body obstruction, and use of certain drugs, such as parasympatholytic or anticholinergic agents. These patients need to be evaluated by a physician to determine the cause of the retention. If the cause is not easily correctable, the patient may need to be hospitalized. Some patients may require **bladder catheterization** with an indwelling Foley catheter device. (See the Appendix, Advanced Practice Procedures in Critical Care.)

CRITICAL THINKING

What measure should you take to protect yourself legally when inserting a Foley catheter into a patient in a home?

PROBLEMS WITH GASTRIC EMPTYING OR FEEDING

Gastric tubes used in the home health care setting are devices that are inserted into the stomach or intestines (Figure 52-6). They are used to remove fluids and gas by suction or gravity, to instill irrigation solutions or medications, and to administer enteral feedings (through *feeding tubes*) (Table 52-4). Two common problems with gastric tubes are aspiration of gastric contents and malfunction of gastric devices.

NOTE

Flexible feeding tubes (such as the Dobhoff feeding tube) are commonly used in patients who cannot take nourishment by mouth. The feeding tubes may be inserted orally or nasally so that the tip of the tube is placed in either the stomach or the duodenum. These tubes generally have a weighted tungsten tip and have a guidewire to prevent them from curling up in the back of the patient's throat.

Aspiration of Gastric Contents. Aspiration of gastric contents may occur in the home health care patient as a result of a nonpatent gastric tube, improper nutritional support via a feeding tube, or patient positioning with

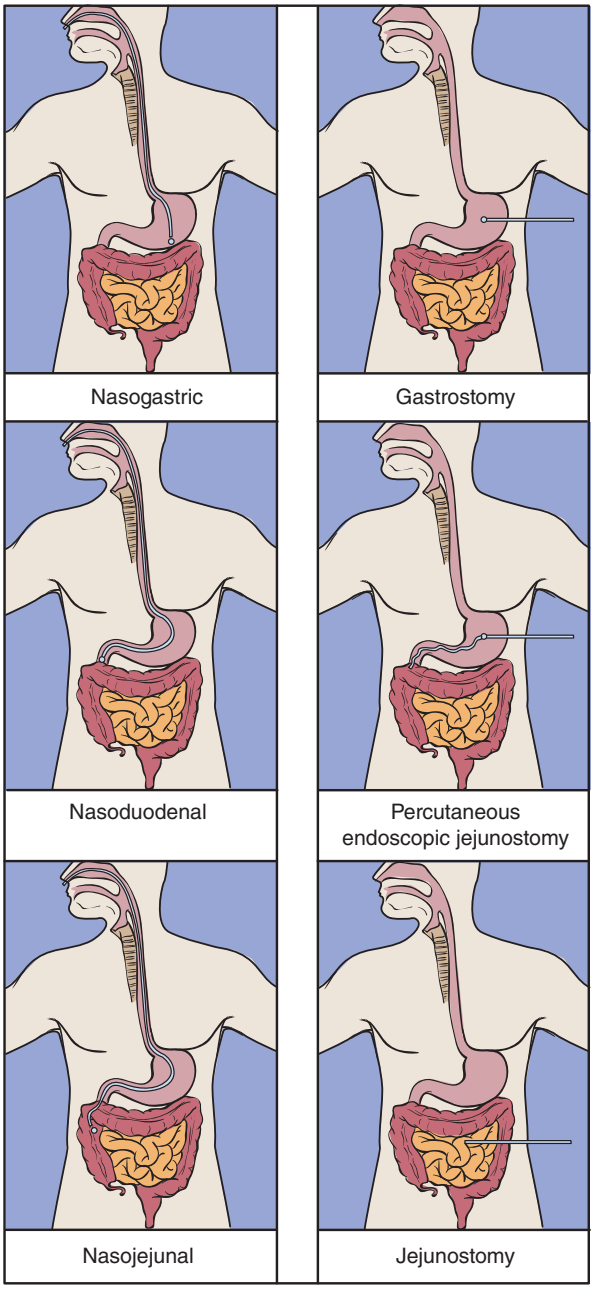

FIGURE 52-6 Tube feeding sites.

these medical devices. The patients at greatest risk for aspiration of tube feedings are those who:

- Are unconscious
- Are confused
- Are seriously debilitated
- Are older adults
- Have tracheostomies or large-bore feeding tubes
- Have impaired gag reflexes
- Cannot sit upright

The paramedic should monitor patients with feeding tubes closely for signs of increased respiratory effort. Lung sounds should be clear on auscultation. Respiratory difficulty or tachypnea may indicate developing aspiration pneumonitis. Other problems that can occur in patients

TABLE 52-4 Feeding Tubes: Types and Placement

Type of Tube	Placement
Nasogastric	Passed via nose into stomach
Nasointestinal	Passed via nose into intestine
Esophagostomy	Passed into esophagus through a surgically created opening in anterior neck
Gastrostomy	Passed directly into stomach through an opening created in abdominal wall
Jejunostomy, percutaneous endoscopic gastrostomy	Passed into jejunum through an opening created in abdominal wall

with feeding tubes include diarrhea, choking, irritable bowel syndrome, and bowel obstruction.

Obstruction or Malfunction of Gastric Devices. A gastric device may become obstructed or malfunction for different reasons. For example, there may be a kinked or clogged tube, or a surgically implanted feeding tube may become displaced. Acute interventions that may be required include unkinking a tube, irrigating a clogged tube, and reinserting a displaced tube (per medical direction; Table 52-5). When transporting a patient with a gastric device, the paramedic must ensure patient comfort. The device should be positioned to allow for proper drainage and to prevent reflux. Time is of the essence in correcting a malfunctioning gastric device. Immediate transport for definitive care is indicated.

Ostomies. An **ostomy** is an artificial opening into the urinary tract, gastrointestinal tract, or trachea. An ostomy may be temporary or permanent. (An **ileostomy** is an opening into the small intestine. A **colostomy** is an opening into the large intestine.) The bowel usually discharges liquid or solid feces into the bag (pouch) once or twice a day; the bag then is changed. Potential complications associated with ostomies include infection, hemorrhage, obstruction, and stoma problems (e.g., necrosis, retraction, stenosis, and prolapse).

Colostomy irrigation, ostomy care, and pouch changes usually are performed for home health care patients by the patients themselves, family members, and home health care practitioners. These procedures require special training. They usually are not considered an acute intervention for paramedic practice. Bowel perforation and significant fluid/electrolyte imbalances may accidentally occur from colostomy irrigation performed by the patient or caregiver.

TABLE 52-5 Managing Tube-Feeding Problems*

Complication	Interventions
Aspiration of gastric secretions	Discontinue feeding immediately. Perform tracheal suction of aspirated contents if possible. Notify physician. Check tube placement before feeding to prevent complications.
Tube obstruction	Flush tube with warm water. If necessary, replace tube. Flush tube with 50 mL of water after each feeding to remove excess sticky formula, which could occlude tube.
Nasal or pharyngeal irritation or necrosis	Provide frequent oral hygiene using mouthwash or lemon-glycerin swabs. Use petroleum jelly on cracked lips. Change position of tube. If necessary, replace tube.
Vomiting, bloating, diarrhea, or cramps	Reduce flow rate. Warm formula. For 30 minutes after feeding, position patient on right side with head elevated to facilitate gastric emptying. Notify physician. Physician may want to reduce amount of formula being given during each feeding.
Constipation	Provide additional fluids if patient can tolerate them. Administer a bulk-forming laxative. Increase fruit, vegetable, or sugar content of feeding.

*This table lists some interventions that the nurse, paramedic, patient, or caregiver may use to solve home tube-feeding problems.

ASSESSMENT AND MANAGEMENT OF PATIENTS WITH GASTROINTESTINAL/GENITOURINARY CRISIS

The paramedic should evaluate a patient with gastrontestinal/genitourinary complaints by obtaining a focused history and performing a physical examination to determine the need for immediate transport for physician evaluation. Depending on the patient's chief complaint, the physical examination may include assessment for the following:

- Abdominal distention
- Abdominal pain
- Aspiration
- Fever
- Intestinal obstruction
- Peritonitis
- Urinary tract infection
- Urinary retention

Acute Infections

More than 160,000 patients with infectious and parasitic diseases are discharged to home health care in the United States each year.[1] Home health care patients with acute infections have an increased death rate from sepsis and severe peripheral infections. They also may have a decreased ability to perceive pain or perform self-care. Patients with chronic diseases, poor nutrition, or an inability to perform self-care are at increased risk for infection and impaired healing. Conditions that may result in the need for acute interventions in the home health care population include the following[8]:

- Airway infections in the immunocompromised patient
- Delayed healing and increased peripheral infection from poor peripheral perfusion
- Skin breakdown and peripheral infections from immobility or sedentary lifestyle
- Infection and sepsis from implanted medical devices
- Wounds and incisions
- Abscesses
- Cellulitis

OPEN WOUNDS

Patients with open wounds who are discharged to home health care may have a variety of dressings, wound packings, and drains that permit drainage of fluid or air. They also may have a variety of wound closure devices (Box 52-6). (Dressings, packings, and wound closure devices can become contaminated; drains can become occluded or displaced.) Wound healing greatly depends on wound management. The patient must be made aware of the importance of taking all prescribed medications (especially antibiotics). The patient also should be informed of the importance of completing all wound care procedures. Wound repair generally is believed to be enhanced by the following:

- Moist environment
- Wound bed free of necrotic tissue, eschar, and environmental contamination or infection
- Adequate blood supply to meet metabolic demands for tissue generation
- Sufficient oxygen and nutrition for cellular metabolism and tissue generation

GENERAL PRINCIPLES IN WOUND CARE MANAGEMENT

Wound care requires assessment of the wound and the surrounding tissues. It also requires evaluation for infection or sepsis. General principles in wound care management include an assessment for the following[9]:

1. Location and size of wound.
2. Color of the wound bed. A red or pink granular wound bed indicates healing. A green, yellow, or black wound bed suggests infection or necrosis (tissue death).
3. Drainage. Clear or blood-tinged drainage is common in a healing wound. Green or yellow drainage suggests infection.
4. Wound odor. A sweet smell may indicate decay. A foul smell may indicate infection.
5. Surrounding skin. The paramedic should assess the skin for redness, inflammation, or signs of tissue breakdown. If the dressing is wet or contaminated, the paramedic should change it after wound evaluation. Medical direction may advise cleaning the wound with normal saline and/or antiseptic solution before redressing it. The debridement of necrotic tissue may be required. Mechanical debridement is achieved by gently rubbing the tissue with a gauze pad moistened with sterile, normal saline. Some patients may need transport for physician evaluation if severe infection or sepsis is suspected.

BOX 52-6 Sampling of Wound Care Devices Found in Home Health Care Patients

Dressings and Wound Packing Material
Combination dressings
Cotton dressings (gauze)
Exudate absorptive dressings
Foam dressings
Hydrocolloid dressings
Hydrogel dressings
Hydrophilic powder dressings
Impregnated cotton dressings
Paste bandages
Transparent film (adhesive or nonadhesive)

Drains
Jackson-Pratt drains
Penrose drains

Wound Closure Techniques
Skin adhesive
Staples
Sutures
Tape
Wires

Maternal/Child Conditions

In the early 1990s, many insurance companies began paying only for 24-hour hospital stays for uncomplicated vaginal childbirth. (These sometimes were called "drive-by deliveries.") In the wake of complaints about inadequate care, states began passing laws in 1995 and 1996. These laws required insurance to pay for 52-hour stays. A similar federal law was passed in 1996. This law took effect in January 1998 and became a Final Rule in 2009. Under this law, health plans must cover hospital stays of at least 48 hours for women who give birth naturally and 96 hours following a cesarean delivery.[10] Problems that may be

encountered when these patient groups return to the home health care setting include the following:

- Postpartum pathophysiologies (e.g., hemorrhage, infection, and pulmonary embolism)
- Postpartum depression
- Septicemia in the newborn
- Infantile apnea
- Failure to thrive
- Sudden infant death syndrome

POSTPARTUM PATHOPHYSIOLOGIES

Postpartum pathophysiologies include hemorrhage, infection, and pulmonary embolism. (Acute interventions for these patients are presented in Chapter 46) Postpartum hemorrhage occurs in about 5% of all deliveries. It frequently takes place within the first few hours after delivery, but it can be delayed up to 6 weeks.[7] Causes of postpartum hemorrhage include incomplete contraction of uterine muscle fibers, retained pieces of placenta or membranes in the uterus, and vaginal or cervical tears during delivery (which are rare).

Postpartum infection affects 2% to 8% of all pregnancies.[7] (The most common infection is endometritis.) The condition occurs when bacteria grow and invade the uterus or other tissues along the birth canal. The symptoms usually develop on the second or third day after delivery. Fever and abdominal pain are the most common signs of infection.

Pulmonary embolism during pregnancy, labor, or the postpartum period is one of the most common causes of maternal death. The embolus often results from a blood clot in the pelvic circulation; it more commonly is associated with cesarean section than with vaginal delivery.

CRITICAL THINKING

A mother is having a postpartum complication that requires urgent transport. What will you do with the baby if they are home alone?

POSTPARTUM DEPRESSION

Postpartum depression affects 10% to 15% of mothers. The depression most likely is caused by a combination of sudden hormonal changes and psychological and environmental factors. The disease can be a short-lived attack of mild depression ("baby blues). Or, in contrast, it can manifest as a depressive illness that requires in-hospital supervision. Risk factors for postpartum depression include the following:

- Adverse socioeconomic conditions
- Anxiety
- Complicated pregnancy or delivery
- Fetal complications
- Low self-esteem
- Poor marital adjustment
- Previous episodes of depression
- Recent life stressors

Recognizing and treating postpartum depression is important. The depression can interfere with the bonding between the mother and infant. It also can seriously affect the mother's ability to care for her newborn (Box 52-7). Many women with postpartum depression fear they will harm their babies. They often feel ashamed and guilty for these feelings. Sensitivity to the possibility of depression is crucial and necessary for successful diagnosis and treatment. (Interventions for depression are presented in Chapter 35)

SEPTICEMIA IN THE NEWBORN

As described in Chapter 47, healthy newborns are vulnerable to several conditions that can require hospital treatment. Examples include jaundice that results from physiological immaturity of bilirubin metabolism, dehydration that can lead to serious electrolyte abnormalities, and sepsis. In addition, neonates are highly susceptible to infection because of diminished nonspecific (inflammatory) and specific (humoral) immunity.

Septicemia in the newborn usually is caused by group B streptococci, *Listeria monocytogenes,* or gram-negative enteric organisms (especially *Escherichia coli*).[11] Signs and symptoms of sepsis may be minimal and nonspecific. ("In the newborn, anything can be a sign of anything.") Examples of signs and symptoms of sepsis in the newborn include the following:

BOX 52-7 Signs and Symptoms of Postpartum Depression

Anxiety
Change of appetite (loss of appetite or overindulgence)
Desire to leave or feelings of being trapped
Difficulty making decisions
Excessive concern or lack of concern for baby
Fantasies of disaster or bizarre fears
Fatigue or exhaustion
Fear of harming self or baby
Forgetfulness or memory loss
Hatred of spouse, self, or baby
Hopelessness
Hostility
Inability to care for baby
Increased alcohol consumption or other drug use
Irritability
Lack of interest in previously enjoyed activities
Lack of sexual interest
Loss of hope
Panic attacks
Rapid mood swings
Severe sleep disturbance
Unexplainable crying (in joy or sadness)

- Temperature instability
- Respiratory distress
- Apnea
- Cyanosis
- Gastrointestinal changes (e.g., vomiting, distention, diarrhea, and anorexia)
- Central nervous system features (e.g., irritability, lethargy, and weak suck)

Risk factors for sepsis include prematurity, prolonged rupture of membranes, and chorioamnionitis (an inflammatory reaction in the amniotic membranes caused by bacterial viruses in the amniotic fluid). The diagnosis generally is confirmed after physician evaluation by a positive blood, urine, or cerebrospinal fluid culture.

INFANTILE APNEA

Infantile apnea is defined by the American Academy of Pediatrics as "an unexplained episode of cessation of breathing for 20 seconds or longer, or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, and/or marked hypotonia (diminished tone)."[12] Apnea often reflects the immature respiratory control centers in some infants. Other causes of infantile apnea include the following[13]:

- Metabolic derangements (e.g., hypoglycemia, hypocalcemia, or hypothermia)
- Infection (e.g., sepsis, pneumonia, or meningitis)
- Central nervous system damage (e.g., hemorrhage, hypoxic injury, or seizures)
- Pulmonary disorders (e.g., respiratory distress, hyaline membrane disease, pneumonia, obstruction, or upper respiratory tract abnormalities)
- Intentional poisoning (child abuse)

The paramedic must assess the presence of apnea carefully and document it. Most infants with the diagnosis of apnea will be hospitalized and observed closely. They are observed using electronic apnea monitoring devices. These devices detect changes in thoracic or abdominal movement and heart rate. Managing apnea in these patients may include the home health care use of apnea monitors, oscillating waterbeds, and CPAP with supplemental oxygen. Some patients also may be prescribed respiratory stimulants (e.g., doxapram or methylxanthines).

FAILURE TO THRIVE

Failure to thrive is an abnormally slow rate of growth and development of an infant. It results from conditions that interfere with normal metabolism, appetite, and activity. Causative factors include the following:

- Chromosomal abnormalities
- Major organ system defects that lead to deficiency or malfunction
- Systemic disease or acute illness
- Physical deprivation (primarily malnutrition related to insufficient breast milk, poverty, or poor knowledge of nutrition)
- Various psychosocial factors (e.g., maternal deprivation)

SHOW ME THE EVIDENCE

Researchers in Los Angeles County conducted this retrospective cohort outcome study to assess causes of 9-1-1 activation for apparent life-threatening events (ALTEs) in infants less than 12 months of age. In these cases the call was initiated for apnea or change in skin color or muscle tone. The mean age of the 60 infants enrolled was 3 months, and 83.3% of the infants did not appear to be in distress. However, the following conditions were identified in the overall group: pneumonia or bronchiolitis (12%), seizure (8%), sepsis (7%), intracranial hemorrhage (3%), bacterial meningitis (2%), dehydration (2%) and severe anemia (2%). Of the study group, two patients were not transported and one was subsequently admitted for failure to thrive. Of those transported to the ED, one was discharged and later readmitted with an intracranial hemorrhage related to child abuse. The authors conclude that when EMS is called for an ALTE the infant should be transported for a thorough medical evaluation.

From Stratton S, Taves A, Lewis R, et al: Apparent life-threatening events in infants: high risk in the out-of-hospital environment, *Ann Emerg Med* 43(6):711-717, 2004, doi: 10.1016/j.annemergmed.2003.10.038.

Failure to thrive can result in permanent and irreversible retardation of physical, mental, or social development. Any suspicions of failure to thrive should be documented carefully. The paramedic should report these suspicions to medical direction as well.

WELL-BABY CARE

Some infants and children have periodic health assessments through well-baby care programs. These programs specialize in medical supervision and services for healthy infants. Well-baby care promotes optimal physical, emotional, and intellectual growth and development. Such health care measures include the following:

- Routine immunizations to prevent disease
- Screening procedures for early detection and treatment of illness
- Parental guidance and instruction in proper nutrition, injury prevention, and specific care and rearing of the child at various stages of development

The recommended preventative health care schedule for children who are developing normally is monthly for the first 6 months of life, every 2 months until 1 year of age, every 3 months during the second year, and every 6 months during the third year, followed by annual visits. Well-baby care may be provided in a clinic ("well-baby clinics"), a physician's office, the office of a community health nursing center, or a school. Nurses or nurse practitioners often provide the care in these programs.

Hospice/Palliative Care

In 2006 **hospice** care served more than 1 million patients throughout the United States.[3] Hospice services include supportive social, emotional, and spiritual services for the

BOX 52-8 Essential Elements of a Palliative Care Program

Palliative care is an accepted specialty of medicine and nursing that concentrates on the total care of patients suffering from any form of terminal illness. Its development, as part of the health care services, is acknowledgment that dying is a normal consequence of living. The support of health professionals and use of modern medical technology can relieve much of the distress normally associated with dying. Essential elements of a palliative care program are the following:

1. The program involves the coordination of care for patients with a terminal illness, at home or in hospital, by a distinct service.
2. The unit of care is the patient and the patient's family, who have the right to make choices and decisions based on an understanding of the illness and to have those decisions respected.
3. The care is provided by an interdisciplinary team.
4. The care is coordinated and delivered by specifically selected and trained nurses.
5. The service is directed by a physician.
6. The emphasis is on control of symptoms, be they physical, social, or emotional.
7. The services are available on a 24 hours a day, 7 days a week, on-call basis.
8. The program must be sensitive to differences in faith and culture and must incorporate the patient's beliefs into decisions on his or her care.
9. Following the death of a patient, the program should ensure that grief support is available for the family. This may be provided by the program itself or by other community services.
10. There is a system of structured staff support and communication.
11. The program is integrated and coordinated with other services, and continuity of care for the patient is provided.
12. Evaluation of the program and its services must be regular. This evaluation may extend into the area of research.
13. The program will provide education for its own staff, other health care providers, and the public.

From Health Canada, Minister of Public Works and Government Services: *Essential elements of a palliative care program,* 2000, Ottawa, Canada.

terminally ill. They also provide support for the patient's family. Hospice care relies on the combined knowledge and skill of a team of professionals. This team includes physicians, nurses, medical social workers, therapists, counselors, chaplains, and volunteers. These persons work together to provide a personal plan of care for each patient and family. The need for hospices likely will continue to rise because of an aging population, the increasing number of persons with acquired immunodeficiency syndrome, and rising health care costs. Medical professionals and the general public are more frequently choosing hospice care over other forms of health care for terminally ill patients. The holistic, patient-family, in-home–centered philosophy is one reason for this.

PALLIATIVE CARE

Palliative care is a unique form of health care. It mainly is directed at providing relief to terminally ill persons through symptom management and pain management. (Palliative care also is called *comfort care.*) This specialty focuses on the needs of the patient and family when a life-threatening illness such as cancer or acquired immunodeficiency syndrome has reached the terminal stage. A chief goal of palliative care is to improve the quality of a person's life as death approaches and to help patients and their families move toward this reality with comfort, reassurance, and strength. Palliative care is not focused on death; it is about specialized care for the living. Well-rounded palliative care programs also address mental health and spiritual needs. Palliative care may be delivered in hospice, home care settings, and hospitals. Medical needs vary depending on the disease that is leading toward death. Thus specialized palliative care programs exist for common conditions such as cancer and acquired immunodeficiency syndrome (Box 52-8).

Emergency medical services and medical direction should work closely with the families and physicians of terminally ill patients in private homes and hospice programs so that they will make the best use of the EMS system. (For instance, they will know when to call 9-1-1.) Even though resuscitation may not be indicated, paramedics may be needed to manage pain, treat acute medical illness or traumatic injury, and provide transport to a hospital. If the patient is not to receive medical intervention to prolong life, the paramedic should provide measures of comfort to the patient and emotional support to family members and loved ones (see Chapter 2).

HOSPICE CARE IN THE HOME SETTING

A patient receiving hospice care may be receiving medication delivery for the relief of pain (e.g., narcotic infusion devices). The patient also will have medical and legal documents such as do not resuscitate orders and advance directives (see Chapter 6). The paramedic should discuss any concerns about effective pain management, overmedication, or interpreting medical or legal documents with medical direction (Box 52-9). It is important to note that not all patients who receive hospice care have "Do Not Resuscitate" orders.

BOX 52-9 Bill of Rights and Responsibilities for Terminally Ill Patients

A. Personal Dignity and Privacy

1. You have the right to considerate, respectful service and care, with full recognition of your personal dignity and individuality, without regard to gender, age, ethnicity, income level, lifestyle, educational background, or spiritual philosophy.
2. You have the right to be dressed as you wish and not to be disrobed or uncovered any longer than necessary for your care.
3. You have the right to privacy and the assurance of confidentiality when receiving care, to refuse visitors or persons not directly involved in your care, and to choose who will receive information about your condition.
4. You have the right to request the presence of a person of your choice during interactions with health care professionals.
5. You have the right to experience all emotions, including anger, sadness, confusion, guilt, depression, impatience, fear, and loss.
6. You have the right to have your end-of-life choices respected by health care professionals, including continuing or discontinuing treatment or requesting medications to self-administer for a hastened death.
7. You have the right to die with your loved ones present and to request the presence of a health care professional, if desired.
8. You have the responsibility to treat your caregiver with respect and to follow their directions when consistent with your wishes.
9. You have the responsibility to make certain that your right to privacy and confidentiality is clearly understood by all parties involved in your care and to communicate to your health care providers when you feel that your rights to privacy and confidentiality are in jeopardy.

B. Informed Participation

1. You have the right to honest, accurate, and understandable information about your current diagnosis and prognosis; the recommended treatment and what it is expected to do; the possibility of success; and the possible risks of complications and side effects, including the probability of their occurrence.
2. You have the right to be informed about alternative forms of treatment, including hospice and home care, and to participate in all decisions affecting your care.
3. You have the right to request and receive a second opinion. When curative care is no longer indicated or desired, you have the right to access palliative care, including pain medication in whatever dosage or schedule you deem necessary to alleviate pain and suffering, even at the risk of hastening death.
4. You have the right to make your own decisions regarding what constitutes your human dignity, as long as you are mentally competent and continue to have basic decision-making capacity. You will be considered mentally competent if you can understand the nature of your condition, the treatment alternatives available, and the likely outcomes of treatment versus nontreatment and can accept responsibility for your decisions.
5. You have the right to access information in your medical record and to know if your health care providers believe that your condition or course of disease will result in death. This information may be needed to make informed decisions about your future.
6. You have the right to forgo eating and drinking naturally in order to permit the process of dying to proceed unencumbered.
7. You have the right and responsibility to complete a directive to physicians (living will).
8. You have the right and responsibility to execute a durable power of attorney for health care so that someone you choose can make health care decisions for you, if needed.

C. Competent Care

1. You have the right to competent medical, nursing, and social services care.
2. You have the right to choose your personal physician and to change your physician at any time.
3. You have the right to know who is responsible for coordinating and supervising your care and to know how to contact that person.
4. You have the right to be informed about who owns and controls the agency or facility involved with your care and the right to referral to institutions, facilities, and practitioners who can provide the care you need.
5. You have the responsibility to choose a primary care physician who is able and willing to carry out your wishes.
6. You have the responsibility to communicate your end-of-life wishes to family, friends, and health care providers.

From Compassion in Dying Federation, Portland, Ore.

SUMMARY

- About 25% of home health care patients have heart and circulatory diseases as their primary diagnosis. Other common diagnoses of home health care patients include cancer, diabetes, and hypertension. Typical EMS calls to a home health care setting may include respiratory failure, cardiac decompensation, septic complications, equipment malfunction, and other medical problems.
- After arrival at the scene of a home health care patient, the scene size-up should include standard precautions, elements of scene safety, and environmental setting. The initial assessment should focus on illness or injury that poses a threat to life. The paramedic should take appropriate measures as indicated.
- Patients with diseases of the respiratory system being cared for at home are at increased risk for airway infections. In addition, the progression of their illnesses may lead to difficulty breathing, making current support equipment inadequate.
- Assessment findings that may require acute interventions in patients with VADs include infection, hemorrhage, hemodynamic compromise from circulatory overload or embolus, obstruction of the vascular device, and catheter damage with leakage of medication.
- Patients with diseases of the digestive or genitourinary system may have medical devices such as urinary catheters or urostomies, indwelling nutritional support devices (e.g., percutaneous endoscopic gastrostomy tube or gastrostomy tube), colostomies, and nasogastric tubes. Acute interventions required for these patients can result from UTI, urosepsis, urinary retention, and problems with gastric emptying or feeding.
- Home health care patients with acute infections have an increased death rate from sepsis and severe peripheral infections. Many also have a decreased ability to perceive pain or perform self-care.
- Maternal/child conditions that one may encounter in the home health care setting during the postpartum period include postpartum hemorrhage, infection, pulmonary embolism, postpartum depression, septicemia in the newborn, infantile apnea, and failure to thrive.
- Hospice services include supportive social, emotional, and spiritual services for the terminally ill. They also provide support for a patient's family. Palliative care is directed mainly at providing relief to a terminally ill person. They do this through symptom and pain management.

CHAPTER

53 Ground and Air Ambulance Operations

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. List standards that govern ambulance performance and specifications.
2. Discuss the tracking of equipment, supplies, and maintenance on an ambulance.
3. Outline the considerations for appropriate stationing of ambulances.
4. Describe measures that can influence safe operation of an ambulance.
5. Identify aeromedical crew members and training.
6. Describe the appropriate use of aeromedical services in the prehospital setting.

KEY TERMS

ambulance A generic term that describes the various land-based emergency vehicles used by emergency medical services (EMS) personnel, including basic and advanced life support units, paramedic units, mobile intensive care units, and others.

fend-off position Positioning the ambulance about 50 feet in front of the scene for safety; diverts and averts oncoming traffic.

KKK A-1822E standards The national standards that provide the foundation of uniformity for the design of ambulance vehicles.

landing zone An area prepared for the landing of an aircraft; generally 100 by 100 feet.

type I ambulance An ambulance design based on the chassis-cabs of light duty pickup trucks.

type II ambulance An ambulance design based on modern passenger/cargo vans.

type III ambulance An ambulance design based on chassis-cabs of light duty vans.

The modern ambulance is more than just a vehicle for transporting a patient to the hospital. Today's ambulance is a well-equipped and efficiently organized vehicle or aircraft. It has advanced communications and technology that bring needed medical supplies, personnel, and advanced life support care to the emergency scene.

(Courtesy Ray Kemp. St. Charles, Mo.)

AMBULANCE STANDARDS

In 1968 the National Academy of Sciences–National Research Council (NAS-NRC) recommended ambulance design standards. These standards included the size, shape, color, electrical systems, and emergency equipment. They led to the development of the federal specifications that

many states now use as ambulance standards. The national standards developed by NAS-NRC and the National Highway Traffic Safety Administration (NHTSA) are known as the **KKK A-1822E standards**. These standards and their revisions provide the basis for uniformity in the design of ambulance vehicles. They cover the three basic ambulance designs: type I, type II, and type III (Figure 53-1). Also, because of the extra weight of equipment used in rescue and emergency care and the space needed for this equipment, the standards include *additional duty* type I-AD and type III-AD (ambulances mounted on large chasses) (Box 53-1). Fire service vehicles (e.g., pumpers, rescue units, and fire trucks) also carry EMS equipment.

The federal standards of design and performance for ambulance vehicles are augmented by other federal standards, state statutes, administrative rules, and city, county, and district ordinances. These influence ambulance design, equipment, and staffing. These additional requirements include the following:

- Air ambulance standards
- Operational staffing standards
- Operational driver standards
- Operational driving standards
- Operational equipment standards

FIGURE 53-1 Basic ambulance designs. **A,** Type I. **B,** Type II. **C,** Type III.

CRITICAL THINKING

Consider your state or regional standards. What do they require for ambulance design, performance, and equipment?

CHECKING AMBULANCES

Completing an equipment and supply checklist at the beginning of every work shift is important. It is essential for safety, patient care, and risk management. It also helps to ensure proper handling and safekeeping of scheduled medications (Figure 53-2). Either paper checklists or special computer software can be used for this purpose. Some equipment (e.g., Glucometers and defibrillators) requires

Box 53-1 Ambulance Types

- **Type I ambulances** are based on the chassis-cabs of light duty pickup trucks.
- **Type II ambulances** are based on modern passenger/cargo vans.
- **Type III ambulances** are based on chassis-cabs of light duty vans.

There are also *AD* (additional duty) versions of both type I and type III designs. They include large-chassis vehicles that allow for increased storage and payload capacity.

Telemetry equipment

routine maintenance, testing, and cleaning (Box 53-2). This ensures safe and effective operation. Some disposable items such as medications, electrocardiogram (ECG) patches, defibrillation pads, and glucose check strips expire and should be checked monthly to ensure they are still within their appropriate shelf life.

The procedures for vehicle maintenance vary by EMS agency. These procedures are in place to improve the vehicles' reliability and extended use of life. The paramedic should follow all agency guidelines and procedures for checking vehicles, equipment, and supplies.

AMBULANCE STATIONING

In the 1970s, the methods for estimating the need for ambulance service and where they should be stationed in a community were based on the availability of ambulances. They also were based on the average response time to the emergency scene. Methods for estimating needs have changed. They have shifted toward determining the percentage of compliance (*standard of reliability*) in providing EMS services within time frames that meet national guidelines. (For example, the American Heart Association reports that most neuro-intact survivors are resuscitated within 5 to 8 minutes of cardiac arrest. Therefore, defibrillation and advanced cardiac life support should be available within that time frame[1]) Factors that may affect an EMS system's standard of reliability include:

- Geographical area
- Population and patient demand
- Traffic conditions
- Time of day
- Appropriate placement of emergency vehicles

Strategies for ambulance stationing often are based on areas with the highest volume of calls (*peak load*). These strategies take into consideration the day of the week and the time of day. Computers, global positioning systems, and other technology may be used to formalize strategic unit deployment and reduce response times. Deployment strategies vary by EMS agency. They range from simple deployment of one vehicle stationed in the middle of a response area to comprehensive automated deployment plans for each hour of the day and each day of the week. The comprehensive plans include "mini-deployment" plans within each hour, depending on the number of ambulances left in the system (*system status management*). The optimal deployment system usually is a compromise between these two extremes.[2]

SAFE AMBULANCE OPERATION

Between 1991 and 2000, there were 300 fatal crashes involving occupied ambulances. These resulted in the deaths of 82 ambulance occupants and 275 occupants of other vehicles and pedestrians.[3] In addition, it has been reported that death for EMS employees attributable to transport-related fatalities is more than double that of other U.S. workers (Table 53-1).[4]

Safe operation of ambulances is crucial. It is essential for the safety of patients, the EMS crew, and others in the vicinity of a response. Most EMS agencies require their personnel to take an emergency driving course. Many also are required to undergo periodic evaluations of their emergency driving skills and knowledge (Box 53-3). In addition to the size and weight of the emergency vehicle and the driver's experience, a number of factors influence safe operation of an ambulance. These include the following:

- Appropriate use of personal restraints
- Appropriate use of escorts
- Environmental conditions
- Appropriate use of warning devices
- Proceeding safely through intersections
- Parking at the emergency scene
- Operating with due regard for the safety of others
- Safely moving a patient into and out of the ambulance

CRITICAL THINKING

How do you think you would feel if you struck another vehicle while driving an ambulance?

Appropriate Use of Personal Restraints

According to the National Safety Council there were more than 1800 ambulance crashes and more than 2700 injuries related to those crashes in 2008.[5] Many of these injuries might have been prevented with the appropriate use of personal restraints. Many EMS agencies incorporate into their standard procedures the following guidelines to protect patients, passengers, and EMS personnel:

- All operators and front-seat passengers of ambulance service vehicles must use seat belts when the vehicle is in motion.

TABLE 53-1 Crashes Involving Emergency Vehicles, United States, 2008

	AMBULANCE		FIRE TRUCK/CAR		POLICE CAR	
	Total	Emergency Use	Total	Emergency Use	Total	Emergency Use
Emergency vehicles in fatal crashes	27	14	24	13	103	52
Emergency vehicles in injury crashes	1,384	873	396	344	7,483	4,440
Emergency vehicles in all crashes	**5,998**	**3,136**	**2,719**	**2,008**	**28,994**	**11,467**
Emergency vehicle drivers killed	1	0	5	4	31	14

National Safety Council analysis of data from National Highway Traffic Safety Administration Fatality Analysis Reporting System (FARS) and General Estimates System (GES). Emergency lights and/or sirens in use.

Box 53-3 Guidelines for Safe Ambulance Driving

1. Be tolerant and observant of other motorists and pedestrians.
2. Always use occupant safety restraints (both driver and passenger).
3. Be familiar with the characteristics of the emergency vehicle.
4. Be alert to changes in weather and road conditions.
5. Exercise caution in the use of audible and visual warning devices.
6. Drive within the speed limit except in circumstances allowed by law.
7. Select the fastest and most appropriate route to and from the incident scene.
8. Maintain a safe following distance.
9. Drive with due regard for the safety of all others.
10. Always drive in a manner consistent with managing acceptable levels of risk.

- Any patient on a stretcher must be secured at all times when the vehicle is in motion or the stretcher is being moved.
- All equipment in the ambulance must be secured to prevent it from becoming a "missile" during a crash.
- All EMS personnel in the patient compartment must use seat belts when not attending to a patient and when the vehicle is in motion.
- All non-EMS personnel in the patient compartment must use seat belts when not attending to a patient and when the vehicle is in motion.
- Whenever possible, if a child is being transported and the child's own restraining device (child safety seat) is available, the child should be placed in the device and belted into the ambulance seat.
- If the child is the patient, he or she should be appropriately secured onto the stretcher with straps or a child seat.

Finally, the emergency vehicle should not be put in motion until the driver, EMS personnel, and all passengers are seated safely and wearing seat belts. (Every occupant of an emergency vehicle needs to be belted.) In addition, the emergency vehicle should be completely stopped before anyone unbuckles their seat belts and exits the ambulance.

Appropriate Use of Escorts

Police escorts during an emergency response can be dangerous and should be used sparingly. Collisions can occur as a result of confusion when motorists in the area may wrongly assume that only one emergency vehicle is on the road. As a rule, paramedics should use escorts only when the EMS crew is responding to a scene in an unfamiliar area. Even then the EMS driver should keep a safe distance between the ambulance and the escort. The use of audible and visual warning devices during escorts should be guided by local protocol. If the paramedic uses audible and visual warning devices, the ambulance and police escort should use different siren tones (per protocol). This alerts other motorists to the fact that a second emergency vehicle is in the area.

Some communities use a *tiered response system*. In such a system, several units and sometimes several agencies

respond to emergency calls. The tiered response system allows for a safer emergency response. It also helps to ensure that the proper resources and personnel are available during an emergency. For example, a fire service unit staffed with basic-level EMTs responds to a car crash with full use of audible and visual warning devices. The EMTs determine that the patient's injury is minor. They request a basic life support (BLS) ambulance (either public or private) to respond to the scene in a nonemergency mode (at normal speed and without warning devices). The BLS ambulance assumes care and provides transport to the hospital.

Environmental Conditions

Poor weather conditions can create significant dangers when paramedics respond to a call. Factors that can affect safe ambulance operation include road and weather conditions, such as fog and heavy rain that reduce visibility, and slippery pavement caused by ice, snow, mud, oil, or water that can cause the ambulance to hydroplane.

When poor environmental conditions are present, the driver of the emergency vehicle should proceed at safe speeds. These speeds should be appropriate for the road and weather conditions. The driver should use low-beam headlights during all responses. This increases visibility for the EMS crew and makes it easier for other motorists to recognize the ambulance.

Dry roads and clear weather do not guarantee a safe response. About 69% of all emergency vehicle crashes occur on dry roads, and about 77% occur during clear weather.[5]

Appropriate Use of Warning Devices

As noted before, during an emergency response and patient transport, lights and sirens should be used according to protocol and state motor vehicle laws. Most EMS agencies authorize the use of these devices during all responses when the cause or severity of the emergency is unknown. In these cases, audible and visual warning devices should be used simultaneously. (If one is indicated, so is the other.) The use of warning devices during patient transport usually is reserved for patients with limb- or life-threatening illness or injury.

When using lights and sirens, paramedics should keep in mind that motorists who drive with the car windows rolled up or who are using an audio device, air conditioning, or the heating system may not be able to hear the sirens or air horns. Therefore the EMS crew should always proceed with caution. They should never assume that the vehicle's lights, sirens, and air horns provide an absolute right-of-way or privileged immunity to proceed. It should be noted that some state and motor vehicle laws grant privileged immunity only to drivers of emergency vehicles that respond using *all* available lights and sirens. Paramedics should be familiar with the motor vehicle laws in their state that cover an emergency response.

CRITICAL THINKING

In what situations do you think the crew member driving an ambulance may be tempted to drive too fast?

Proceeding Safely Through Intersections

Approximately 53% of ambulance crashes in the United States occur in intersections where an ambulance proceeds against a red light.[6] It is important that the driver of an emergency vehicle stop at all controlled intersections. The driver should try to make eye contact with all motorists before going through the intersection. Another safety measure for going through an intersection is making a secondary stop to assess the intersection before crossing. A final measure is using the siren's "yelp" mode or air horn to alert nearby traffic. Some emergency vehicles now have traffic signal preempting devices. These devices can change the traffic light at an intersection to green (in the ambulance's direction of travel).

SHOW ME THE EVIDENCE

These authors examined data from ambulance crashes in Denver from 1989 to 1997. Within that period there were 206 collisions, with 192 occurring when the ambulance was moving and the other 14 occurring while it was parked. Of that group, 39 (18%) resulted in injury or fatality to 81 individuals. There were two deaths, both civilian drivers in the study group. Factors that predicted injury were T-bone collision, intersection collision, and alcohol intoxication of the civilian driver. In 71% of crashes the emergency vehicle driver had a record of multiple crashes. Based on their findings the authors emphasize the need to visually ensure the intersection is clear before proceeding into it, to make eye contact with other drivers, and to use visual and audible warning signals.

From Custalow C, Gravitz C: Emergency medical vehicle collisions and potential for prevention, *PEC* 8(2):175-184, 2004.

Parking at the Emergency Scene

When parking the ambulance at a scene, the paramedic should make sure that the vehicle's location allows for traffic flow around the area. If law enforcement and fire service personnel have secured the scene, the paramedic should position the ambulance about 100 feet past the scene. (This should be on the same side of the road.) The ambulance should be positioned uphill (about 200 feet). It also should be positioned upwind if the presence of hazardous materials is suspected. If law enforcement and fire service personnel have not secured the scene, the paramedic should position the ambulance about 50 feet in front of the scene. This is the **fend-off position** (Figure 53-3). In this position, the emergency vehicle deflects and averts from the scene other vehicles that may strike the ambulance or providers.

Other safety precautions a paramedic can take when parking an ambulance at an emergency scene include the following[7]:

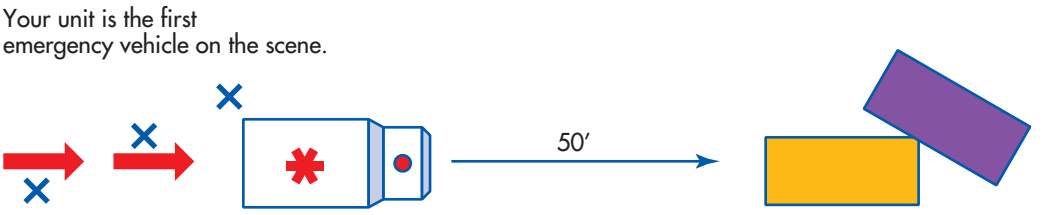

FIGURE 53-3 The "fend-off" position.

- Emergency lighting should be used when the vehicle blocks traffic.
- The parking brake should be set. (Setting the parking brake before putting the transmission in "Park" allows the entire weight of the vehicle to be shared between the emergency brake and the transmission.)
- Another person should be asked to help guide the vehicle when it is backing up. (This person should be visible in the vehicle mirrors at all times while the ambulance is slowly backing up.)
- Reflective gear should be worn when paramedics work near the roadway.

When choosing a parking area for the ambulance, the paramedic also should consider the possibility of collapsing structures, fires, explosive hazards, and downed electrical wires.

Operating With Due Regard for the Safety of All Others

Most states allow privileges for drivers of emergency vehicles. For instance, they are allowed to drive slightly above the speed limit. They also are allowed to proceed through a controlled intersection (after a stop) during an emergency response (Box 53-4). However, these privileges must take into consideration the safety of all people using the roads. This "due regard for the safety of all others" carries legal responsibility. The paramedic and the EMS agency can incur liability if damage, injury, or death results from failure to observe this principle (see Chapter 6). The paramedic should be aware of local and state laws and regulations that cover the operation of an emergency vehicle.

NOTE
An ambulance service is 10 times more likely to be sued for a motor vehicle crash than for a medical error.[8]

LOOK AGAIN
See Chapter 6: Medical and Legal Issues, pp. 101-102.

Safely Moving a Patient Into and Out of an Ambulance

After initial stabilization at the scene, the patient must be packaged and safely placed in the emergency vehicle for transport. The paramedic crew should use safe lifting practices (see Chapter 2). These techniques help to prevent personal injury. They also ensure that the patient is positioned securely on the ambulance stretcher. The patient compartment of the ambulance is equipped with locking devices. These prevent the stretcher from moving while the ambulance is in motion. Unnecessary equipment should be stowed before transport. Also, objects such as monitors should be secured in a locking device to minimize the risk of injuries in a collision. All those traveling in the ambulance (except for the paramedic providing patient care) should have their personal restraints securely fastened. Before the vehicle leaves the scene, the driver of the ambulance should be signaled that it is safe to put the vehicle in motion.

NOTE
Whenever possible, children should be transported secured in a proper child safety seat. Except in the most critical cases, care can be delivered effectively when the child is restrained in this way.

During transport, the patient should be closely monitored for any changes in status. If emergency care is required while the ambulance is in motion (e.g., intubation, defibrillation), the driver of the vehicle should be advised to slow the vehicle. When possible, the driver should safely park the vehicle and stay parked until the procedure has been successfully performed.

Upon arrival at the hospital, the ambulance should come to a full stop. At that point, personal restraints can be removed and the vehicle can be exited. All patient care equipment must be secured before the stretcher is released from the locking device. (This includes, for example, immobilization devices, intravenous lines, and airway adjuncts.) Using safe lifting techniques, the patient's stretcher should be removed from the ambulance. The patient should be appropriately transferred to health care personnel at the facility.

AEROMEDICAL TRANSPORTATION

Like many other aspects of prehospital emergency care, air evacuation is rooted in military history. During the Prussian siege of Paris in 1870, soldiers and civilians were evacuated by a hot-air balloon. In 1928 a Marine pilot used an engine-powered aircraft to evacuate the wounded in

Box 53-4 The Two-Second Rule and Braking Distance Chart

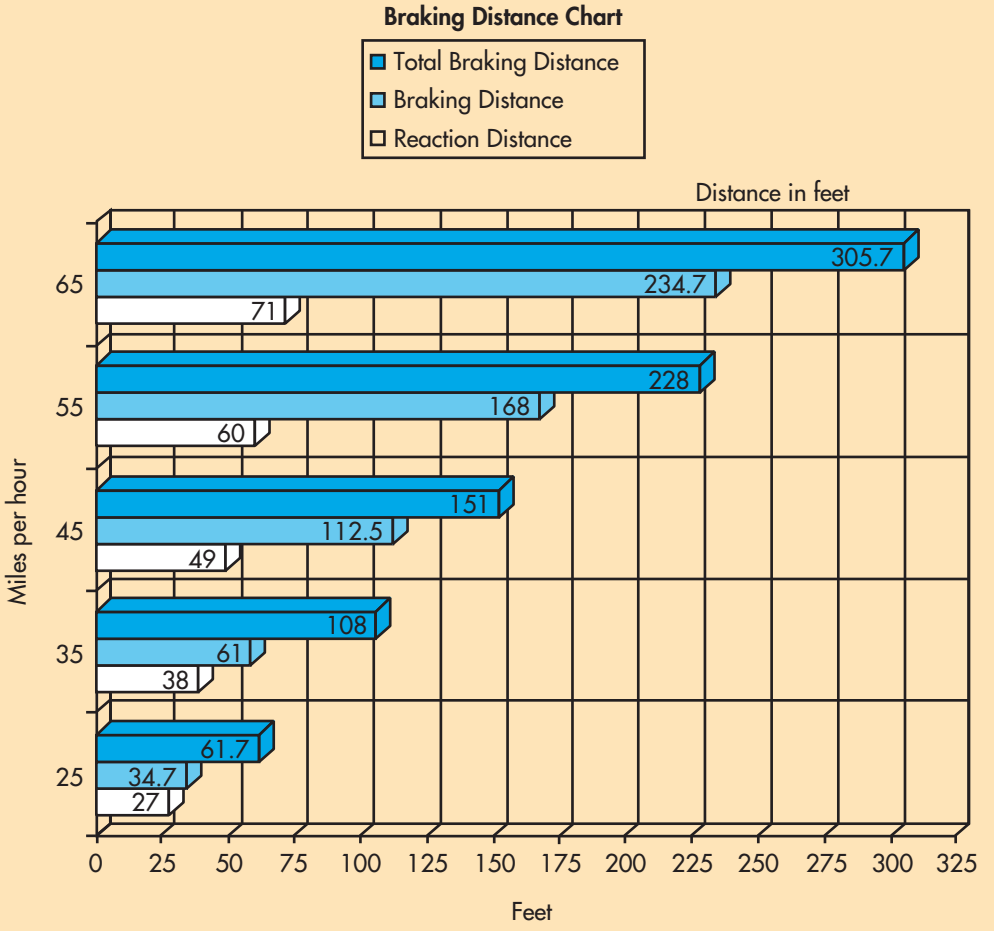
Most rear-end collisions are caused by drivers who follow too closely behind the vehicle in front of them. Therefore it is important that the paramedic keep enough space (following distance) between the emergency vehicle and the vehicle in front to avoid a crash if the car in front brakes suddenly.

A quick method for gauging the recommended distance is the 2-second rule. It works like this:

1. You (the driver of the emergency vehicle) note an object by the side of the road (e.g., a tree or sign) that the vehicle in front of you will soon pass.
2. Count "one thousand and one, one thousand and two." If you reach the object before the phrase is complete, you are too close to the vehicle in front of you.
3. This rule applies with good road and weather conditions. If the road and weather conditions are not good, the following distance should be increased to a 4- or 5-second count.

Braking distance is based on average reaction time, average vehicle weight, average road conditions, and average brakes. Wet roadways, poor brakes, poor tires, heavy vehicle weight, and poor reaction times lengthen the braking distance. The following chart shows braking distance at various speeds.

NOTE: Larger emergency vehicles (e.g., those mounted on a freightliner-type chassis) have different handling characteristics and longer braking and stopping distances than conventional type I, II, or III emergency vehicles.



Miles per hour × 1.5 = feet per second
An average reaction time is about ¾ or 0.75 of a second

From Los Angeles Unified School District Police Department: *Braking distance chart,* Los Angeles, Calif, 1999, Los Angeles Police Department.

Nicaragua.[9] However, the first full-scale use of aircraft for medical evacuation did not occur until 1950, during the Korean conflict. The experience gained in Korea formed the basis for helicopter rescue in Vietnam. In Vietnam, nearly 1 million casualties were transported by air. In the more recent military confrontations involving the United States in Panama, Grenada, and the Middle East, massive advanced aeromedical support capabilities and plans were on site before the conflicts began. Response times of 25 minutes were achieved for air evacuation of wounded soldiers in the Persian Gulf. Field surgical units were set up to handle the 1500 to 3000 casualties estimated to occur within the first 24 hours of the war; most of the injured soldiers arrived by air transportation.[10]

Currently, more than 390 air medical service programs using fixed wing aircraft (Figure 53-4) and/or rotary wing (helicopter) aircraft (Figure 53-5) have been established throughout the United States.[11] Fixed wing aircraft services are not usually as high profile as helicopters. Often they are used for interhospital transfer of patients and to deliver organs for transplantation when the distance is greater than 100 miles.

FIGURE 53-5 Rotary wing aircraft. (Courtesy Air Rescue Consortium of Hospitals, St. Louis, Mo.)

Aeromedical Crew Members and Training

The staffing of air ambulances includes a pilot and various health care professionals. (These may include EMTs, paramedics, respiratory therapists, nurses, physicians, and others.) Air ambulance crews undergo specialized training in flight physiology and advanced medical equipment and procedures. The American College of Surgeons (ACS) Committee on Trauma and the Association of Air Medical Services have established guidelines for personnel qualifications. The Department of Transportation (DOT) and the NHTSA funded the development of the *Air Medical Crew National Standard Curriculum* in 1988. Many flight programs have used this curriculum to teach flight physiology, aircraft components and construction, safety regulations, aviation and navigation terminology, and operational safety (Box 53-5).

NOTE

According to the National Transportation Safety Board, there were 55 EMS-related aviation accidents (fatal and nonfatal) in the United States between January 2002 and January 2005. It was reported that "many of these could have been prevented with simple corrective actions, including oversight, flight risk evaluations, improved dispatch procedures, and the incorporation of available technologies."[12] In 2008, 29 people died in air ambulances crashes.[13]

Use of Aeromedical Services

The local EMS system develops the criteria for requesting aeromedical services to the scene of an emergency. As described in Chapter 37, the paramedic generally should consider air transport when emergency personnel have determined that one or more of the following is a factor:

Box 53-5 Selected Organizations Associated With the Air Medical Industry

- Air Medical Physicians Association (AMPA)
- Association of Air Medical Services (AAMS)
- Commission on Accreditation of Air Medical Services (CAAMS)
- Commission on the Accreditation of Medical Transport Services (CAMTS)
- International Association of Flight Paramedics (IAFP)
- International Society of Air Medical Services (Australasia) (ISAS)
- National Association of Air Medical Communications Specialists (NAACS)
- National EMS Pilots Association (NEMSPA)
- National Flight Nurses Association (NFNA)
- National Flight Paramedics Association (NFPA)
- Shock Trauma Air Rescue Society (STARS)

- The time needed to transport a patient by ground to an appropriate facility would pose a threat to the patient's survival and recovery.
- Weather, road, or traffic conditions would seriously delay the patient's access to advanced life support.
- Critical care personnel and specialized equipment are needed to care for the patient adequately during transport (Box 53-6).

LOOK AGAIN

See Chapter 37: Trauma Overview and Mechanism of Injury, pp. 1079-1081.

NOTIFICATION OF AEROMEDICAL SERVICES

Most aeromedical transportation providers accept requests for medical services from physicians, EMS and fire service personnel, or other on-scene public service agency personnel. Local and state guidelines cover aeromedical activation. The paramedic should consult with medical direction and follow all state laws, administrative rules, and city, county, and district ordinances and standards when using aeromedical services. When notified that an aeromedical response may be needed, the flight crews of some services move to the aircraft so that they are ready for the flight. (They are placed on *stand-by*.) If paramedics determine that the situation does not require an aeromedical response, the appropriate agency should be notified as soon as possible. This makes the crew available for other flights.

Box 53-6 Advantages and Disadvantages of Air Medical Services

Advantages

- Transports are rapid and usually smooth.
- Access to accident sites is quick.
- Traffic, trains, mountains, ship canals, and other barriers can be avoided.
- Travel is still possible when road conditions are poor.
- Sophisticated communication equipment is available.
- Quality of care is improved in rural areas where only basic life support is available.

Disadvantages

- In urban settings, ground ambulances are usually faster within a 30-mile range.
- If the helicopter is on another flight, no other aircraft may be available.
- Inclement weather may prevent the aircraft from traveling.
- Space and weight restrictions may limit access to the patient and restrict the crew, patients, and equipment that can be carried.
- Helicopter transports are more expensive than transports by ground ambulance.
- Helicopter crashes have fewer survivors.

If paramedics request air service for medical, trauma, or search and rescue events, they should advise the flight crew of the type of emergency response, the number of patients, the location of a **landing zone** (LZ), and any prominent landmarks and hazards (e.g., vertical structures or power lines). Direct ground to air communication must be available between a designated LZ officer and the aeromedical staff on the responding aircraft. If possible, the fire department should be dispatched to the LZ to provide fire-suppression support. Law enforcement personnel also should be available for securing the scene.

LANDING SITE PREPARATION

The space requirement for a helicopter LZ generally is 100 by 100 feet. The ideal LZ should have no vertical structures that can hamper takeoff or landing. It should be relatively flat and free of high grass, crops, or other factors that can conceal uneven terrain or hinder access. The LZ also should be free of debris that can injure people or damage structures or the helicopter. If patients are close to the LZ, the paramedic should provide protection by covering wounds and eyes. Rescue personnel close to the landing site should wear protective equipment such as reflective clothing, helmets with lowered face shields, and safety glasses.

If a nighttime LZ is used, emergency vehicles with lighted bar lights should be situated at the perimeters of the LZ. If white lights are used, they should be directed *down* to the center of the LZ as spotlights because white lights (spotlights or headlights) directed toward the aircraft can temporarily blind the pilot. Traffic cones with reflectors can help identify the LZ. Flares should not be used because the helicopter rotor wash can blow the flares from the site and create a fire hazard. A fire crew should wet down dusty LZs, especially if vehicle traffic is moving in the area. This prevents the pilot and vehicle drivers from being temporarily blinded by the dust.

Helpful radio communications with the pilot include notification of wind direction and any possible obstructions or hazards. Wind direction can be determined by throwing grass or dirt, by wetting a finger, or by observing smoke patterns from smoke canisters. If hazardous materials are present, the paramedic should advise the flight crew of the substance, the location of the hazardous materials site, and the possibility of patient contamination. The pilot generally does not land the aircraft until all danger of fire or explosion has been eliminated. (The pilot has the final decision to use or change an LZ to another location.) When the aircraft is coming in to land, one emergency responder should stand facing the LZ so that the pilot will see the landing area. LZ hand signals that may be useful to the pilot are shown in Figure 53-6.

SAFETY PRECAUTIONS

Everyone should be clear of the landing area during takeoffs and landings. A distance of 100 to 200 feet is best (Figure 53-7). In addition, paramedics should take the following precautions[14]:

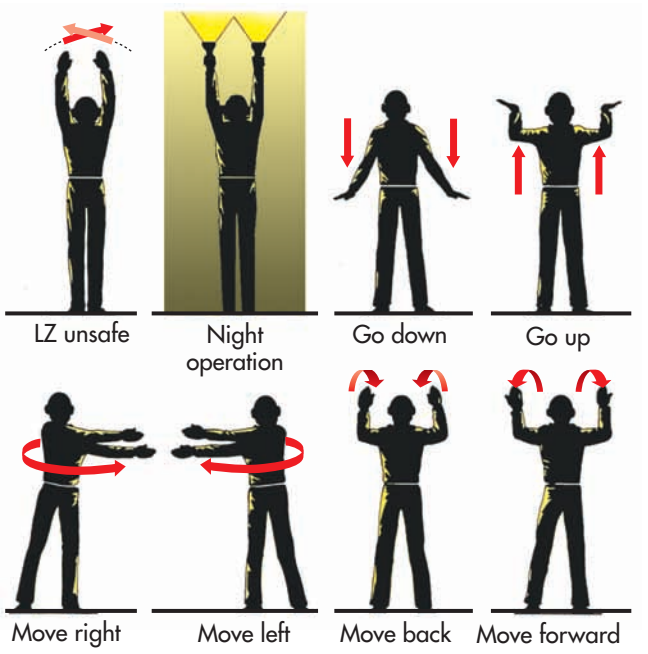

FIGURE 53-6 Landing zone hand signals.

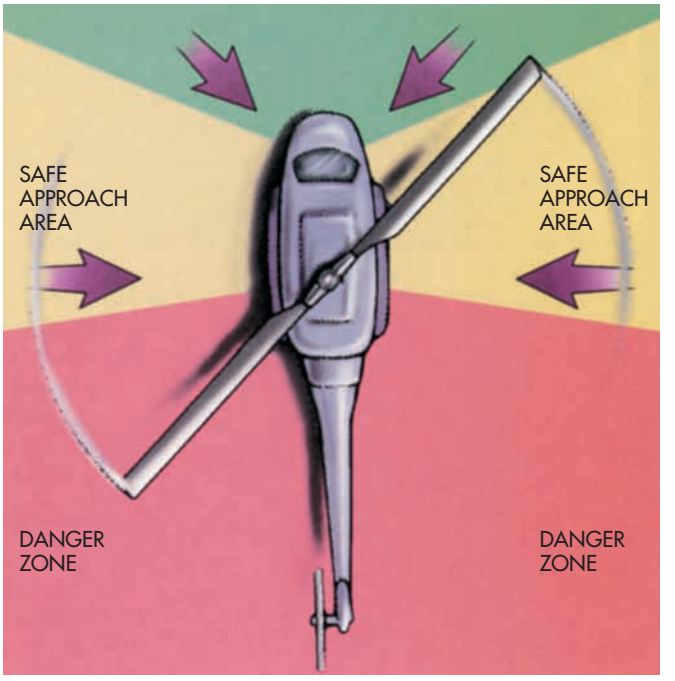

FIGURE 53-7 Safe-approach zones.

- Never allow ground personnel to approach the helicopter unless the pilot or flight crew asks them to do so.
- Allow only necessary personnel to help load or unload patients.
- Secure any loose objects or clothing that could be blown by rotor downwash (e.g., stretcher, sheets, or blankets).
- Do not allow smoking.
- After the aircraft is parked, make eye contact with the pilot, move to the front beyond the perimeter of the rotor blades, and *wait for a signal from the pilot* to approach.
- Approach the helicopter in a crouched position, staying in view of the pilot or other crew members.
- *Never approach the rear of the aircraft from any direction.* The tail rotors on most aircraft are near the ground and spin at 3400 revolutions per minute. This makes them virtually invisible. Tail rotor injuries are often fatal.
- Carry long objects horizontally and no higher than waist high.
- Depart the helicopter from the front and within view of the pilot.

PATIENT PREPARATION

Preparing a patient for air transport requires special measures. Some medical procedures must be done *before* the patient is loaded into the aircraft. For example, the patient's airway should be established and secured before loading. Also, application of a traction splint must be done before loading. Special equipment (e.g., automated chest compression devices) must be positioned according to the aircraft's configuration. Most aeromedical crews perform a brief patient assessment before liftoff. They do so to verify the patient's condition. Patients who are combative may require physical or chemical restraint during flight.

CRITICAL THINKING

How do you think an alert patient would feel while waiting for helicopter transportation?

SUMMARY

- The federal KKK A-1822 standards provide the foundation of uniformity for the design of ambulance vehicles.
- Completing an equipment and supply checklist at the start of every work shift is important. It is essential for safety, patient care, and risk management. It also helps to ensure proper handling and safekeeping of scheduled medications.
- The methods for estimating ambulance service needs and placement in a community have changed. Compliance in providing EMS services within time frames that meet national standards is the method that now is commonly used.
- Factors that influence safe ambulance operation include proper use of escorts, awareness of environmental conditions, proper use of warning devices, proceeding

Continued

safely through intersections, correct parking at the emergency scene, and operating with due regard for the safety of all others. Moving patients safely in and out of the ambulance is also essential.

- The staffing of air ambulances includes a pilot and various health care professionals. These individuals undergo specialized training in flight physiology and the use of special medical equipment and procedures.
- When paramedics request aeromedical service, the flight crew should be advised of the type of emergency response, the number of patients, and the location of the landing zone as well as the presence of any prominent landmarks and hazards. Paramedics should always follow strict safety measures during helicopter landings. This helps to prevent injury to air medical crews, ground crews, the patient, and bystanders.

CHAPTER

54 Medical Incident Command

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Outline the components that define a major incident.
2. Identify the components of an effective incident command system.
3. Outline the activities of the preplanning, scene management, and postdisaster follow-up phases of an incident.
4. Identify the five major functions of the incident command system.
5. List command responsibilities during a major incident response.
6. Describe the section responsibilities in the incident command system.
7. Identify situations that may be classified as major incidents.
8. Describe the steps necessary to establish and operate the incident command system.
9. Given a major incident, describe the groups and/or divisions that would need to be established and the responsibilities of each.
10. List common problems related to the incident command system and to mass casualty incidents.
11. Outline the principles and technology of triage.
12. Identify resources for the management of critical incident stress.

KEY TERMS

apparatus A vehicle used for fire suppression or rescue; this category does not include staff vehicles.

command The act of directing, ordering, or controlling by virtue of explicit, statutory, regulatory, or delegated authority.

command post The area from which command directs operations for an incident.

communications center A facility used to dispatch emergency equipment and coordinate communications between field units and personnel.

disaster A term that usually is associated with a man-made or natural event that involves damage across a large area or to a community's infrastructure.

disaster management The mobilization of resources and the methods used to meet the needs of a disaster response.

divisions Subdivisions of the incident command system that encompass specific geographical areas of responsibility as deemed necessary by the incident commander.

emergency operations center The main communications center where department heads, government officers and officials, and volunteer agencies gather to coordinate their response to an emergency event.

extrication/rescue group The group or division responsible for managing patients who are trapped at the scene. This involves search, rescue, initial triage, tagging, and treatment before transfer of the patients to the treatment group.

finance/administration section The section responsible for tracking costs and the way reimbursement is handled.

groups Subdivisions of the incident command system that encompass specific functional areas of responsibility as deemed necessary by the incident commander.

incident command system (ICS) A management program designed to control, direct, and coordinate emergency response operations and resources.

incident commander The person assuming command in the incident command system.

infrastructure The fundamental facilities and systems serving a country, city, or area, such as transportation and communication systems, power plants, and schools.

interoperability The ability of multiple organizations to communicate effectively.

lifesaving intervention Lifesaving care such as controlling major hemorrhage, opening the airway, and providing rescue breathing, chest decompression, and auto injector antidotes.

local/regional threshold Refers to when the number of casualties or the nature of the event overwhelms the available resources.

logistics section The section that is responsible for providing supplies and equipment, facilities, services, food, and communications support. The main function of this section is to provide gear and support to the responders.

major incident An event for which available resources are insufficient to manage the nature of the emergency.

mass casualty incident An event for which available resources are insufficient to manage the number of casualties.

medical direction A process of ensuring that actions taken on behalf of ill or injured people are medically appropriate, including prospective, concurrent, and retrospective aspects of emergency medical services quality improvement, hiring, and education.

METTAG system A method of triage that uses the international agreement on color coding and priorities to alert emergency care personnel and staff members of the receiving hospital to the patient's category.

mutual aid An agreement with neighboring emergency agencies to exchange equipment and personnel when necessary.

operations section A section that directs and coordinates all emergency scene operations. It also ensures the safety of all personnel. EMS operation areas generally fall under this section.

planning section The section responsible for providing past, present, and future information about the incident and the status of resources.

postdisaster follow-up An after-action review of an incident that includes the "lessons learned" from the incident; also includes methods of improvement.

preplan The element of preplanning for a major incident that addresses common goals and the specific duties of each group.

preplanning The first phase of preparing for a major incident or disaster.

primary triage Triage performed at the incident site to rapidly categorize patient conditions for treatment.

rehabilitation area A part of the major incident response plans of many fire and EMS agencies. This area usually is set up outside the operational area; allows rescue personnel to get physical and psychological rest.

SALT triage A method of triage that uses Sort-Assess-Life-saving interventions-Treatment and/or Transport to categorize patients.

scene management The development of a strategy to manage the incident scene.

secondary triage The retriaging of patients in a treatment area.

section chiefs The managers or supervisors of ICS sections.

single command The type of command where one person is responsible for the entire operation.

SMART tag system A method of triage that uses five color triage coding cards that have military bar codes for tracking patients.

span of control The number of people one section chief can manage effectively.

staging area A designated area where incident-assigned vehicles are directed and held until needed.

standard operating procedures Established procedures and guidelines to be carried out in a certain operation or a given situation.

START field guide A method of triage that focuses on the patient's ability to walk, respiratory effort, pulses/perfusion, and mental status.

support branch The section that is in charge of gathering and distributing equipment and supplies at a major incident.

tracking log A system of recordkeeping that includes patient identification, transporting unit, patient priority, and hospital destination.

transportation group The group that communicates with the receiving hospitals, ambulances, and air medical services for patient transport during a major incident.

treatment group The group that provides advanced care and stabilization until the patients are transported to a medical facility. Most paramedics and hospital personnel are assigned to this group.

triage A method used to sort or categorize patients according to severity of injury.

triage tagging system A system of tags, tapes, ribbons, and labels is used to indicate a victim's triage category.

unified command A type of command where specialized organizations are identified (e.g., EMS, fire, police, health department, American Red Cross), and personnel unify to complement command.

*A **major incident** is an event for which the available resources are insufficient to manage the number of casualties or the type of emergency. Major incidents include highway crashes, air crashes, major fires, train derailments, building collapses, acts of violence or terrorism, search and rescue operations, hazardous materials releases, and natural disasters. These incidents stress and may overwhelm local, regional, state, and even national and international resources.*

(Courtesy Ray Kemp, St. Charles, Mo.)

NOTE

The term **disaster** usually is associated with a man-made or natural event that involves damage across a large area or to a community's **infrastructure**. (For example, this may include roads, power, communications, or housing.) A subcategory of a disaster is a **mass casualty incident** (MCI), which involves many injuries and/or fatalities. The mobilization of resources and the methods used to meet the needs of a disaster response constitute **disaster management.**

CRITICAL THINKING

What effect do you think lack of organization could have on rescue operations, scene safety, patient care, and transportation in a major incident?

INCIDENT COMMAND SYSTEM

Historically, emergency management of a major incident often resulted in the response of many different agencies (EMS, fire service, rescue organizations, law enforcement, and others). Often times, each of these agencies operated independently with little or no interagency organization. This made it difficult to determine who was in charge of the scene. It also made it difficult to determine what emergency services were needed or were being provided.

The **incident command system** (ICS) was developed to address these concerns. This system organizes interagency functions and responsibilities. In 2004 the ICS was included as part of the National Incident Management System (NIMS) of the Department of Homeland Security (Box 54-1). All emergency response agencies at every level of government are required to use the incident command system at *all* incidents[1] regardless of the type, size, or complexity.

The ICS provides for a number of arrangements: (1) single jurisdiction and single agency involvement; (2) single jurisdiction and multiagency involvement; and (3) multijurisdiction and multiagency involvement. This allows the ICS to be adapted to the needs of any agency or to the size, nature, or geographical location of a particular incident requiring emergency management. The ICS also must be capable of being expanded from dealing with a nonmajor incident to a major one in a logical way. Use of the ICS as standard operating procedure for small incidents allows a smooth transition when a major incident occurs. Other components of the ICS include common elements of organization, terminology (Box 54-2), and procedures. The system should be put into place with the least possible disruption to existing systems (EMS, fire, and law enforcement agencies). It should be simple enough to keep operating and upkeep costs to a minimum.

The ICS system can easily be used at a minor incident in which the units dispatched to the scene are sufficient to handle the event. It can be expanded if more units are needed for a minor incident that becomes a major one. Use of the ICS is critical whenever it becomes apparent that the need for extended operations will quickly overwhelm the responding units. (An example is an event that involves many patients or one that may last several hours to days.)

Federal law now requires use of the ICS in response to all types of incidents. The ICS is a flexible system. It is used in both public and private sectors in all incidents. Much of the success of the ICS is due to its application of a common

BOX 54-1 NIMS Concepts

NIMS provides an organized set of *scalable* and *standardized* operational structures, which is critical for allowing various organizations and agencies to work together in a predictable, coordinated manner. In summary, NIMS is[1]:

- A comprehensive, nationwide systematic approach to incident management.
- A core set of doctrine, concepts, principles, terminology, and organizational processes for all hazards. It is not a detailed operational or resource plan.
- Scalable, so it may be used for all incidents (from day-to-day to large-scale).
- Essential principles for a common operating picture and communications interoperability.
- Standardized resource management procedures for coordination among different jurisdictions and organizations.

BOX 54-2 Important Terminology for Medical Incident Command Systems

apparatus: A vehicle used for fire suppression or rescue; this category does not include staff vehicles.

command: The act of directing, ordering, or controlling by virtue of explicit, statutory, regulatory, or delegated authority.

command post: The area from which command directs operations for an incident.

communications center: A facility used to dispatch emergency equipment and coordinate communications between field units and personnel.

division: A subdivision of the incident command system (ICS) that encompasses a specific geographic area of responsibility as deemed necessary by the incident commander.

group: A subdivision of the ICS that encompasses a specific functional area of responsibility as deemed necessary by the incident commander.

medical direction: A process of ensuring that actions taken on behalf of ill or injured people are medically appropriate, including prospective, concurrent, and retrospective aspects of emergency medical services (EMS) quality improvement, hiring, and education.

mutual aid: An agreement with neighboring emergency agencies to exchange equipment and personnel when necessary.

staging area: A designated area where incident-assigned vehicles are directed and held until needed.

organizational structure and key principles in a standardized way. ICS organization is built around the following five major components (Figure 54-1)[2]:

1. Command
2. Finance/administration
3. Logistics
4. Operations
5. Planning

The five major components of ICS are also known as *C-FLOP* (*c*ommand, *f*inance/administration, *l*ogistics, *o*perations, *p*lanning). They are the foundation on which organization develops. They apply during a major event, in preparation for a major event, or in management of the response to a major event.

Command Function

At most incidents the responsibility of command should belong to *one* person who assumes the function of command. This should be an individual with the ability to coordinate a variety of emergency activities. This is the cornerstone of the ICS structure.

The initial command should be determined by a preplanned system of arriving emergency units and personnel (e.g., the first or second arriving EMS, fire, or law enforcement unit). The person assuming command is the **incident commander** (IC). This person must be familiar with the ICS structure. The IC also must be familiar with the operating procedures of other responding agencies. The IC need not be the person with the highest rank or the most medical training (although this is commonly the case). Rather, the IC should be the person best able to manage the emergency scene effectively.

Command must be established immediately. The commander must be clearly identified. Also, all others at the scene must be informed as to who is in command. As a more qualified person arrives, command may be transferred per **standard operating procedures** (SOPs). This transfer of command is usually done face to face. Once established, command should take the following steps:

- Assume an effective command mode and position.
- Transmit brief reports by radio to the communications center, identifying the location of the command post.
- Evaluate the situation quickly.
- Develop a management strategy.
- Request more resources and provide assignments as needed.
- Implement a personal accountability and safety system.
- Control and assign **divisions** and/or **groups** as required (these should be consistent with the needs of the incident, SOPs, or disaster plans); also, provide these units with operating objectives.
- Provide ongoing effective command and progress reports until relieved by a higher ranking person.
- Develop the command organization by delegating authority to subordinates (this helps to accomplish incident needs and objectives).
- Review and evaluate the effectiveness of site operations and revise these operations as needed.

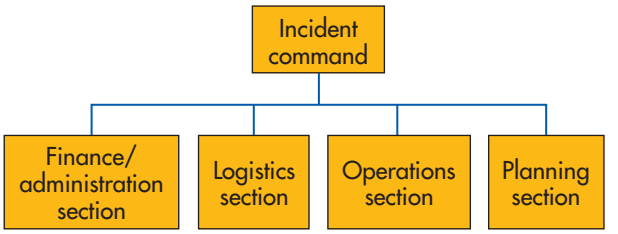

FIGURE 54-1 Incident command system organization (C-FLOP).

BOX 54-3 Single and Unified Command Structures

- In a *single command structure,* a single incident commander (IC) is solely responsible (within the confines of authority) for establishing objectives and for devising the overall management strategy for the incident. The incident commander is directly responsible for follow-through. The IC must ensure that all functional area actions are directed toward accomplishment of the strategy. Implementation of the overall strategy is the responsibility of a single individual (section chief). This person reports directly to the incident commander.
- In a *unified command structure,* the individuals designated by their jurisdictions (or by departments within a jurisdiction) must jointly determine objectives, strategies, and priorities. As in the single command structure, the section chief is responsible for carrying out the plan.

- Return units to service and end command when appropriate.

TYPES OF COMMAND

Command may take a single or unified form (Box 54-3). With **single command,** one person is responsible for the entire operation. This type of command often works well for incidents with limited jurisdictions or responsibilities. It also works best in small events of short duration.

Unified command may be needed in large events or as a small incident evolves. In unified command, specialized organizations are identified (e.g., EMS, fire, police, health department, American Red Cross), and personnel unify to complement command. This type of command stimulates cooperation (the "right" agency leads command at the "right" time) and provides for balanced decision making. It also facilitates **interoperability** (the ability of multiple organizations to communicate effectively) when many different communication frequencies and communications equipment are used by responding agencies. The concept of unified command allows agencies with different legal, geographical, and functional authorities and responsibilities to work together effectively. This is done without affecting individual agency authority, responsibility, or accountability[3] (Figure 54-2). Unified command may be indicated in incidents such as those with:

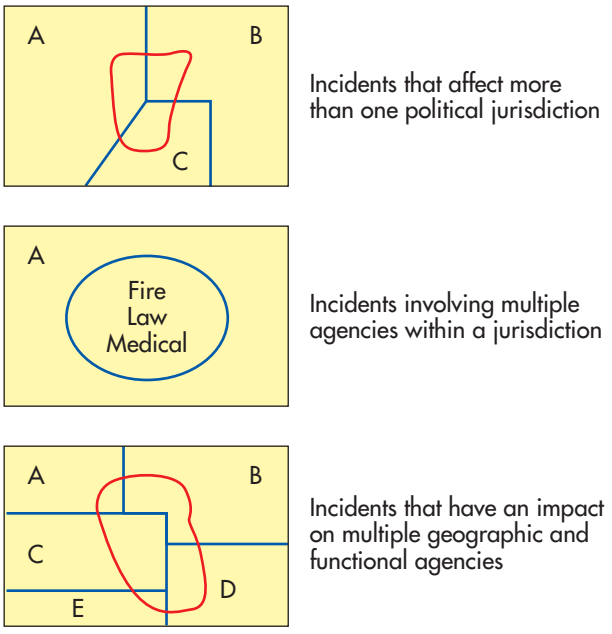

FIGURE 54-2 Application of unified command.

- More than one political jurisdiction
- Multiple agencies within a jurisdiction
- Multiple geographical and functional agencies

CRITICAL THINKING
Where do you think command should be located in a major incident that is confined to one area?

In either single or unified command, the IC may delegate authority for certain activities by activating additional **sections** (operations, planning, logistics, or finance/administration). These sections help to meet the needs of the situation. The incident commander bases the decision to expand (or contract) the ICS organization on three major incident priorities[4]:

1. *Life safety.* The IC's first priority is *always* the safety of the responders and the public.
2. *Incident stability.* The IC is responsible for deciding on strategies to minimize the effect of the incident on the area. These strategies also should maximize the response effort while using resources effectively.
3. *Property conservation.* The IC is responsible for minimizing damage to property while achieving the incident objectives.

When expansion of command is required, the IC establishes the other general staff positions (Figure 54-3).

Section Responsibilities

In the ICS, a manageable **span of control** (the number of people one section chief can manage effectively) falls within the range of three to seven, with five being the optimum.

In some cases the span of control indicates that the incident organization must be expanded to allow effective management of the situation. In such cases the IC assigns one or more of the general staff sections (planning, operations, logistics, and/or finance/administration) to **section chiefs.** Section chiefs must be strong supervisors and managers. Their chief role in the ICS is to "make things happen." They enact the plans and strategies of the incident commander. They also ensure that all rescuers in their sections are working toward a common goal. Which of the four sections may be needed varies, depending on the scope of the incident. The IC makes this determination (Figure 54-4).

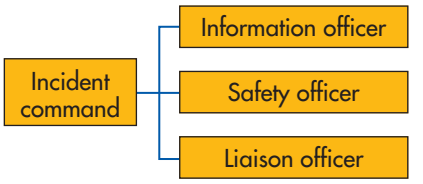

FIGURE 54-3 Command staff positions. The information officer handles all media inquiries and coordinates the release of information to the media with the public affairs officer at the emergency operations center (EOC). The safety officer monitors safety conditions and develops measures for ensuring the safety of all assigned personnel. The liaison officer is the on-scene contact for other agencies assigned to the incident.

Section chiefs should not become involved in physical tasks. (Examples of such tasks are carrying litters or operating rescue equipment.) This allows them to maintain control and supervise the section. General responsibilities of section chiefs include the following:

- Accomplishing the objectives set by command
- Monitoring work progress
- Redirecting activities as necessary
- Coordinating related activities with other sections
- Requesting additional resources as needed for the section
- Monitoring the welfare of personnel from each section
- Providing command with frequent reports
- Reallocating resources within the section

The section chief should report to command when a job is assigned, when a job is accomplished, or if a job cannot be accomplished.

FINANCE/ADMINISTRATION SECTION

The **finance/administration section** (Figure 54-5) is important for tracking costs and the way reimbursement is handled. This section is seldom used in small-scale incidents. However, it is considered essential if the incident grows in magnitude and costs (e.g., a presidential declaration of a disaster). Functions of the finance/administration section during a major incident may include time accounting, procurement, payment of claims, and estimation of costs.

LOGISTICS SECTION

The **logistics section** (Figure 54-6) is responsible for providing supplies and equipment (including personnel to operate the equipment), facilities, services, food, and communications support. The main function of this section is to provide gear and support to the responders. The essential equipment for supporting a medical incident includes

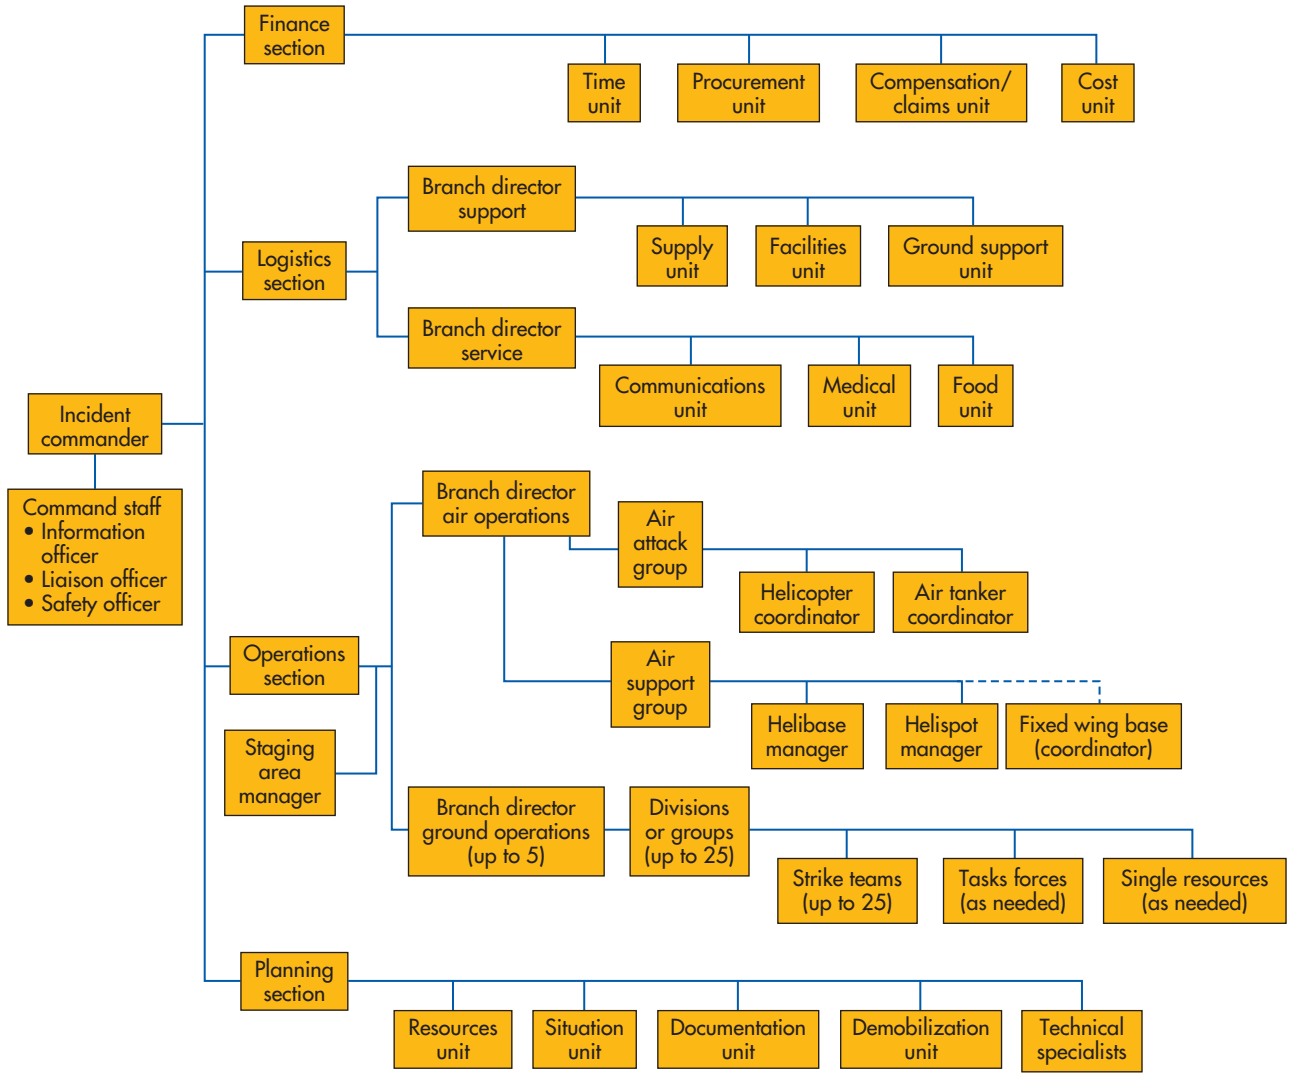

FIGURE 54-4 Command section organizational plan.

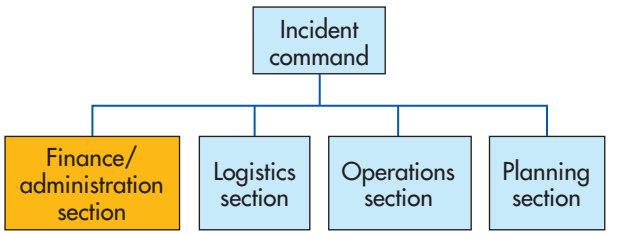

FIGURE 54-5 Finance/administration section.

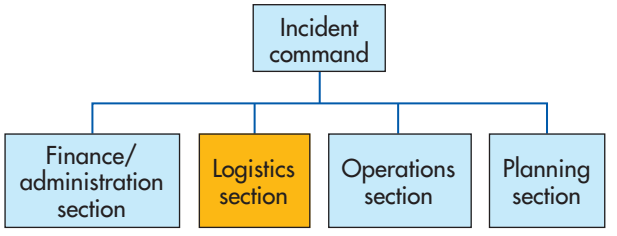

FIGURE 54-6 Logistics section.

supplies for airway, respiratory, and hemorrhage control, burn management, and patient packaging and immobilization. Resources for moving and transporting patients (people, ambulances, buses) also may be needed. *The medical unit* of the logistics section cares for the incident responders; it does not care for the civilian victims. Often part of the logistics section is used for routine daily incidents. For example, *responder rehabilitation* (described later in this chapter) and the *support branch* are parts of the logistics section.

OPERATIONS SECTION

The **operations section** (Figure 54-7) directs and coordinates all emergency scene operations. It also ensures the safety of all personnel. (EMS operation areas generally fall under this section.) The operations section chief is in charge of the tactical operations at an incident. This person is responsible for the following activities:

- Accomplishing tactical objectives
- Directing front-end activities

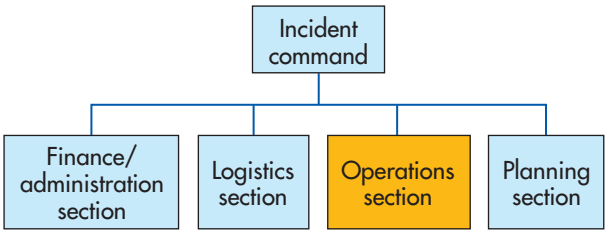

FIGURE 54-7 Operations section.

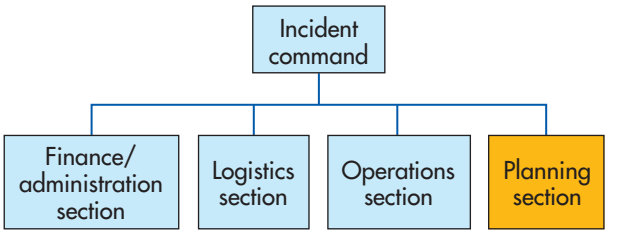

FIGURE 54-8 Planning section.

- Participating in planning
- Modifying action plans as needed
- Maintaining discipline
- Accounting for personnel
- Updating command on the progress or lack of progress of an operation

PLANNING SECTION

The staff function of the **planning section** (Figure 54-8) is to provide past, present, and future information about the incident and the status of resources. This section's duties also may include the creation of a written or verbal **incident action plan** (IAP). (The incident commander determines the need for an IAP.) The IAP defines the response activities and use of resources for a specified period. These operational periods can vary in length; however, they should be no longer than 24 hours (12-hour operational periods are common for large-scale incidents). IAPs may be indicated when (1) resources from several agencies are used; (2) several jurisdictions are involved; or (3) the incident is complex (e.g., changes in shifts or personnel are required).

Declaring a Major Incident

Declaring a major incident is a critical phase of the response. If an EMS unit is dispatched to a scene that has this potential, the crew should be advised or should declare (per established protocol) that they are responding to a possible major incident or mass casualty incident (MCI) and will confirm on arrival. This information allows other agencies to be contacted, and those agencies can be placed on standby. It also allows time for determination of the availability of other resources. Medical direction and area hospitals should also be alerted. The receiving hospitals need information on the number of patients and the severity of injuries as soon as possible. That way, they can begin to prepare for the patients' arrival. A possible major incident should be declared when:

- More than two ambulance units are required for adequate treatment, particularly in rural areas where communities may have only one ambulance
- Hazardous or radioactive materials or chemicals in significant quantity are involved
- An MCI results in a large number of patients and requires special EMS resources, such as helicopters, rescue teams, or several rescue or extrication units

PREPARING FOR A MAJOR INCIDENT

Preparation for a major incident involves three phases: preplanning, scene management, and postdisaster follow-up (or after-action review).[4]

Phase 1: Preplanning. Phase 1 of the preparation for a major incident is **preplanning.** Efforts by agencies to work together and to plan ahead are crucial to the management of a major incident. All agencies that will be called upon in an incident must agree to the **preplan.** The preplan also must address common goals and the specific duties of each group. Multiagency efforts succeed as a result of frequent meetings and practice sessions or exercises (drills or "tabletop" exercises). The preplan should include a system of sorting or prioritizing care, treatment, and transportation.

NOTE
The details of a disaster preparedness plan can be found through the community's local emergency disaster planning committee (LEPC).

Another component of the disaster is the identification of hazards in a community (a risk assessment). Such hazards may include the manufacture, storage, and transport of hazardous materials; fire threats; the population base at various times of the day; and violence and other potential social problems. An inventory of resources that may be needed during a major incident includes the following:

- Shelter and mass feeding
- Air evacuation
- Medical equipment and supplies
- Heavy equipment, power generators, and lighting
- Communications equipment
- Law enforcement personnel
- Specialized rescue services

Phase 2: Scene Management. Phase 2 of preparation involves the development of a strategy to manage the incident scene **(scene management).** Some major incidents can be managed with local resources and personnel (closed or contained incidents). However, other incidents may affect large geographical areas and many jurisdictions (open or uncontained incidents). In these incidents, many

federal, state, and local agencies become involved. Regardless of the size of the incident or the number of agencies involved, scene management calls for a coordinated effort. This effort must ensure an effective response and the efficient and safe use of resources.

NOTE
The procedure for managing a major multiagency, multijurisdictional incident is outlined in the federal National Incident Management System (NIMS). This procedure should be adopted for local use.

Phase 3: Postdisaster Follow-Up. Phase 3 involves a **postdisaster follow-up** (or *after-action review*). This includes the "lessons learned" from the incident. It also includes methods of improvement. These may include improvement of emergency response, planning, and community protection. This phase also should assess stress-related anxiety and illness among emergency workers that may have resulted from the incident.

MASS CASUALTY INCIDENTS

The ICS at a mass casualty incident is expanded when the number of casualties or the nature of the event overwhelms the available resources (the **local/regional threshold**). In communities where the local threshold is low, frequent use of the ICS for practice is encouraged. (For example, it can be used when an incident involves more than one patient.) When a mass casualty incident is identified, command must quickly determine how best to expand the ICS to meet the needs of the event. In other words, sections, groups, and **divisions** must be put into place according to the size and scope of the incident.

Typically, initial expansion of the ICS for a mass casualty incident requires the establishment of a *medical group* (including triage and treatment subcomponents, called *units*); a *transport group;* and an *extrication/rescue group* for disentanglement and/or removal of victims from hazardous areas. If more than five groups (or divisions, if assigned geographically) are activated, an operations section typically is established (Figure 54-9).

CRITICAL THINKING
How do you think you will feel when you arrive first on the scene of a mass casualty incident?

Scene Assessment

The first EMS unit to arrive at the scene should make a quick and rapid assessment (size-up) of the situation. If the arriving unit is a two-paramedic crew, one paramedic assumes the function of command; the second paramedic begins triage. A more precise and full assessment should be performed as soon as safety and time allow. This fuller assessment should include the following:

- The type of incident and the potential duration
- Whether entrapment or special rescue resources may be needed
- The number of patients in each triage category (described later in this chapter)
- Initial assignments for incoming units
- The need for any additional resources to manage the incident

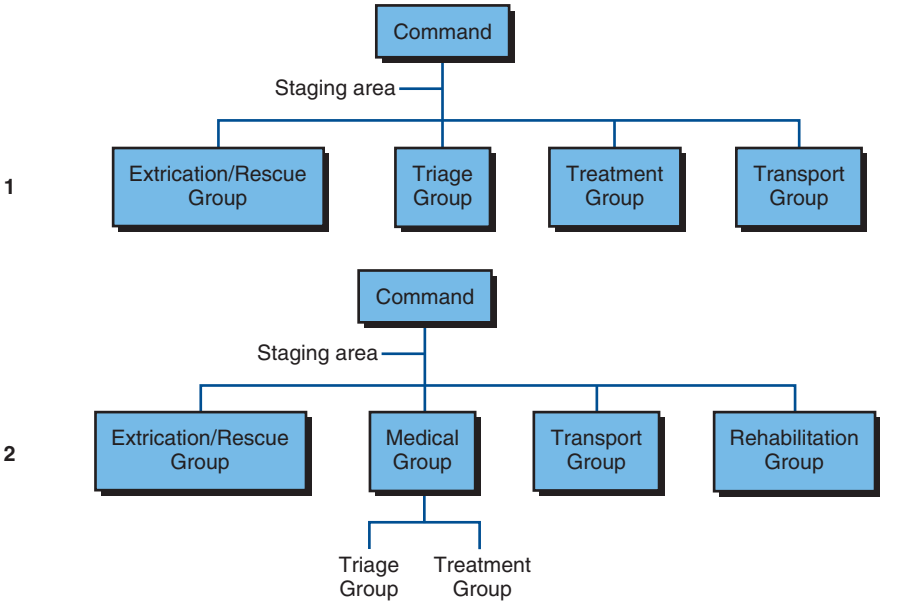

FIGURE 54-9 Two examples of ICS of mass casualty incidents.

NOTE
The scene assessment must be updated continually. This helps in the identification of specific or changing needs.

Communications

Command must immediately establish radio contact with the main communications center or the **emergency operations center** (EOC). Most jurisdictions maintain an EOC as part of their community's preparedness program. An EOC is where department heads, government officers and officials, and volunteer agencies gather to coordinate their response to an emergency event. Command and the EOC share similar goals. However, they function at different levels of responsibility. The incident commander is responsible for on-scene activities. The EOC is responsible for the entire community-wide response to the event. Radio traffic can be very distracting; therefore incident personnel must observe strict radio and/or phone procedures. Moreover, they should use clear, plain English. All transmissions should be short and to the point.

NOTE
Runners (messengers), cell phones, and satellite phones (SAT phones) are used when radio communications fail (e.g., in a large-scale disaster). Communications is often considered the #1 problem in major incidents.

Obtaining Resources

More units should be requested as soon as the need has been identified or anticipated. (The communications center should have a written SOP for requesting **mutual aid.**) Support may include obtaining food, shelter, and clothing for victims. The IC is responsible for providing instructions for the deployment of the resources. (Personnel should stay with their vehicle until instructions are received.) Staging techniques that may be used to deploy resources effectively include the following:

- Lining vehicles up at the scene to facilitate egress
- Staging away from a limited access highway
- Identifying a formal staging area with an assigned staging officer

The "tool box" theory of strategic deployment of resources can be used. It involves identifying the resources ("tools") specific to the incident, using only the needed resources, and issuing instructions for the deployment of resources.

Group or Division Functions

As stated previously, the number of groups or divisions needed at a major medical incident varies. Common groups and their responsibilities include extrication/rescue, treatment, and transportation. The staging area, rehabilitation area, and support branch are also important parts of an incident organization.

EXTRICATION/RESCUE GROUP

The **extrication/rescue group** is responsible for managing patients who are trapped at the scene. This involves search, rescue, initial triage, tagging, and treatment before transfer of the patients to the treatment group. Patient care for this group includes only assessment and treatment of life-threatening injuries. Examples include the need to open the airway, control severe bleeding, and cover open chest wounds. In addition, the rescue/extrication group is responsible for site safety and personnel safety (e.g., supplying self-contained breathing apparatus; atmospheric monitoring if indicated for explosive or oxygen-deficient atmospheres; protective clothing) and for evaluating and directing the resources needed for extrication and rescue. Rescue/extrication group responsibilities include the following:

- Determining whether triage and the primary treatment will be conducted on site or in the treatment group area
- Attaching tagging assignments to injured patients
- Evaluating the resources needed for extrication of trapped patients and for their delivery to the treatment group
- Ensuring site safety
- Evaluating resources needed for triage and the primary treatment of patients
- Communicating resource requirements to command
- Allocating assigned resources
- Supervising assigned personnel and resources
- Collecting, assembling, and assessing the walking wounded
- Reporting progress to command
- Reporting "all clear" to command when all patients have been extricated and delivered to the treatment group
- Coordinating with other groups

CRITICAL THINKING
What dilemmas might you face in doing triage at a multiple casualty incident?

TREATMENT GROUP

The **treatment group** works closely with the rescue/extrication group in patient care. As patients are delivered, they are recategorized according to their medical needs. The treatment group provides advanced care and stabilization until the patients are transported to a medical facility. Most paramedics and hospital personnel are assigned to this group.

With a large number of patients, the area usually is further divided into *immediate* and *delayed treatment zones.* This helps in the determination of priorities for patient transport. Immediate treatment patients include those

with life-threatening injuries; delayed treatment patients include the walking wounded and those whose care and transport can be delayed if necessary. It should be noted that triage monitoring is a function of all groups involving ill or injured patients. It is a continuing component of the ICS. Treatment group responsibilities include the following:

- Locating a suitable treatment area that satisfies hazardous material (hazmat) concerns, if applicable (e.g., uphill/upwind/upstream), and reporting that location to the rescue/extrication group and command
- Evaluating resources required for patient treatment and reporting these needs to command
- Providing secondary triage of patients arriving in the treatment area; tagging patients if not already done
- Providing suitable immediate and delayed treatment areas
- Allocating resources
- Assigning, supervising, and coordinating personnel in the group
- Reporting progress to command
- Coordinating with other divisions and groups

On-Scene Physicians. Physicians who are on-scene can provide valuable help during an MCI. The roles of the physicians may include providing on-scene medical direction, making difficult triage decisions and secondary triage decisions in a treatment area, and performing emergency surgery to facilitate extrication. Physicians also can perform specialized invasive procedures at the scene, as well as a more detailed patient assessment. In addition, they may provide direction for specific treatments that may be beyond the scope of normal paramedic practice.

Disposition of the Deceased. Depending on the scale of the incident, personnel may be assigned to disposition of the deceased. The duties of these individuals may include the following:

- Working with the medical examiner, coroner, law enforcement personnel, and other appropriate agencies to coordinate disposition
- Assisting in the establishment of an appropriate and secure area for a morgue, if needed

When possible, the deceased victims should be left in the location in which they were found until a plan has been made for removal and storage of the bodies.

TRANSPORTATION GROUP

The **transportation group** communicates with the receiving hospitals, ambulances, and air medical services for patient transport. This group must work closely with the treatment group. They help to determine appropriate destinations for injured patients. Also, the arrival and departure of transfer vehicles must be coordinated with the staging area. Transportation group responsibilities include the following:

- Determining patient transportation needs and obtaining appropriate transportation
- Evaluating resources required to manage patient transportation
- Establishing an ambulance staging area (if command has not already done so) and patient loading areas
- Establishing and operating a helicopter landing zone
- Communicating with hospitals to determine hospital surge capacity and capability to handle specialty patients
- Coordinating patient transportation allocations with the treatment group and hospitals
- Tracking patients leaving the site with a written log (including patient identification, the transporting unit, and the destination facility)
- Reporting resource requirements to command
- Coordinating with other divisions and groups
- Advising command when the last patient has been transported

Staging Area

Staging areas are needed for large incidents. They help to prevent vehicle congestion and delays in response. All emergency vehicles (fire, law enforcement, EMS) should report to this area for direction. Other agencies, such as disaster relief services and news media, also may be supervised by the staging area manager. The responsibilities of the staging area manager include the following:

- Coordinating with law enforcement personnel to block streets, intersections, and other areas to allow the establishment of a staging area
- Ensuring that all equipment and vehicles are parked in an appropriate manner
- Maintaining a log of all equipment in the staging area and an inventory of all specialized equipment and medical equipment that may be needed
- Reviewing with command the resources that must be maintained in staging, as well as coordinating this request with the dispatching center
- Assuming a visible position for incoming equipment and vehicles (e.g., leaving emergency lights operating on one vehicle and wearing an identification vest)
- Coordinating with other divisions and groups

Rehabilitation Area

A **rehabilitation area** (*rehab area*) is part of the major incident response plans of many fire and EMS agencies. This area usually is set up outside the operational area. It allows rescue personnel to get physical and psychological rest. With smaller incidents, the rehab unit leader usually reports directly to command. In large-scale incidents or whenever a logistics group is established, the rehab unit leader reports to the logistics chief. (In large-scale incidents, more than one rehab area may be needed.)

One duty of the rehab unit leader is to ensure that personnel receive medical care and treatment as needed. Another duty is to keep accurate logs of those who enter and leave the area. Records of medical care and treatments are kept for each person who enters the rehab area. (Medical care of rescue personnel is further addressed in Chapter 57.)

CRITICAL THINKING
Why do you think a rehabilitation area is important?

Support Branch

The **support branch** is in charge of gathering and distributing equipment and supplies. This branch may be responsible for obtaining medical supplies from area hospitals, rescue supplies, and other equipment needed at the incident. Support branch responsibilities include the following:

- Determining the medical supply needs of other divisions and groups
- Establishing a suitable location for supply operations
- Coordinating procurement of medical supplies from hospitals with the transportation group
- Coordinating procurement of medical supplies that are not available from hospitals
- Reporting additional resource requirements to command
- Allocating supplies and equipment as needed
- Reporting progress to command
- Coordinating with other divisions and groups

NOTE
Often only specific parts of the logistics group are needed at an incident. One of these is the rehabilitation unit; the other is the support branch. Depending on the span of control, these two units can be implemented without the establishment of a logistics group section chief; they report directly to command.

Identification and Communication

When an ICS is in place, all responders must know its organizational structure and the lines of radio communication. Although clothing and identification vary by system, the following guidelines usually apply:

- Color-coded vests identify personnel. For example, the commander may wear a white vest; EMS group managers, blue vests; fire group managers, red; law enforcement group managers, green; and so on.
- With the exceptions of command and division/group communications, most communications are face to face. Radio use is intended for command operations.
- Radio communications use operation titles instead of personal or unit names: "Treatment group to command" or "Rescue/extrication group to treatment group." This system ensures that all participants can reach the appropriate person by one radio designation.

RADIO COMMUNICATIONS

Communications is a key function during a major incident. Preplanning includes identifying the radio frequencies to be used in major incident responses. It also includes planning for the ways these frequencies are to be used. For example, all responding units should have multichannel radios that use a common frequency. Within this common frequency, separate frequencies should be used for EMS, fire, and other support operations. Division and group officers should have portable radios set on a channel that permits direct communication with command. These channels may be assigned in advance or by the dispatching agency at the time of the incident. In addition, state, regional, and local communications systems should undergo a periodic review. This review should include the controls for activating communications, system frequencies, and portable and mobile radio equipment. Other communications considerations include the following:

- Radio traffic must be clear, concise, and in plain English.
- Messages should be given thought and prepared before transmission.
- The speaker should clearly identify the unit number or division or group.
- All radio traffic should be minimized.
- Face to face communication is preferable and encouraged.

Common Problems at Mass Casualty Incidents

In addition to common failures of incident command systems (Box 54-4), there are common problems specific to mass casualty incidents. These include the following[4]:

- Failure to adequately provide widespread notification of the event
- Failure to provide rapid initial stabilization of all patients
- Failure to move, collect, and organize patients quickly in a treatment area
- Failure to provide proper triage
- Provision of overly time-consuming care
- Transport of patients prematurely
- Improper use of personnel in the field
- Failure to distribute patients to medical facilities properly
- Failure to communicate with local hospitals regarding patient flow and hospital capacity
- Lack of proper preplanning and of adequate training for all personnel

PRINCIPLES AND TECHNOLOGY OF TRIAGE

Triage is a method of categorizing patients according to priorities of treatment (Box 54-5). Assessment of the severity of injury is based on abnormal physiological signs, obvious anatomical injury (including the mechanism of injury), and concurrent disease factors that might affect the patient's prognosis. It should be stressed that triage is an ongoing process during a major incident. Constant monitoring of the patient's condition may reveal a need to change the initial grouping and priority of treatment. The

BOX 54-4 Common Failures Seen in the Incident Command System

Incident Command Failures
- To establish a single, unified command
- To establish staging
- To request additional resources early
- To delegate authority
- To wear identification vests

Dispatch Failure
- To coordinate the response of on-duty and off-duty emergency personnel to the scene

Communications Failures
- To designate a single radio channel for disaster operations
- To adopt standard operating procedures that limit radio traffic during incident operations

Staging Operation Failures
- To establish a central staging area (command)
- To select a large or easily accessible staging area (staging manager)
- To frequently inventory specialized equipment and personnel (staging manager)

General Division/Group Failures
- To provide adequate progress reports to command
- To become involved in physical tasks, such as carrying litters or operating rescue equipment (division/group supervisor)
- To control the perimeter (law enforcement)
- To advise command of available personnel

Extrication/Rescue Group Failures
- To triage and tag patients
- To treat patients where they are found (as opposed to stabilizing them and moving them to a treatment area) (rescuers)
- To provide adequate safety precautions

Treatment Group Failures
- To collect patients into an organized treatment area
- To establish a sufficiently large treatment area
- To organize the treatment area and monitor patients
- To effectively coordinate transportation arrangements with the transportation group

Transportation Group Failures
- To establish adequate access and egress routes for vehicles
- To have adequate personnel to assist in transportation
- To alert or update hospitals
- To advise hospitals when the last patient has been transported

Support Branch Failures
- To plan for the medical supply needs of mass casualty events
- To provide rapid transport of supplies to the scene

BOX 54-5 Primary Versus Secondary Triage

Triage may be classified as primary or secondary. **Primary triage** is used at the site to rapidly categorize patient conditions for treatment. During primary triage, the paramedic records the location of the patient and the transport needs. A triage label, tag, ribbon, or tape is then attached to the patient. No care is given during primary triage except for immediate lifesaving measures to ensure an airway or control hemorrhage. The goal is to sort patients quickly.

Secondary triage is used at the treatment area, where patients are triaged again. They are labeled (usually with paper tags) to assign priorities of care. Secondary triage often is not needed at small-scale incidents.

criteria for triage classifications are determined by the size of the incident, the number of injured patients, and the available personnel. National guidelines have been established for field triage (*SALT triage*).[5] Another widely recognized model is the **s**imple **t**riage **a**nd **r**apid **t**reatment (START) technique. The paramedic must be familiar with local methods of triage categorization.

SALT Triage

SALT triage (Sort-Assess-Lifesaving interventions-Treatment and/or Transport) was developed as a national all-hazards mass casualty initial triage standard for all patients (e.g., adults, children, special populations). SALT was designed to allow agencies to easily incorporate it into their current MCI triage protocol through simple modification.

Step 1: Sort

SALT begins with a global sorting of patients, prioritizing them for individual assessment. If possible, patients should be asked to walk to a designated area and should be assigned last priority for individual assessment. Those who remain should be asked to wave (i.e., follow a command) or be observed for purposeful movement. Those who do not move (i.e., are still) and those with obvious life threats should be assessed first since they are the most likely to need lifesaving interventions.

Step 1: Group sorting
- Priority 1: Still/obvious life threat
- Priority 2: Wave/purposeful movement
- Priority 3: Walk

Step 2: Assess

The individual assessment should begin with limited rapid lifesaving interventions:
- Controlling major hemorrhage through the use of tourniquets or direct pressure provided by other patients or other devices
- Opening the airway through positioning or basic airway adjuncts (no advanced airway devices should be used)
- If the patient is a child, consider giving two rescue breaths

- Chest decompression
- Auto injector antidotes

A **lifesaving intervention** (LSI) should only be performed within the responder's scope of practice and only if the equipment is immediately available. Patients should be prioritized for treatment and/or transport by assigning them to one of five categories: *immediate, expectant, delayed, minimal, dead*. Patients who have mild injuries that are self-limited if not treated and can tolerate a delay in care without increasing their risk of mortality should be triaged as *minimal* and should be designated with the color green. Patients who are not breathing even after lifesaving interventions are attempted should be triaged as *dead* and should be designated with the color black. Patients who do not obey commands, **or** do not have a peripheral pulse, **or** are in respiratory distress, **or** have uncontrolled major hemorrhage should be triaged as *immediate* and should be designated with the color red. Providers should consider if these patients have injuries that are likely to be incompatible with life given the currently available resources; if this is true, then the provider should triage these patients as *expectant* and should be designated with the color gray. The remaining patients should be triaged as *delayed* and should be designated with the color yellow.

This prioritization process is dynamic and may be altered by changing patient conditions, resources, and scene safety. Triage labeling systems should account for the dynamic nature of triage and be easily modifiable for a single patient. After *immediate* patients have received care, patients designated *expectant, delayed,* or *minimal* should be reassessed as soon as possible with the expectation that some patients will have improved and others will have decompensated. In general, treatment and/or transport should be provided for *immediate* patients first, then *delayed,* and then *minimal. Expectant* patients should be provided with treatment and/or transport when resources permit. Efficient use of transport assets may include mixing categories of patients and using alternate forms of transport. Some patients may only require treatment at the scene and not transport (Figure 54-10).

START Technique of Primary Triage

The ***START Field Guide*** was developed by Hoag Memorial Presbyterian Hospital in Newport Beach, California. It describes a 60-second assessment. This assessment focuses on the patient's ability to walk, respiratory effort, pulses/perfusion, and mental status (Figure 54-11). This assessment is used to classify a victim's status as *minor, delayed, immediate,* and *dead.* The *START Field Guide* allows rescuers to quickly identify victims at greatest risk of early death. Rescuers can then advise other rescuers of the patient's need for stabilization by tagging the patient with color-coded triage tags (described in the following section).

TRIAGE PROCEDURE

The paramedic should first assess the patient's ability to walk. Patients who can walk and understand basic commands are categorized as *minor* ("walking wounded"). They will be further triaged and tagged as more rescuers arrive. Patients who are *minor* should be directed to remain in their location for further assistance or to walk to a treatment or transportation site. The initial START triage is directed toward patients who cannot walk.

NOTE

The mnemonic "30-2-can-do" is used as the START triage prompt. *30* refers to the patient's respiratory rate; *2* refers to capillary refill time; and *can-do* refers to the patient's ability to follow commands. A respiratory rate of fewer than 30 breaths/min, a capillary refill time of less than 2 seconds, and the ability to walk and follow commands is considered a minor patient.

Patients who meet the "30-2-can-do" criteria but who cannot walk are categorized as *delayed*. Patients who are unconscious, have rapid breathing, have delayed or absent capillary refill, or have an absent radial pulse are categorized as *immediate*. Patients who are not breathing should have their airway opened. If they resume spontaneous breathing, they are considered *delayed.* If breathing does not resume after opening the airway, the patient is categorized as *dead*.

CRITICAL THINKING

What conditions might a patient have if the respiratory rate is fewer than 10 or more than 30 breaths per minute?

As mentioned previously, repositioning the airway and controlling severe hemorrhage are the only treatments given in initial triage. However, in a mass casualty event, these measures should not delay the triage of other patients. Depending on the circumstances and the number of casualties, the walking wounded may be able to help provide airway support and control severe hemorrhage for more seriously wounded victims.

SHOW ME THE EVIDENCE

Researchers sought to determine the accuracy of START triage. They hypothesized that this triage tool would be 90% sensitive and specific for predicting injury. Of the 163 triaged on the scene at a 2003 train crash, they were able to find and retrospectively review 148 hospital records. On the scene patients were triaged 22 red, 68 yellow, and 58 green. Patient outcome records showed 2 red, 26 yellow, and 120 green. No level met their predicted criteria although the tool was 100% sensitive for determining red (immediate) patients and 89.3% specific for green patients. They felt that in this instance there was a sufficient amount of undertriage but it did produce a large amount of overtriage. They conclude that the tool was effective to prioritize patient transport to hospitals from the scene.

From Kahn CA, Schultz C, Miller K, et al: Does START triage work? An outcomes assessment after a disaster, *Ann Emerg Med* 54(3):424-430, 2009.

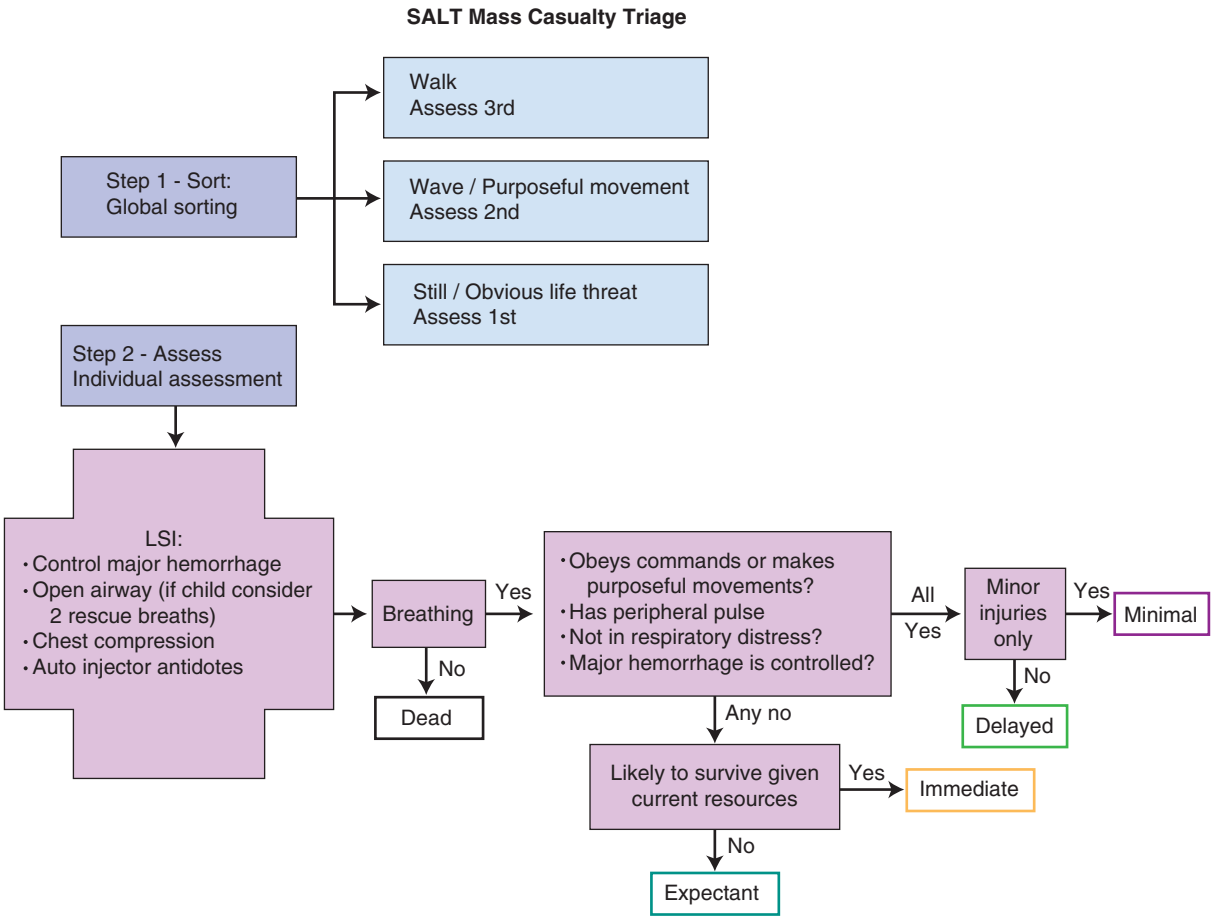

FIGURE 54-10 SALT Triage Scheme.*

TABLE 54-1 International Color Coding and Priorities

Patient Status	Color Code	Priority
Immediate	Red	Priority no. 1 (P-1)
Delayed	Yellow	Priority no. 2 (P-2)
Hold	Green	Priority no. 3 (P-3)
Deceased	Black	Priority no. 0 (P-0)

Triage Tagging/Labeling

Many types of tags, tapes, ribbons, and labels are used to indicate a victim's triage category **(triage tagging system).** Two commonly used labeling methods are the **METTAG system** and the **SMART tag system**. The METTAG system uses the international agreement on color coding and priorities to alert emergency care personnel and staff members of the receiving hospital to the patient's category (Table 54-1). *Red* identifies the victims who are most critically injured; *yellow,* those less critically injured; *green,* those with injuries that are not life or limb threatening; and *black,* patients who have died or whose injuries preclude survival (Figure 54-12). Triage tags and labels should be used routinely for practice so that EMS crews become familiar with their use. The SMART tag system uses four color triage coding cards that have military bar codes for tracking patients[6] (Figure 54-13):

1. Priority 1 (red) indicates immediate treatment.
2. Priority 2 (yellow) indicates urgent treatment.
3. Priority 3 (green) indicates delayed treatment.
4. Black cards indicate death.

Regardless of the labeling system used, categorization must identify the priority of the patient's condition, prevent retriage of the same patient, and serve as a tracking system during treatment and transport. Therefore all tags and labels should have the following characteristics:

- Be easy to use.
- Rapidly identify the patient's priority.
- Allow for easy tracking.

*This field triage decision scheme, originally developed by the American College of Surgeons Committee on Trauma, was revised by an expert panel representing emergency medical services, emergency medicine, trauma surgery, and public health. The panel was convened by the Centers for Disease Control and Prevention (CDC), with support from the National Highway Traffic Safety Administration (NHTSA).

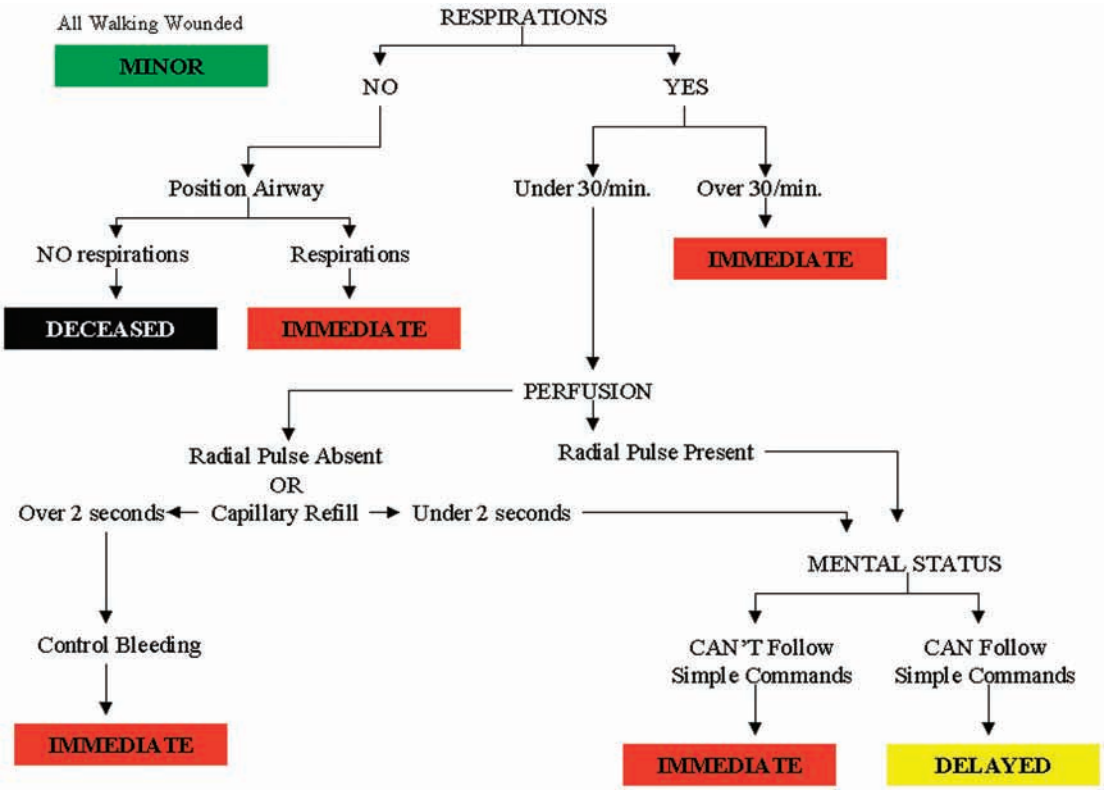

FIGURE 54-11 The simple triage and rapid treatment (START) system sorts patients into critical or delayed categories. Patients are quickly removed from the scene according to their triage group.

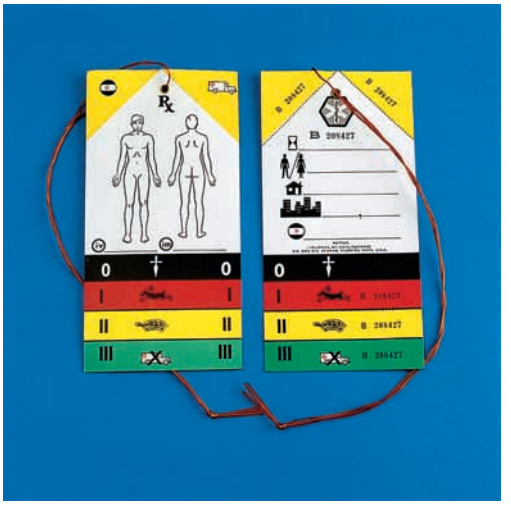

FIGURE 54-12 METTAG card.

FIGURE 54-13 SMART triage tag with bar code.

- Allow room for some documentation.
- Prevent patients from retriaging themselves.

Tracking Systems for Patients

As described previously, the transportation group officer must keep a tracking or destination log that integrates the triage tagging system. In addition, the log should have the patient's name or triage label identification number. A **tracking log** is similar to a shipping manifest. It must have the following information:

- Patient identification
- Transporting unit
- Patient priority
- Hospital destination

Transportation of Patients

The way patients are transported depends on their triage priority and situation. Ambulances typically are used. However, buses may be used to transport a large number of stable patients. Air ambulances are usually reserved for the transport of patients in critical condition.

CRITICAL INCIDENT STRESS MANAGEMENT

As described in Chapter 2, *critical incident stress* is a potential hazard for rescue personnel. For this reason, critical incident stress debriefings often are conducted after a disaster. To review, the basic types of services that should be made available include the following[7]:

- Preincident stress training for all personnel
- On-scene support for obviously distressed personnel
- Individual consults when only one or two rescuers are affected by an incident
- Defusing services immediately after a large-scale incident
- Mobilization services after a large-scale incident
- Critical incident stress debriefing 24 to 72 hours after an event for any emergency personnel involved in a stressful incident
- Follow-up services to ensure that personnel are recovering
- Specialty debriefings to nonemergency groups when no other timely resources are available in the community
- Support during routine discussions of an incident by emergency personnel
- Advice to command staff during large-scale events

Other approaches that can aid stress management include employee assistance programs, counseling, spouse support programs, family life programs, pastoral services, and periodic stress evaluations.

SUMMARY

- Major incidents are events for which available resources are not adequate to manage the number of casualties or the type of emergency.
- The ICS organizational structure should be adaptable to any agency or to any incident requiring emergency management. The ICS also must be expandable. It must be able to expand from dealing with a nonmajor incident to a major one in a logical way.
- The five major functions of the ICS organization are command, planning, operations, logistics, and finance/administration.
- The responsibility of command should belong to one person. This should be a person who can effectively manage the emergency scene. In multiagency and/or multijurisdictional incidents, unified command may be used.
- The planning section should provide past, present, and future information about the incident and the status of resources. The operations section directs and coordinates all operations. It also ensures the safety of all personnel. The logistics section is responsible for providing supplies and equipment (including personnel to operate the equipment), facilities, services, food, and communications support. The finance/administration section tracks incident and reimbursement costs.
- All participating response agencies must agree to the preplan (phase 1 of the ICS). The preplan must address common goals and the specific duties of each group. Phase 2 requires the development of a strategy to manage the emergency scene. Phase 3 includes a post-disaster review of lessons learned from the incident and the determination of ways to improve the response effort.
- The need to expand the ICS at a medical incident is based on the number of casualties and the nature of the event.
- The first EMS unit to arrive at the scene should make a quick and rapid assessment of the situation. Command must immediately establish radio contact with the communications center or emergency operations center. Additional units should be requested as soon as the need has been identified.
- Common divisions or groups that may need to be established include extrication/rescue, treatment, and transportation. A staging area and support branch may also be needed. The rescue/extrication group is responsible for managing trapped patients at the scene. The treatment group provides advanced care and stabilization until the patients are transported to a medical facility. The transportation group communicates with the receiving hospital, ambulances, and aeromedical services for patient transport. The staging area is used in large incidents to prevent vehicle congestion and delays in response. The rehabilitation area allows rescue personnel to receive physical and psychological rest. The support branch coordinates the gathering and distribution of equipment and supplies for all divisions and groups.
- Problems of mass casualty incidents and incident command systems stem from numerous issues related to communication, resource allocation, and delegation.

- Triage is a method used to categorize patients for priorities of treatment. START triage uses a 60-second assessment. It focuses on the patient's ability to walk, respiratory effort, pulses/perfusion, and neurological status. The METTAG system is one of a number of tape, tag, and label systems used to categorize patients during triage.
- Critical incident stress debriefing is part of a critical incident stress management program. Such debriefing should be part of postdisaster standard operating procedures.

CHAPTER

55 Rescue Awareness and Operations

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe factors that must be considered to ensure appropriate timing of medical and mechanical skills during a rescue.
2. Outline each phase of a rescue operation.
3. Identify the appropriate personal protective equipment (PPE) for rescue operations.
4. Describe important considerations for emergency medical services (EMS) crews in a surface water rescue.
5. Discuss important considerations for EMS crews in rescues associated with hazardous atmospheres, including confined spaces and trench or cave-in situations.
6. Describe hazards that may be present during an EMS rescue operation on a highway.
7. Describe important considerations for EMS crews in a rescue involving hazardous terrain.
8. Outline special considerations for prehospital assessment and management during a rescue operation.

KEY TERMS

basket stretcher A litter designed of a rigid frame made of wire, mesh, or plastic.

confined spaces Spaces that have limited access or egress and are not designed for human occupancy or habitation.

cross-trained personnel Emergency personnel who are trained in more than one type of emergency service (e.g., fire, EMS, and law enforcement).

disentanglement The process of making a pathway through the wreckage of an accident and removing wreckage from patients.

dynamic rope Rescue rope that is usually used when climbing toward or above an anchor point.

egress An exit pathway.

engulfment Mechanical entrapment that places a person in a confined space.

flat terrain rescue A type of rescue on level land that may involve various obstructions, such as level land with large rocks, loose soil, and waterbeds or creeks.

hazard control The phase of rescue that involves managing, reducing, and minimizing risks from uncontrollable hazards; ensuring scene safety; and providing personal protective equipment appropriate for the incident.

hazardous atmospheres Oxygen-deficient environments that may occur in confined spaces.

high-angle rescue A type of rescue that requires the use of hands (e.g., rappelling) to maintain balance for victim retrieval.

lock-out process The disabling and securing of electrical equipment to prevent any unauthorized person from entering the area or gaining access to the controls that have been shut off.

low-angle rescue A type of rescue on steep slopes where terrain can be walked on without the use of the hands, but secure footing may be difficult.

oxygen-deficient atmospheres Confined spaces in which there is an inadequate concentration of oxygen.

patient packaging Completion of emergency care procedures needed to transfer a patient from the scene to the emergency vehicle.

personal flotation device A safety device worn in water to reduce the risk of drowning.

power take-off A splined driveshaft, usually on a tractor or other farm machinery, used to provide power to an attachment or separate machine.

rappelling A controlled descent by rope.

rescue The act of delivery from danger or imprisonment.

rescue versus body recovery The chance to save a human life (rescue) versus body recovery without the goal of saving a human life.

risk versus benefit analysis An analysis that considers personal safety before rescue is attempted. (*Does the risk outweigh the benefit or vice versa?*)

safety officer In a rescue operation, the official who remains alert to the stress of the operation on the rescuers.

static Kernmantle A type of rope used in life-safety rescue operations; comprising a core and sheath.

static rope A type of rope used in rescue that provides for minimal stretch (a low elongation factor).

supplemental restraint system Refers to air bags; a safety device in automobiles that deploys to prevent driver/occupant injury.

supplied-air breathing apparatus A device that provides a nearly unlimited supply of air from a source located outside the confined space.

surface water rescue The rescue of a patient who is afloat on the surface of a body of water.

systems operations approach A form of rescue management where extrication is performed by fire service personnel, specialized units, or both—and where patient care is the duty of EMS personnel.

Rescue is defined as "the act of delivery from danger or imprisonment." Many of the day-to-day activities of EMS personnel and other public service agencies are embraced by this definition when they respond to an emergency where people have been traumatized or stranded. Rescue requires specialized medical and mechanical skills, with the right amount of each being applied at the appropriate time.

NOTE
Rescue skills have become highly specialized. Techniques have been devised and refined for farm rescue, high-angle rescue, rescue in confined spaces, search and recovery, and others. In addition, many rescue agencies require training and certification by an authority or jurisdiction. A number of rescue skills may be needed in a specific area. Also, many different techniques may be involved in a rescue. This chapter focuses on concepts that are basic to all rescue operations.

APPROPRIATE TRAINING FOR RESCUE OPERATIONS

Rescue work requires training and expertise so that medical and mechanical skills are carefully balanced. This helps to ensure that patients receive effective treatment and timely extrication. The rescue effort must be driven by the patient's needs, both medical and physical. The success of any rescue depends on a coordinated effort between medical care and specialized rescue efforts. A coordinated effort allows the following:

- Patient access and assessment for treatment needs
- Initiation of treatment at the site
- Release of the patient from entrapment or imprisonment
- Continuous medical care throughout the incident

Role of the Paramedic in Rescue Operations

Most rescues in the United States are accomplished through a **systems operations approach.** In this form of rescue management, extrication is performed by fire service personnel, specialized units, or both—patient care is the duty of EMS personnel. In another type of rescue system, rescue services are provided by fire, EMS, or law enforcement agencies that have **cross-trained personnel.** In this system, the roles and responsibilities for rescue and patient care are shared.

(Courtesy Ray Kemp. St. Charles, Mo.)

The primary role of the paramedic in rescue operations is to have proper training and appropriate personal protective equipment (PPE) that allow for safe access to the patient and treatment at the site and throughout the incident. Paramedics often are the first responders to many scenes that require rescue. Therefore they should:

- Understand the hazards associated with various environments
- Know when it is safe to gain access or attempt rescue
- Have the skills to perform a rescue when it is safe and necessary
- Understand the rescue process and know when certain techniques are indicated or contraindicated
- Be skilled in patient packaging techniques to allow safe extrication and medical care

CRITICAL THINKING
What kind of emotions do you think you would see in a critical life-threatening rescue?

NOTE
Medical monitoring and rehabilitation (*rehab*) of other rescuers at the scene also is an important role for paramedics. Medical monitoring and rehab will be further addressed in Chapter 57.

Safety

Safety during any rescue operation is paramount because of the potential for associated risks. For example, rescues may involve hazardous materials, inclement weather, temperature extremes, fire, electrical hazards, toxic gases, unstable structures, heavy equipment, road hazards, and sharp edges and fragments. Initial scene assessment for hazards, use of personal protective measures, and constant monitoring throughout the operation are essential for every rescue response.

The priorities for safety in any rescue are (1) personal safety, (2) the safety of the crew, (3) the safety of bystanders, and (4) rescue of the trapped and injured. The reasons for this order of priority are as follows:

- When well-trained and properly equipped rescuers act safely, remaining vigilant for hazards, they minimize the risk of personal injury and of complicating the scene by becoming another patient who requires care and possibly extrication.
- The crew is the support team for the rescuer. Therefore crew safety is essential to ensure an effective rescue and to provide mutual support for each team member. Operating with disregard for the safety of fellow team members increases the risk of injuries. It also complicates the operation.
- Uninvolved people must be evacuated and kept clear of hazards. Bystanders or untrained "helpers" only increase the risk of additional injuries. They also complicate the rescue operation.
- Rescue of the trapped or injured is the last priority. These people are already trapped or injured. Carrying out the first three priorities safely maximizes the chance for a successful rescue.

Phases of a Rescue Operation

A rescue operation has seven phases: (1) arrival and scene size-up, (2) hazard control, (3) gaining access to the patient, (4) medical treatment, (5) disentanglement, (6) patient packaging, and (7) transportation. As is stressed throughout this text, paramedics should not enter a scene until it has been secured and made safe by trained personnel. Personal safety is always a priority.

Arrival and Scene Size-Up

The first phase of a rescue is the arrival and scene size-up. This phase requires the paramedic to determine what is needed at a specific emergency event. This involves quickly gathering facts about the situation, analyzing the problems, and determining the appropriate response. During this phase, the EMS crew must:

- Understand the environment and risks
- Establish command and conduct a scene assessment
- Determine the number of patients and triage as necessary
- Determine whether the situation is a search, rescue, or body recovery
- Perform a risk versus benefit analysis that considers personal safety before rescue is attempted
- Request additional information
- Make a realistic time estimate in accessing and evaluating patients or other people at the scene

Scene size-up is an ongoing evaluation of the emergency scene. It begins when the call is received and when information is obtained from the dispatch center. The paramedic must constantly be alert to situations that may change the needs of a particular incident. If power lines are downed during an extrication, for example, electrical utility services may be needed that were not initially required. Three elements of the assessment phase are response, other factors, and resources.

RESPONSE

During the initial response to a scene, information often is limited. En route, the EMS crew and the dispatcher should gather as much detail about the situation as possible. Essential information includes exact location, type of occupancy (manufacturing, mercantile, residence), number of victims, type of situation, and hazards involved. Weather conditions (e.g., extreme heat or cold, rising water, rain, high winds) also can affect rescue attempts, the patient's status, and the need to expedite the operation.

As described in Chapter 17, standardized dispatch protocols guide the initial emergency response. This predetermined system is based on the level of the reported emergency. For example, if the event is a single-car crash, a first-responder fire company and EMS unit may be dispatched. If the event involves a bus wreck with many patients, several fire companies and EMS units may respond. As the dispatch center receives information about the actual severity of the event, the dispatch protocol upgrades or downgrades the response as needed. The center advises the responding units of the updated reports.

CRITICAL THINKING

Is there any disadvantage to routinely sending too much emergency equipment to a scene?

OTHER FACTORS

Other factors to be considered in determining the type of response needed are the description of the scene and the time of day. An emergency in a highly populated area may call for special vehicles and equipment for extrication and fire suppression. Examples of such a scene would be a high-rise apartment, a school, or a shopping mall. An emergency in a rural or wilderness setting may require helicopter rescue or other resources. If hazardous materials are present, special response and decontamination equipment may be needed for bystanders, patients, and rescue personnel.

The time of day may affect on-scene needs. For example, rush-hour traffic and crowd control may be a concern; extra lighting may be needed for early morning, evening, or night rescue. These and other factors determine the personnel requirements and the scene management operations.

RESOURCES

The ability to assess an emergency quickly and correctly requires preplanning. It also requires the development of a systems approach to the response. The available resources are a critical part of any response. The responding crew may not have the personnel, training, or expertise to handle the event. Resources that may be required include the following:

- Additional emergency vehicles for a large number of patients
- Area hospital availability and personnel
- Aeromedical services
- Law enforcement personnel
- Fire service for automobile extrication, fire suppression, or lighting
- Water rescue, teams with self-contained underwater breathing apparatus (SCUBA), and other specialized rescue units
- Hazardous materials teams
- Urban search and rescue teams

Hazard Control

Hazard control is the phase of rescue in which on-scene dangers are quickly identified and managed by the first-arriving crew. This involves minimizing risks from uncontrollable hazards, making sure the scene is as safe as possible, and ensuring that all personnel are equipped with PPE appropriate for the incident. Examples of possible hazards at a scene include fire, unstable structures, confined spaces, swift water, poisonous substances, dangerous animals, and unruly crowds. Hazard control for specific types of incidents is discussed throughout this chapter.

Gaining Access to the Patient

Rapid access to an ill or injured patient who requires extrication or rescue can be critical to the patient's eventual outcome. For patients who have multisystem trauma, assessment, stabilization, and extrication should be rapid. However, these procedures must be accomplished with the safety of both the patient and the rescue team as a top priority. To safely gain access, the paramedic must determine the best method of reaching the patient, deploy appropriate personnel to the patient, and stabilize the patient's physical location.

Extrication tools and equipment (Figure 55-1) can cause injuries. To reduce the risk, paramedics should use the least amount of force needed. They should clear the area of unnecessary people. In addition, extraneous noise should be kept to a minimum. Also, a **safety officer** should remain alert to the stress of the operation on the rescuers. This officer should rotate personnel to prevent heat exposure disorders and injuries resulting from fatigue. Rescuers should wear approved protective clothing. Also, protective covering for the patient should be supplied.

FIGURE 55-1 Extrication tools and equipment.

Paramedics may not directly take part in freeing the patient. However, they have chief responsibility for patient care. In addition, they serve a key role as observers for potentially hazardous procedures. The "team concept" is the most important element in any rescue system or operation. Teamwork maximizes safety, efficiency, and effectiveness. It is a basic element of prehospital care. In addition, it has powerful implications for the safety of responders.

Medical Treatment

After the team has gained access to the patient, medical treatment can begin. The paramedic should perform a rapid primary survey to identify and manage any life-threatening situations. Care may be limited by circumstances and the physical working area. However, the paramedic may be able to initiate some stabilization procedures, such as spinal immobilization, airway management, oxygen administration, and intravenous (IV) fluid therapy. If the paramedic recognizes rapidly fatal or potentially fatal conditions, a "load and go" approach must be taken. In these cases, rapid extrication and transport are indicated.

A physical examination should be performed after the primary survey has been completed and life-threatening conditions have been managed. Another crew member may perform the examination at the same time of the primary survey if it does not interrupt the initial assessment and emergency care.

Disentanglement

Disentanglement involves making a pathway through the wreckage of an incident and removing wreckage from patients. The main responsibilities of the paramedic during

disentanglement are to release the patient from entrapment and to perform a **risk versus benefit analysis**. (*Does the risk outweigh the benefit or vice versa?*) This analysis should take personal safety into account. This phase of rescue is driven by the needs of the patient. It may call for specialized rescue personnel and equipment. Paramedics should be aware of the available resources in their area. They also should know how to mobilize these resources. Disentanglement often is time-consuming; the EMS crew should be prepared for extended scene time.

CRITICAL THINKING

What rescue teams are accessible to your community?

Patient Packaging

Stabilizing a patient physically and preparing the person for transport is known as **patient packaging.** This may require special rescue capabilities. For instance, the patient may need to be moved over hazardous terrain or lifted by hoist to a helicopter. As with all other aspects of rescue, the coordination of activities and the sharing of patient care responsibilities among the various agencies offer the greatest chance of a successful outcome.

It is the paramedic's responsibility to ensure the patient is ready to be removed from the scene. It also is the paramedic's duty to protect the patient from additional injury during disentanglement and **egress** (exit pathway). The patient should be covered with blankets or tarpaulins and provided with ear and eye protection. In addition, a face mask with supplemental oxygen or air should be applied. This protects the patient from toxic fumes, if present.

For minimum packaging for transport, the patient's airway and cervical spine must be stabilized, IV lines and oxygen tubing must be secured, and the patient must be immobilized on a long spine board. When time allows, extremity fractures should be immobilized and open wounds covered with sterile dressings and secured with bandages. A scene delay for patients who require rapid stabilization and transport may lessen the patient's chances of survival.

Use of other patient care equipment should be considered as the patient is removed from the area of entrapment. Communication and coordination with other rescuers must continue during this process. The exit pathway must be clear and secure. No additional danger for the patient or the rescuers should exist during the removal phase.

During disentanglement and patient packaging, the paramedic should consider the patient's emotional needs. Patients often are anxious and frightened by the rescue operations. When possible, paramedics should maintain a rapport with the patient. They should (1) provide reassurance that the patient is receiving good care; (2) prepare the patient for unexpected movements or procedures that may cause discomfort; and (3) explain all rescue maneuvers.

Transportation

If the patient is to be transported immediately to the ambulance, a wheeled stretcher, basket stretcher, scoop stretcher, or long spine board should be available. While the patient is transported to the emergency vehicle, the terrain, equipment, and personnel requirements for moving the patient should be considered (e.g., the need for air evacuation, specialized resources, and extra personnel). The ambulance should be appropriately warmed or cooled, based on the patient's needs and the rescue setting. The rescue is considered complete once the patient is en route to the hospital. As in any other patient transport, the EMS crew continues emergency care, and medical direction is advised of the patient's status.

RESCUER PERSONAL PROTECTIVE EQUIPMENT

Personal protective equipment for EMS personnel historically has been adapted from other fields (e.g., the fire service). The standards for protective clothing and PPE established by the National Fire Protection Association[1] and the federal Occupational Safety and Health Administration (OSHA)[2] have been adopted by many fire and EMS agencies, including a number of municipal and industrial fire services throughout the United States. It generally is agreed that, at minimum, EMS providers involved in rescue and other rescue personnel should have access to the following PPE:

- Impact-resistant protective helmet with ear protection and chinstrap
- Safety goggles with elastic strap and vents to prevent fogging
- Lightweight, puncture-resistant turnout coat
- Slip-resistant, waterproof gloves
- Boots with steel insoles and steel toe protection
- Self-contained breathing apparatus (SCBA)

The same PPE is not appropriate in all situations. Adequate protection depends on the level of rescuer involvement and the nature of the incident. Other PPEs may be appropriate in some rescue events (Box 55-1).

SHOW ME THE EVIDENCE

This research performed a retrospective review of the rate of injury or illness of Southern Arizona Rescue Association (SARA) volunteers during wilderness rescue over 30 years. This group averages 60 to 80 rescue operations per year. SARA volunteers had a similar number of lost work days for health services personnel as fire department personnel. Injuries were primarily musculoskeletal although there was one near drowning, one scorpion sting, and one chipped tooth reported. There were no deaths. The author cautions against generalizing this information to other rescue squads because of the uniqueness of the geographical terrain and because incident operations occurred mostly at night; in addition, SARA volunteers had an average of 8 years' experience.

From Iserson K: Injuries to search and rescue volunteers, *West J Med* 151:352-353, 1989.

Box 55-1 Supplemental Personal Protective Equipment

Head Protection That Meets Safety Standards for the Appropriate Use
- Compact firefighters' helmet that meets National Fire Protection Association (NFPA) standards for most vehicle/structural applications
- Climbing helmet for confined-space and technical rescue uses
- Padded rafting/kayaking helmet for water rescue

Eye Protection
- Adequate face shield (face shields on most fire helmets are inadequate)
- American National Standards Institute (ANSI)–approved safety glasses or goggles with solid shields (preferred)

Hearing Protection
- Required for high-noise areas
- Ear plugs or ear muffs should be available

Hand Protection
- Gloves that allow adequate dexterity and protect against cuts and punctures

Foot Protection
- Gear that provides ankle support to limit range of motion
- Tread that provides traction and prevents slips
- Insulation from environmental extremes
- Steel toe/shank that meets safety requirements

Flame/Flash Protection (When Fire Is Possible)
- Nomex/PBI/flame-retardant cotton to provide limited flash protection, turnout clothing, jumpsuits/flyers/coveralls (*Note:* This clothing does not provide complete protection from punctures or cuts. The thermal protection offered by turnout clothing may increase heat stress.)

Personal Flotation Device (When Operating on or Around Water)
- Meets Coast Guard standards for flotation
- Type II or type III (preferred for most water rescue work)
- Attached whistle and strobe light
- Attached knife for cutting

Visibility
- Reflective trim on all outerwear
- Orange clothing or safety vests for use during highway operations

Extended, Remote, or Wilderness Protection
- Additional or different personal protective equipment, if needed, for bad weather conditions not normally encountered (e.g., cold, rain, snow, wind)
- Personal drinking water and snacks
- Possible shelter needs

Personal Protection from Blood-Borne Pathogens

OSHA has established criteria for workplace protection from blood-borne and airborne diseases.[3,4] These measures for personal protection (described in Chapter 14) should be observed whenever the potential exists for exposure to a patient's body fluids or to communicable diseases.

LOOK AGAIN
See Chapter 14: Venous Access and Medication Administration, pp. 380-381.

SURFACE WATER RESCUE

Surface water rescue is the rescue of a patient who is afloat on the surface of a body of water. People are drawn to moving water for recreation. Many, including rescuers, underestimate the power and hazards of water. The hydraulics of moving water are affected by several variables. These include the depth and velocity of water and any obstructions to flow. Water rescue is very dangerous and requires special training and skills. Water rescue should never be attempted by a single rescuer or by an untrained one.

Obstructions to Flow

Water that moves over a uniform obstruction can create recirculating currents ("drowning machines") (Figure 55-2). These can trap victims and make escape difficult. Recirculating currents commonly are found in rivers and on low-head dams and often appear harmless. (The height of the dam is no indication of the degree of hazard.) The force of the moving water is very deceptive and makes for a hazardous rescue. Trapped victims often succumb to fatigue, hypothermia, and drowning.

Strainers are obstructions (e.g., trees, grating wire, or mesh) that allow current to flow through but that can trap objects such as boats or people. The force of the water against the victim makes escape difficult. Rescue teams must approach strainers cautiously to avoid becoming entrapped themselves.

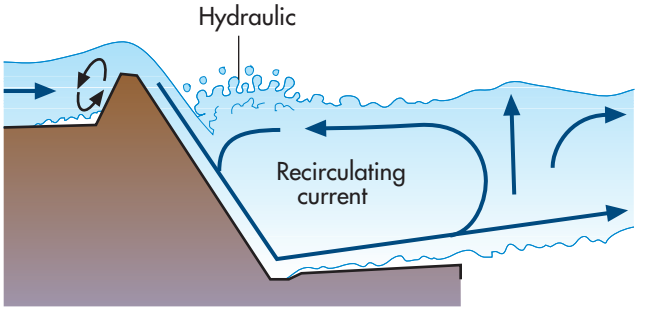

FIGURE 55-2 Low-head dams range in height from 6 inches to 10 feet. They can create dangerous hydraulics.

Foot or Extremity Pin

It generally is considered unsafe to walk in fast-moving water that is over knee-high depth. Doing so may lead to entrapment of an extremity in a strainer, and the victim can be dragged under the water's surface. With a foot or extremity pin, it is crucial to remember that *the body part must be extricated in the same way it became trapped.*

Flat Water

About 3600 deaths occur each year in flat (static) water (lakes, ponds, and marsh) as a result of drowning.[5] Factors that contribute to these deaths include alcohol or other drug use. Another factor is a cool water temperature, which leads to hypothermia. These factors can quickly incapacitate a victim and result in drowning. Most people who drown never planned on being in the water. **Personal flotation devices** (PFDs) that are worn routinely and fastened properly when a person is on or around the water can save lives by reducing the likelihood of drowning. PFDs are required during water rescue operations. Type I or type II PFDs are preferred for water rescue work. Specialty type III, IV, and V PFDs are suitable for some rescue situations.[6]

Water Temperature

As described in Chapter 45, immersion in water with a temperature below 98° F (37° C) can cause hypothermia. A person cannot maintain body heat when the water temperature is below 92° F (33° C). Water causes heat loss 25 times faster than exposure to air at the same temperature. (The colder the water, the faster the rate of heat loss.) At a water temperature of 35° F (1.7° C), a person immersed for 15 to 20 minutes likely will die of hypothermia and drowning.[7]

Sudden immersion in cold water may trigger laryngospasm. This can lead to aspiration, severe hypoxia, and unconsciousness. If hypothermia develops, the victim often is unable to follow directions (e.g., grab a safety device) or help himself or herself to safety. PFDs lessen heat loss and the energy required for flotation. In cases of sudden immersion, a single victim should assume a fetal position (the heat escape–lessening posture [HELP]). Multiple victims should *huddle* together to reduce heat loss (Figure 55-3).

COLD PROTECTIVE RESPONSE

The cold protective response is the *mammalian diving reflex* (see Chapter 45). This response increases the chance of a victim's survival in cold water. To review, this protective response includes parasympathetic stimulation from immersion of the face in cold water. It leads to bradycardia, peripheral vasoconstriction that shunts blood to the core, and hypotension. The effectiveness of this protective response depends on the victim's age, posture in the water, and lung volume, as well as the water temperature.

The rapid development of hypothermia sometimes can improve brain viability in patients who suffer prolonged submersion. Therefore hypothermic patients should be presumed salvageable. ("A victim is never cold and dead—only warm and dead.") The patient must be rewarmed in a hospital before an accurate assessment can be made.

Rescue Versus Body Recovery

Rescue versus body recovery refers to the chance to save a human life (rescue) versus recovering a body without the goal of saving a human life. In addition to temperature, other factors affect the outcome of a patient who has been submerged in water. These include the length of time the victim has been submerged, known or possible trauma, environmental conditions, the victim's age and physical condition, and the time until rescue or removal is achieved. Because successful resuscitation with full neurological recovery has occurred in victims of prolonged submersion in extremely cold water, resuscitation should be initiated by rescuers at the scene unless physical evidence of death is obvious (e.g., putrefaction, dependent lividity, or rigor mortis).[8]

In-Water Spinal Immobilization

In-water spinal immobilization (see Chapter 41) requires special training. Only rescuers trained in water rescue should enter the water. To review, the steps required for in-water spinal immobilization are as follows[9]:

1. Turn the patient to a supine position by rotating the entire upper half of the body as a single unit.

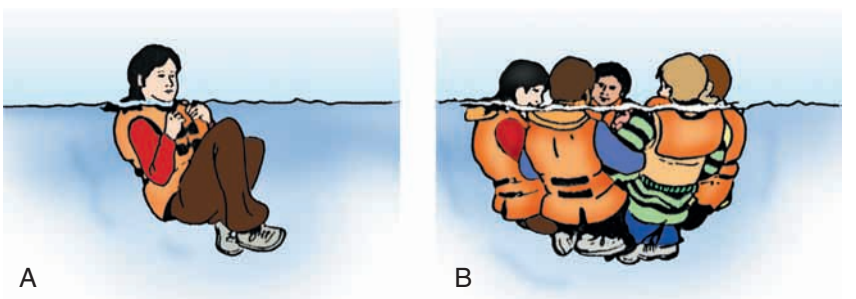

FIGURE 55-3 HELP and HUDDLE. When a person is floating in cold water, body heat can be conserved by using a body position that reduces the escape of heat. **A,** If the person is alone, the HELP position should be used. **B,** If several people are present, they should *huddle* together.

2. Using spinal precautions, begin artificial ventilation (if needed). Do not attempt to clear the airway of water.[10]
3. Float a long spine board under the patient's body.
4. Apply a rigid cervical collar.
5. Secure the patient to the spine board with straps, cravats, or other devices.
6. Float the patient to the edge of water and remove the patient from the water and completely stabilize. Cover the patient to prevent hypothermia. Begin cardiopulmonary resuscitation (CPR) if indicated.

Overview of Rescue Techniques

As previously stated, rescuers should never underestimate the power of moving water. Also, they should never attempt water rescue without highly specialized training. The recommended water rescue model is *reach-throw-row-go.*

- *Reach.* If the victim is close to shore, the paramedic should try to reach out to the person. An oar, a large branch, a pole, or some other rescue device should be used for this purpose. Before a rescue attempt, paramedics should don a PFD. They also should make sure their footing is secure so that they are not pulled into the water by the victim.
- *Throw.* While the paramedic remains on the shore, a flotation device (e.g., a water throw bag attached to polypropylene rope) should be thrown to the victim. That way, the victim can be pulled to shore.
- *Row.* If reach and throw methods are unsuccessful or if the victim is unconscious, trained rescuers should row out to the victim in a boat if one is available.
- *Go.* If a boat is unavailable and reach and throw methods are not viable options, trained rescuers should go to the patient by wading or swimming.

A shore-based rescue attempt by a first responder, either by coaching the victim in self-rescue or by reaching or throwing, is the method of choice. Boat-based or "go" techniques require specialized training.

SELF-RESCUE TECHNIQUES

If paramedics inadvertently enter dangerous water, they should use self-rescue techniques as follows:

1. Cover your mouth and nose during entry.
2. Protect your head and keep your face out of the water.
3. If in flat water, assume the HELP position.
4. If in moving water, do not attempt to stand up.
5. Float on your back with your feet downstream and your head pointed toward the nearest shore at a 45-degree angle.

HAZARDOUS ATMOSPHERES

Hazardous atmospheres are oxygen-deficient environments that may occur in **confined spaces.** (Confined spaces have limited access or egress and are not designed for human occupancy or habitation.) According to the National Institute of Occupational Safety and Health (NIOSH), nearly 60% of the deaths associated with confined spaces are people attempting rescue of a **victim.**[11] Examples of confined spaces include the following:

- Grain bins and silos
- Wells and cisterns
- Storage tanks
- Manholes and pumping stations
- Drainage culverts
- Underground vaults
- Trenches and cave-ins

Hazards Associated With Confined Spaces

According to OSHA, there are six major hazards associated with confined spaces. These include oxygen-deficient atmospheres, chemical/toxic exposure or explosion, engulfment, machinery entrapment, electricity, and structural concerns.

OXYGEN-DEFICIENT ATMOSPHERES

Oxygen-deficient atmospheres are not a visible hazard. Therefore rescuers often presume that an atmosphere is safe. The available oxygen in confined spaces must be tested by trained personnel. They use an atmospheric monitoring meter at the top, middle, and bottom of a confined space before entry. Any confined space that has an oxygen concentration less than 19.5% must be considered an atmospheric hazard.[12] An oxygen level that is too high (above 22%) in a confined space may produce rapid combustion. This also is a serious safety hazard.

CHEMICAL/TOXIC EXPOSURE OR EXPLOSION

Oxygen can be removed from the atmosphere by certain chemical reactions. Examples include reactions that occur during the formation of rust on steel structures and while pouring concrete, and natural decaying processes that displace oxygen by producing dangerous gases (e.g., methane). In addition, the presence of some chemicals and gases can lead to toxic exposure (see Chapter 57) (Box 55-2). They also may pose a high risk of explosion. Some dusts and particulate materials found in grain bins, silos, and storage tanks can be highly explosive when mixed with air. Many gases are heavier than air. Therefore these gases are found in higher concentrations at the bottom of storage vessels. As

Box 55-2 Toxic Gases That May Be Found in Confined Spaces

Hydrogen sulfide (H_2S)
Carbon dioxide (CO_2)
Carbon monoxide (CO)
Chlorine (Cl)
Low or high oxygen (O_2) concentrations
Methane (CH_4)
Ammonia (NH_3)
Nitrogen dioxide (NO_2)

with oxygen content, trained personnel should monitor for toxic or explosive gases in confined spaces using an appropriate testing device.

CRITICAL THINKING
Why can workers easily become disabled in situations that may involve exposure to toxic gases?

NOTE
Some silos are designed to produce oxygen-limiting conditions. This aids the fermentation process. These silos usually can be identified by their blue exteriors.

ENGULFMENT

Mechanical entrapment can occur when earth, grain, coal, or any other dry material that can flow engulfs a person in a confined space. **Engulfment** can produce an oxygen-deficient atmosphere and subsequent suffocation. In addition, those trapped by engulfment may be victims of physical (crushing) injury. They also are at an increased risk from explosive hazards.

MACHINERY ENTRAPMENT

Some structures, such as grain bins and silos, often have augers, screws, conveyors, and other machinery to move material stored in them. These and other mechanical devices can entrap a person, requiring extrication. Before rescue is attempted, trained and experienced personnel should identify and secure all such devices.

DID YOU KNOW?
The Power Take-Off (PTO)
A power take-off (PTO) is a splined driveshaft, usually on a tractor or other farm machinery. The PTO is used to provide power to an attachment or separate machine. The power transfer shaft that connects to the PTO can be a safety hazard to farm workers and emergency responders at the scene. Rescue personnel should never approach a PTO shaft until the machinery has been shut off, disengaging the PTO. In addition, it is important never to step over a rotating PTO shaft, but to walk around the machinery instead. The PTO shaft is responsible for many farm injuries. Clothing, such as shirt sleeves and long pant legs, and long hair can easily get caught on the shaft, resulting in severe injury or death. The rotating PTO shaft has caused more farm workers to lose arms and legs than any other single farming accident.[13]

ELECTRICITY

Electrical hazards from the power supply of motors and materials-management equipment may be present in some situations. Like machinery, all electrical devices must be identified and secured by experienced personnel. (These devices include electrical boxes and switches.) This helps to ensure the safety of the rescuer. This **lock-out process** must prevent any unauthorized person from entering the area or gaining access to the controls that have been disconnected. Motors and other electrical devices can "store" power that can lead to entrapment or injury. Chemical, steam, and water lines also must be secured or blocked by trained personnel during all rescues.

STRUCTURAL CONCERNS

The supporting structures of a confined space must be identified before entry to aid in safe rescue and extrication. For example, most cylindrical structures are supported by central I beams. These beams allow relatively easy maneuvering. However, noncylindrical structures may have L-, T-, and X-shaped spaces. These can affect entry and rescue procedures. They also can complicate the extrication pathway.

CRUSH COMPARTMENT SYNDROMES SECONDARY TO ENTRAPMENT

As described in Chapter 38, compartment syndrome can be caused by crushing mechanisms, which lead to ischemic muscle damage, tissue necrosis, and crush syndrome. These injuries can be severe. They are associated with rupture of internal organs, major fractures, and hemorrhagic shock. The degree of injury produced by the crushing force depends on three elements: (1) the amount of pressure applied to the body; (2) the length of time the pressure is exerted on the body; and (3) the specific body region where the injury occurs. A massive crush injury to vital organs may cause immediate death.

Patients with crush syndrome are victims of compressive forces that crush tissue. This causes prolonged hypoxia. The patient may appear stable for hours or days, as long as the compressive forces remain in place. When the patient is released from the entrapment, the reperfusion of the trapped body part may lead to detrimental processes. These include volume loss into the tissue and the release of myoglobin, lactic acid, and other toxins into the circulation. As described in Chapter 38, these events occur simultaneously and may ultimately lead to death. If the patient's condition or the mechanism of injury is suspicious for compartment syndrome or crush injury, the paramedic should consult with medical direction. Management of crush syndrome is controversial. Prehospital care must be supervised through a medical direction physician familiar with this pathological process.

LOOK AGAIN
See Chapter 38: Bleeding and Soft Tissue Trauma, pp. 1109-1110.

Emergencies in Confined Spaces

OSHA requires a permit before workers may enter a confined space.[12] This standard has forced industrial, municipal, and government response teams to be better prepared

to manage confined-space incidents. Requirements for obtaining a permit include the following:

1. The area must be made safe or workers must wear PPE.
2. Fall-arresting and retrieval devices must be in place.
3. Environmental monitoring must be available at the site before entry.

Sites without permits at which no atmospheric monitoring is performed are likely locations for emergencies. At these sites, rescuers often may encounter oxygen-deficient atmospheres. Other types of emergencies that can occur in confined spaces (in both permitted and nonpermitted locations) include the following:

- Falls
- Medical emergencies
- Explosion
- Entrapment
- Exposure to toxic gases and chemicals

SAFE ENTRY FOR RESCUERS

As previously stated, safe entry for rescuers in a confined-space operation requires specialized training. No rescuer should enter the space until a rescue team has made the area safe. Safe entry cannot be made without the following[11]:

- Proper and thorough training in confined-space rescue
- Atmospheric monitoring to determine the oxygen concentration, hydrogen sulfide level, carbon monoxide level, explosive limits, flammable atmosphere, and toxic air contaminants
- Proper ventilation
- Secured electrical systems (lock-out/tag-out of all power)
- Dissipation of stored energy
- Disconnection of all pipes (blinding/blanking) to prevent flow into the site
- Appropriate respiratory protection

Supplied-Air Breathing Apparatus. Close quarters make access and extrication difficult in confined-space rescue. Because of this, use of the typical "bottle on back" SCBA is usually dangerous. The device provides a limited air supply, can cause entrapment, and may have to be removed in order to reach the victim. The **supplied-air breathing apparatus** (air-line SABA) is preferred in confined-space operations (Figure 55-4). These lightweight devices provide a nearly unlimited supply of air from a device located outside the confined space.

Potential complications of the SABA include equipment malfunction, damaged or entangled air lines, and limitations imposed by the length of the air hose. Trained rescuers carry a small, personal reserve air supply (escape bottle) that can be used for a short time if needed.

ARRIVING AT THE SCENE

An EMS crew that arrives at the scene of a confined-space emergency should proceed as follows:

1. Perform a scene size-up and determine the nature of the emergency by obtaining a copy of the OSHA permit (Figure 55-5) for the site from the permit/entry supervisor. Determine the number of workers (victims) in the confined space.
2. Request specialized rescue teams.
3. Establish a safe perimeter away from the incident. Allow only rescue team members to enter the space.
4. Assist workers at the site with any remote retrieval devices they may be using.

NOTE: Scene safety is of prime importance for all involved in the rescue. Only specialized rescue personnel should directly perform rescue activities. EMS personnel who are not trained in specialized rescue should assist the rescue team only if they can do so safely without entering the space.

Rescue From Trenches and Cave-Ins

Most trench collapses occur in trenches less than 12 feet deep and 6 feet wide. Federal law requires either shoring or a trench box for evacuations that are 5 feet or deeper. Often these collapses occur when contractors forsake safety measures because of the increased cost of providing them. Factors that contribute to collapse include the following:

- Cave-in of lips on one or both sides of the trench
- Walls that shear away and cave in
- Piling of excavated dirt too close to the edge, causing collapse
- The presence of intersecting trenches
- Ground vibrations
- Water seepage

NOTE
One cubic foot of soil weighs 100 pounds; 2 feet of soil on a person's chest or back is equal to 700 to 1000 pounds of pressure, which can cause burial and can rapidly lead to suffocation.

FIGURE 55-4 Supplied-air (air-line) breathing apparatus (SABA).

FIGURE 55-5 Example of a confined-space entry permit.

ARRIVAL AT THE SCENE

On arrival at the scene of a collapse that has resulted in burial, paramedics should keep in mind that a second collapse is likely and should not approach the lip. EMS personnel should not attempt a rescue unless the trench is less than waist deep. Instead, they should take the following steps in scene management:

1. Secure the scene, establish command, and secure a safe perimeter.
2. Shut down nonessential equipment that can cause vibrations.
3. Request specialized rescue teams.
4. Prevent entry into the trench or cave-in area.

Access to the patient should be attempted by trained personnel only after proper shoring is in place. The process of shoring and excavating can be labor and time intensive. However, scene safety is necessary for a successful recovery.

CRITICAL THINKING

Consider an EMS and rescue team that, for safety reasons, will be unable to go in after a person who is buried in a trench collapse. How do you think they will feel?

HIGHWAY OPERATIONS

Traffic flow is a major hazard in EMS highway operations. Factors associated with highway hazards include emergency responses to limited and unlimited access highways, emergency vehicle crashes, and the backup of traffic that impedes flow to and from the scene. Because of the potential problems in traffic flow, EMS personnel must work closely with law enforcement personnel to help ensure a safe response. Paramedics can take the following steps to reduce traffic hazards:

- Position an apparatus (pumper, rescue, or other emergency vehicle) across the traffic direction in the fend-off position. This protects the scene from traffic hazards.
- Stage unnecessary apparatus off the highway (this is essential on limited access highways); establish a staging area away from the scene.
- Position an apparatus to reduce traffic flow and provide for a safe ambulance loading area.
- Use only essential warning lights so that drivers are not distracted or confused. (Consider the use of amber scene lighting.) Turn off headlights that might blind nearby motorists.
- Use traffic cones and flares to redirect traffic away from workers and to create a safe zone. (Use flares safely in proximity to the scene. Do not extinguish them once they have been ignited.)
- Make sure that all rescuers wear high-visibility clothing (e.g., orange highway vests, reflective trim).

Other scene hazards associated with highway operations include fuel and fire hazards, electrical power, unstable vehicles, air bags and supplemental restraint systems (SRS), and hazardous cargoes.

Fuel and Fire Hazards

Gasoline spills from crashes are a common fire hazard encountered by EMS providers. The chances that flammable liquids will ignite can be reduced by turning off the vehicle ignition switch, forbidding smoking, and avoiding use of flares near the spill. EMS personnel should approach the scene with fire extinguishers and should keep the extinguishers ready throughout extrication (Box 55-3). Ideally, a fire apparatus with a charged hose line should be at the scene.

The vehicle should be put in park and the engine stopped immediately after gaining access. The battery of a crashed car generally should be left connected so that power electric door locks, windows, seat mechanisms, and trunks can be operated. However, if the battery is to be disabled, the ground cable should be disconnected first to reduce the chance of sparking. Sparking may ignite spilled fuel or leaking battery gases. Most newer American cars have positive ground cables that can be identified by battery markings or by locating the ground wires attached to the frame, engine, or body of the vehicle. The battery cable can be cut with wire cutters or disconnected with battery pliers. The disconnected cable should be folded back onto itself. Then it should be securely taped to insulate it from any bare metal contact that might reestablish the electrical ground to the system. Both cables should be disconnected and secured.

Box 55-3 Fire Extinguishers

Portable fire extinguishers are classified by their anticipated effectiveness in suppressing four classes of fires:

- Class A—Ordinary combustibles
- Class B—Flammable liquids
- Class C—Energized electrical equipment
- Class D—Combustible metals

ABC all-purpose extinguishers are suitable for more than one class of fire. They should be carried by EMS crews. These dry chemical extinguishers can be used to suppress fires of ordinary combustible materials, flammable liquids, and electrical equipment.

Class A and class B fire extinguishers are given a numerical rating in addition to the letter classification. This rating designates the size of fire the extinguisher can be expected to suppress. A 20-B extinguisher generally extinguishes 20 times as much fuel as a 1-B extinguisher.

Fire suppression agents work by reducing heat and eliminating the oxygen needed to maintain combustion. Eliminating oxygen may present a danger to the rescuer and patient; therefore paramedics must work carefully in confined spaces. In addition, crew members and patients should avoid undue exposure to the fumes of any fire suppression agent. All rescuers should use an appropriate breathing apparatus.

Vehicle fires associated with crashes usually are caused by ruptured fuel tanks and fuel lines ignited during the crash. (Catalytic converters are capable of igniting spilled fuel.) Paramedics should not try to fight fully involved vehicle fires unless they have been trained and are properly equipped to do so. If the fire service has not arrived and victims are in a burning vehicle, the EMS crew should quickly determine whether the victims can be safely removed. If the victims are trapped and the vehicle is not fully engulfed by flames, an attempt should be made to stop the fire from spreading. This should be done using fire extinguishers.

Burning vehicles present very serious potential hazards. They may explode with deadly force at any time. All actions must be directed toward rescuer safety and protection. When paramedics must approach a burning vehicle, they should crouch low and approach from the side, staying clear of bumpers that may fly off during explosions. PPE also should be worn to guard against dangerous and caustic smoke.

ALTERNATE FUEL SYSTEMS

Some automobiles operate with alternate fuel systems. Examples include cars that are powered by natural gas, high-voltage electrical storage cells, and hybrid vehicles that use a combination of fuel sources. These alternate fuel sources are capable of producing fire hazards and injury from explosion of high-pressure cylinders and storage cells. Electric vehicles also carry enough voltage to cause serious burns, electric shock, and death. Hybrid vehicles often can be identified by a hybrid label and the presence of orange sleeves that cover components under the hood, in the rear, and under the car. Each automobile manufacturer has specific guidelines for emergency personnel to follow when working at a crash scene. The following are general guidelines for rescue[14]:

- Remain a safe distance from the vehicle if it is on fire.
- Always power down windows, open locks and latches, and move electric seats before disabling any vehicle. Put the vehicle in park. Chock the wheels as soon as possible in case a car in the "sleep mode" has its gas pedal depressed inadvertently by a driver.
- Verify that the vehicle is absolutely not under any power. *Always assume the vehicle is powered up despite no engine noises.* Shutting the vehicle off shuts down the hybrid system, shuts down the fuel pump, stops the electrical flow to air bags, and isolates the high-voltage current from the battery pack. (Many conventional and hybrid vehicles use a keyless entry/start ignition/start system.) High-voltage capacitors can store a voltage current for up to 10 minutes, even after the vehicle is shut down. During this "drain time," the vehicle should be considered unsafe.
- Never touch, cut, or open any orange cable or components protected by orange sleeves. Always consider a high-voltage cable to be live or hot.

Electrical Power

Downed electrical wires are dangerous. Modern transformers are programmed to retest broken circuits at certain time intervals. The dead lines can suddenly surge with lethal current. Rescuers must be familiar with the power system in their area. They should check with the local power company for information and the availability of training sessions for the response team. Only utility workers and trained rescuers using proper equipment should secure downed electrical wires.

Rescuers should never approach the patient until the scene is safe. Rescuers who experience tingling sensations in the soles of the feet, legs, or thorax as they enter an area should not proceed. Rather, they should retreat from the area. Victims inside a vehicle that is in contact with downed wires should be advised to remain inside unless they are at additional risk of injury (e.g., explosion, fire). Leaving the vehicle is dangerous and poses a significant risk of electrical injury.

When it is absolutely necessary to touch a patient who is in contact with a source of electricity, trained personnel may use nonconductive equipment such as leather gauntlets, wooden poles, polypropylene rope, and other specially designed equipment. However, none of these measures provides absolute safety from electrical injury.

Unstable Vehicles

Unstable vehicles are a common hazard in rescue events. All unstable vehicles must be stabilized before access is gained. The mechanism of the crash, the position and number of vehicles, and the environment of the scene must all be considered when assessing the stability of vehicles.

Some vehicles are obviously unstable. (For example, a vehicle may be positioned on its side or on its roof.) However, even a car on its wheels that appears to be stable may be unstable from possible movement of the tires and swaying of the vehicle's suspension system. All wrecked vehicles should be approached cautiously. Standard methods of stabilizing vehicles include supporting the vehicle with wooden cribbing, wheel chocks, and air bags and securing the vehicle with ropes, cables, and chains to poles, trees, and other vehicles and structures (Figure 55-6). Figure 55-7 shows equipment used to stabilize vehicles. Specialized training is required for paramedics involved in this aspect of rescue management.

Air Bags and Supplemental Restraint Systems

Air bags as a **supplemental restraint system** (SRS) are required safety features in all cars manufactured in the United States. The three main types of air bags are frontal impact, side impact, and head protection bags. (These devices can be located in numerous places inside the vehicle.) Air bags generally are considered an effective safety device in crashes. However, children and small adults in the

FIGURE 55-6 Vehicle stabilization.

passenger seat have been fatally injured after air bag deployment.[15]

> **NOTE**
> Most air bags are designed to automatically deploy in the event of a vehicle fire when temperatures reach 300° to 400° F. This safety feature helps to ensure that such temperatures do not cause an explosion of the inflator unit within the air bag module.

Once deployed, air bags are not dangerous. However, they do produce a residue that can cause minor skin or eye irritation. Irritation from this residue is temporary. It can be avoided by wearing gloves and eye protection; by keeping the residue away from the patient's eyes and wounds; and by thoroughly washing after exposure. Emergency personnel should be trained in detection and scene management of SRS equipment. Rescue guidelines for air bag–equipped cars have been provided by the National Highway Traffic Safety Administration and automobile and air bag

FIGURE 55-7 Equipment used to stabilize vehicles.

manufacturers and have been coordinated with the U.S. Fire Administration (Box 55-4).[16]

Hazardous Cargoes

Most hazardous substances transported in the United States travel by road. Therefore paramedics should be suspicious of crashes that involve commercial vehicles. Methods that can be used to identify carriers of hazardous cargoes (e.g., United Nations class identification number and North American number [UN/NA number] and placards) and the management of hazardous materials incidents are discussed in Chapter 57.

Automobile Anatomy

Vehicle rescue operations require a basic understanding of the anatomy of automobiles (Figure 55-8). The following are several important features:

- *Construction, roof,* and *support posts.* Most vehicles are of unibody rather than frame construction. The support posts (A, B, C, and D posts), floor fire wall, and trunk are integral to the integrity of unibody construction. Cutting the support posts can threaten the stability of these vehicles.
- *Fire wall* and *engine compartment.* A fire wall separates the engine and occupant compartments. The fire wall often collapses onto the occupant's legs during high-speed, head-on collisions. The car battery is usually located in the engine compartment.
- *Glass.* Safety glass is composed of glass-plastic and laminate glass and is usually found in the windshield. It is designed to stay intact when the glass is broken or shattered (it fractures into long strands). Tempered glass has high tensile strength and may not remain intact when it is shattered or broken (it fractures into small pieces).
- *Doors.* Most car doors contain a reinforcing bar. They are designed to provide structural integrity to the vehicle and protection to the occupants during front-impact and side-impact collisions. Doors also have a case-hardened steel "Nader" pin or latch that is designed to prevent the car door from opening during impact. If the pin is engaged, it may be difficult to pry open the door; it must be disengaged first.

Box 55-4 Rescue Guidelines for Air Bag–Equipped Cars

Incident With a Deployed Air Bag

Deployed air bags are not dangerous. However, not all air bags deploy during a crash. Also, side-impact air bags operate independently of the frontal air bags. Rescuers should practice the *5-10-20 rule* for safe distancing to reduce the severity and risk of injury should unintentional deployment occur. The rule is as follows:

- Side-impact curtain and air bags—Maintain a safe distance of 5 inches or more.
- Driver-side frontal air bags—Maintain a safe distance of 10 inches or more.
- Passenger-side frontal air bags—Maintain a safe distance of 20 inches or more.

In addition, rescuers should not place any hard board or device between an air bag and a patient or rescuer.

Once the air bag is deployed, it will not deploy again.

Incident With an Undeployed Air Bag

Undeployed air bags can suddenly deploy during a rescue. This releases a tremendous amount of energy. The energy can be dangerous to both the patient and the rescuer. If a patient is pinned behind an undeployed air bag, the car battery should be deactivated as soon as possible. Before they disconnect the battery, paramedics should determine whether they will need to move a power seat, unlock electric doors, or power down electric windows. The procedure for deactivating the battery is as follows:

1. Turn off all electrical units and the ignition switch. Carefully disconnect both battery cables (disconnect the negative cable first).
2. Cables that need to be cut should be cut twice to ensure that the cut ends will not touch and arc. Make sure the battery terminals cannot make contact with metal body parts that could reactivate an electrical circuit. Do not attempt to turn on the ignition switch to test a battery disconnect; verify it by attempting to turn on the lights.
3. For additional safety, maintain the 5-10-20 rule near air bags that have not deployed.

NOTE: If the incident involves fire, normal fire extinguishing procedures should be used. Heat may trigger an undeployed air bag. However, it will not cause the activating canister to explode.

RESCUE STRATEGIES

Rescue strategies for vehicle crashes should begin during the initial scene size-up. They sometimes can be based on the details provided by the dispatching center before arrival. On arriving at the scene, the EMS crew should begin hazard control, establish command, and call for appropriate backup. Important elements of the scene size-up include the following:

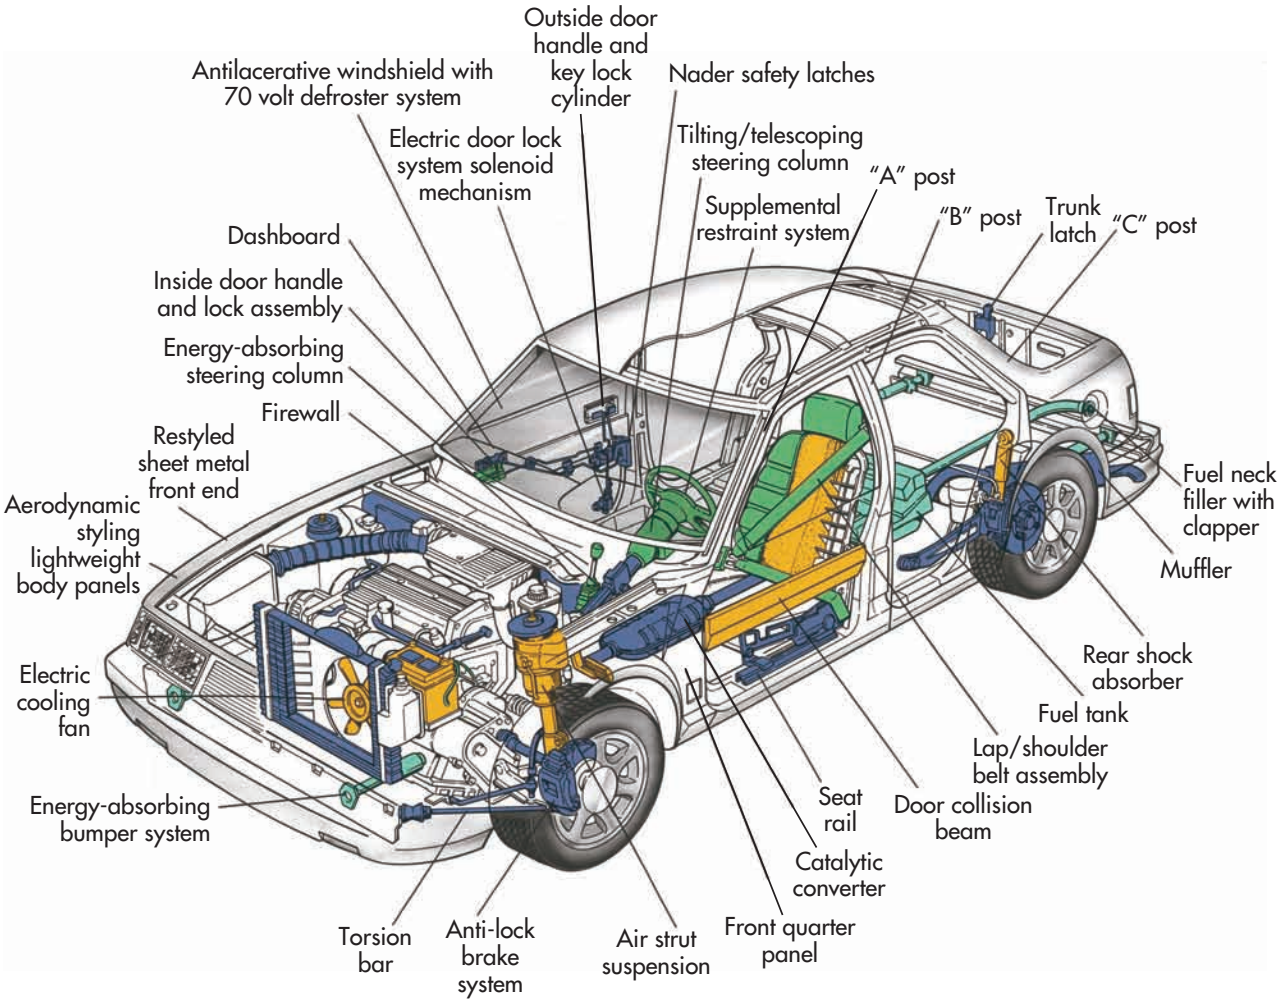

FIGURE 55-8 Anatomy of a car.

- Scene safety (including protecting the scene from traffic hazards)
- Location of the crash
- Vehicle stability
- Electrical hazards
- Fire hazards
- Hazardous materials
- Special rescue needs
- Number and location of patients

After performing the initial scene size-up and ensuring scene safety, the responding crew should assess the degree of entrapment and the fastest means of extrication. The paramedic should try to gain access to trapped victims by first trying to open all car doors. When a door cannot be readily opened by the patient or rescuer, another option is the side windows. (Glass windows can be shattered by striking the glass in a lower corner or by using a spring-loaded center punch.) Initial care can then be provided until the patient has been extricated. Trained rescue personnel with extrication tools can gain access to the patient by door removal, roof removal, front or rear windshield openings, or a dash roll-up maneuver (Figure 55-9). Paramedics involved in the rescue or who are near the site should wear PPE that provides adequate hand, eye, and body protection. (Persons trapped in a vehicle should also be protected during extrication.) Clothing with reflective striping improves safety during day and night operations.

HAZARDOUS TERRAIN

Hazardous terrain can pose major difficulties during rescue operations. An example is a car crash that occurs on an embankment. Other examples are rescues for sport enthusiasts such as rock climbers, snow skiers, and mountain bikers. Three common classifications of hazardous terrain are low-angle, high-angle, and flat terrain with obstructions (Box 55-5). Highly specialized training and equipment are required for rescues in both low-angle (weight supported by ground) and high-angle (weight supported by rope) environments.

The term *low angle* (steep slope) refers to terrain that can be walked on without the use of the hands. However, secure footing may be difficult on steep slopes. This makes it hazardous to carry a litter even with several rescuers. In these situations, **low-angle rescue** is used to prevent falls and

FIGURE 55-9 Extrication scenes. (Courtesy O'Fallon Fire Department, O'Fallon, Mo.)

Box 55-5 Terms and Definitions Related to Rescue Over Hazardous Terrain

anchoring: Attaching a high-angle rope to a secure point.
belay: A method of attaching a safety rope and controlling the rope so that if the person or load starts to fall, the belay rope prevents the fall.
high angle: An environment in which rescuers need to be secured with rope for safety. Most of the rescue load is supported by the rope system.
low angle: An environment in which the weight of the stretcher is supported primarily by the tender's legs, but rope systems are required to facilitate movement and for protection against falls.
rappelling: A method of descent that involves lowering oneself with a rope.
scrambling: Movement over rough terrain that is not steep enough to require the use of a rope.

tumbles through the use of ropes to counteract gravity during litter carrying (Figure 55-10).

The term *high angle* (vertical) refers to terrain (cliffs, sides of buildings) that is so steep the hands must be used to maintain balance (slopes of more than 40 degrees). In these situations, rescuers are completely dependent on rope or aerial apparatus for litter movement. **High-angle rescue** requires **rappelling** (controlled descent by a rope) by trained personnel to retrieve victims. Falls are likely to result in serious injury or death (Figure 55-11). Box 55-6 and Figure 55-12 discuss ropes and basic knots used in rescue.

CRITICAL THINKING
What factors in the environment can increase the danger of steep-slope rescue?

Flat terrain rescue may include various obstructions that can make rescue difficult. Examples include level land with large rocks, loose soil (scree), and waterbeds or creeks. In these situations, extra personnel and resources may be needed to extricate a victim safely and to ensure safe litter movement.

FIGURE 55-10 Low-angle rescue. (Courtesy O'Fallon Fire Department, O'Fallon, Mo.)

FIGURE 55-11 High-angle rescue. (Courtesy O'Fallon Fire Department, O'Fallon, Mo.)

Box 55-6 Ropes and Knots

There are generally two types of rope used for life safety rope: **static rope** and **dynamic rope.** The preferred rope used for life safety rescue operations is **static Kernmantle.** (Kern means core and mantle means sheath.) Dynamic rope is usually used when climbing toward or above an anchor point. Static rope provides for minimal stretch (a low elongation factor). Dynamic rope is designed to stretch (a higher elongation factor). All ropes used for rescue operations should meet the NFPA minimum standards for life safety rope. These ropes will have a minimum safety factor of 15:1 for a two-person **load**.[17]

Knots are used in rescue operations to fasten and secure a rope by tying or interweaving. Although there are many knots used in rescue operations, common knots often belong to the figure 8 family. These include (Figure 55-12):

Figure 8
Figure 8 on a bite
Figure 8 follow-through
Double-loop figure 8
Figure 8 bend
Inline figure 8

Note: A common phrase used by rescue personnel when teaching the tying of knots: *If you can't tie a knot—tie a lot!* Wrapping and re-wrapping ropes around a stable structure often can provide stability.

Patient Packaging With Litters

The **basket stretcher** is the standard for rough terrain evacuation. The rigid frame of this device offers protection for the victim. It also is relatively easy to carry with adequate personnel. Patients generally are immobilized on a long backboard and secured in the basket. Alternative spinal immobilization devices (e.g., vest-type devices) also can be used in conjunction with the basket stretcher. Using the basket stretcher itself as a spinal immobilization device should be considered a last resort. The older "military style" devices do not provide adequate spinal immobilization.

Basket stretchers have two basic designs: wire mesh (Stokes) and plastic. Wire mesh generally is the stronger of the baskets. It also is relatively inexpensive. The design allows for air and water to flow through the device. This makes it ideal in water rescue when used with supplemental flotation. Plastic basket stretchers generally are weaker than steel mesh. However, they provide better protection for the patient. (Plastic bottoms with steel frames are considered superior designs.) Most basket stretchers are equipped with adequate restraints. However, all require additional strapping or lacing (e.g., harness, leg stirrups) to prevent movement, as well as padding for rough-terrain evacuation or extraction. A plastic helmet or litter shield should be available to protect the patient.

PATIENT MOVEMENT

Methods of moving a patient over rough terrain may include evacuation and litter-carrying over flat terrain. However, special rescue equipment may be required for low-angle and high-angle evacuation. Such equipment may include load-lifting straps, anchors, and rope-lowering and rope-hauling systems. In addition, the use of aerial apparatus (e.g., tower-ladder or bucket trucks, aerial ladders) also may be required in some high-angle rescue operations. Moving a patient during low-angle and high-angle evacuations requires specialized knowledge and skills.

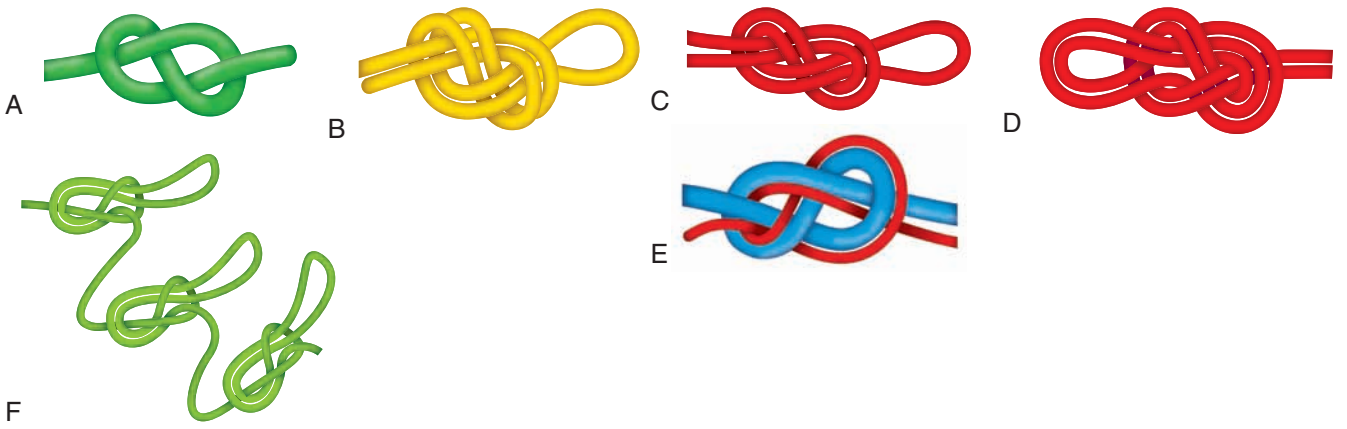

FIGURE 55-12 Knots. **A,** Figure 8. **B,** Figure 8 on a bite. **C,** Figure 8 follow-through. **D,** Double-loop figure 8. **E,** Figure 8 bend. **F,** Inline figure 8.

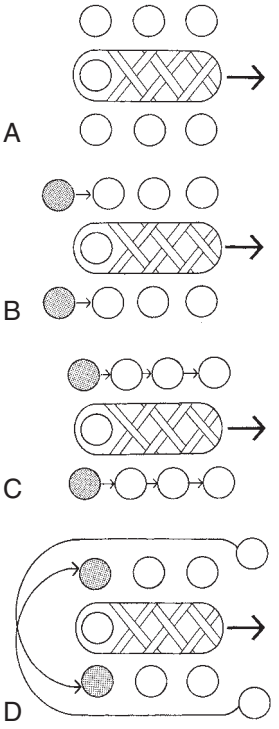

FIGURE 55-13 Litter-carrying sequence. **A,** Six rescuers are usually required to carry a litter; they may need relief over long distances (more than ¼ mile). **B,** Relief rescuers can rotate into position while the litter is in motion by approaching from the rear. As relief rescuers move forward, others progressively move forward **(C)** until the forward-most rescuers can release the litter (peel out) and move to the rear **(D)**. Rescuers in the rear can rotate sides so that they can alternate carrying arms. Carrying straps (webbing) can also be used to distribute the load over the rescuers' shoulders. In most cases the litter is carried feet first with a medical attendant at the head monitoring airway, breathing, level of consciousness, and so on.

LITTER-CARRYING PROCEDURES

Carrying a litter across rough, flat terrain requires a minimum of six rescuers: four to carry the litter and two to observe or "scout" for potential hazards (e.g., loose rocks, holes, tree branches). Team members should be matched in height. This ensures that equal weight is shared and that the litter remains level. Load-lifting straps sometimes are used to spread the weight of the load over other parts of the rescuer's body (e.g., around the rescuer's shoulders and back). As described in Chapter 2, proper lifting techniques should be used to protect and support the rescuer's back. Figure 55-13 shows a basic litter-carrying sequence.

Helicopter Use in Hazardous Terrain Rescue

As described in Chapter 53, helicopters can be used for transport and for rescues. When they are used for rescue, the helicopter team (civilian and military) is geared toward performing the rescue rather than providing medical care and transport. The rescue helicopter team has specialized knowledge and skills. They are required to hover or land in tight places and to transport people and equipment. Special rescue techniques that these helicopters use may include cable hoisting to extract people from the ground, and short-haul (sling load) operations that allow personnel and equipment to be carried beneath the helicopter as an external load. Rescue helicopters have the same safety concerns and limitations as those used for medical transport described in Chapter 53. All personnel at the scene should be familiar with the elements of scene safety, hazards, and restrictions for helicopter use.

LOOK AGAIN
See Chapter 53: Ground and Air Ambulance Operations, pp. 1471-1475.

ASSESSMENT PROCEDURES DURING RESCUE

Patient assessment during rescue operations often is complicated by factors such as weather and temperature extremes, available access, equipment limitations, patient entrapment, and cumbersome PPE that affects rescuer mobility. Other factors that can affect the paramedic's ability to perform a thorough assessment and that can result in a compromised physical examination include the following:

- Difficulty completely exposing a patient
- Restrictive clothing and PPE required for personal safety
- Working in a cramped space
- Limited lighting
- Difficulty transporting medical equipment to the patient

Specific Assessment and Management Considerations

During rescues, paramedics may need to downsize medical equipment. They may not be able to carry the normal bags and "street packaging." Ideally, paramedics should be able to carry the equipment hands-free. In addition to ensuring adequate lighting to perform assessment and treatment, paramedics should have access to the equipment listed in Box 55-7.

EXPOSURE OF PATIENTS

Patients who need to be rescued may be at high risk for developing hypothermia. They should be covered to ensure thermal protection. Also, the patient should be protected with shields (e.g., backboards or blankets) to prevent injury from equipment and debris during the extrication.

ADVANCED LIFE SUPPORT MEASURES

Advanced life support (ALS) measures should be provided only if necessary. However, good basic life support (BLS) techniques are mandatory. As a rule, ALS equipment such as IV lines, endotracheal (ET) tubes, and electrocardiographic (ECG) leads will complicate the extrication process. (Advanced airway support and volume replacement, however, may be essential.) Airway control with administration of supplemental oxygen must always be a priority during the rescue.

PATIENT MONITORING

Monitoring of the patient's vital signs and level of consciousness is necessary throughout the rescue. In high-noise and tight spaces, blood pressure may need to be measured by palpation. It also may be necessary to use compact devices such as a pulse oximeter. Paramedics should create and continue a rapport with the patient when possible. They should explain the procedures performed and why they are necessary. Providing emotional support during the rescue is crucial.

Box 55-7 Paramedic Equipment

Airway
- Oral and nasal airways
- Manual suction device
- Intubation equipment

Breathing
- Thoracic decompression device
- Small oxygen tank and regulator
- Masks and cannulae
- Pocket mask and bag-valve-mask device

Circulation
- Bandages and dressings
- Triangular bandages
- Occlusive dressings
- Intravenous fluid administration set
- Blood pressure cuff and stethoscope

Disability
- Extrication collars

Exposure of Body Surface
- Scissors

Miscellaneous
- Headlamp and flashlight
- Space blanket
- Pneumatic splints

Personal Protective Equipment
- Leather gloves
- Latex gloves
- Eye shields
- Other equipment as indicated

IMPROVISATION

Because of space and equipment limitations, some patient care may have to be improvised during a rescue. For example, an upper extremity fracture can be temporarily stabilized by tying it to the patient's torso; a lower extremity fracture can be tied to the patient's uninjured leg (buddy splinting). Formable splints (e.g., structural aluminum malleable [SAM] splint) also can be very useful for securing extremity fractures or dislocations.

PAIN CONTROL

Pain control for patients who require rescue may include drug therapy (narcotics, analgesics) and other methods. Examples of nondrug therapy to manage pain includes splinting and positioning, distraction (talking to the patient and asking questions), and methods such as creating sensory stimuli (e.g., mildly scratching the patient) when a painful procedure or maneuver is performed. Pain medication can mask serious injury and alter a patient's level of consciousness. Therefore the paramedic should follow established protocol regarding the use of drug therapy in these situations.

SUMMARY

- Rescue is a patient-driven event. It requires specialized medical and mechanical skills. The right amount of each must be applied at the right time. The main role of the paramedic in rescues is to have the proper training and the appropriate PPE. These allow safe access to the patient and the provision of treatment at the site and throughout the incident.
- The seven phases of a rescue operation are arrival and scene size-up, hazard control, gaining access to the patient, medical treatment, disentanglement, patient packaging, and transportation.
- The standards for protective clothing and personal protection equipment established by the National Fire Protection Association and OSHA have been adopted by many fire and EMS agencies. The appropriate PPE depends on the level of rescuer involvement and the nature of the incident.
- Water rescue should never be attempted by a single rescuer or by one who is untrained.
- Water hazards include obstructions to flow and foot or extremity pins that can trap victims and drag them under water. Some factors that contribute to flat water drowning are alcohol or other drug use. Also, cool water temperatures contribute to such drownings.
- Hazardous atmospheres are environments with low oxygen. These environments can occur in confined spaces. The six major hazards associated with confined spaces are oxygen-deficient atmospheres, chemical/toxic exposure and explosion, engulfment, machinery entrapment, electricity, and structural concerns.
- Traffic flow is the biggest hazard in EMS highway operations. Other scene hazards associated with highway operations include fuel or fire hazards, electrical power, unstable vehicles, air bags and supplemental restraint systems, and hazardous cargoes.
- Hazardous terrain can create major difficulties during rescue events. Three common classifications of hazardous terrain are low-angle, high-angle, and flat terrain with obstructions.

CHAPTER

56 Crime Scene Awareness

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe general techniques for determining whether a scene is violent and choosing the appropriate response to a violent scene.
2. Outline techniques for recognizing and responding to potentially dangerous residential calls.
3. Outline techniques for recognizing and responding to potentially dangerous calls on the highway.
4. Describe signs of danger and emergency medical services (EMS) response to violent street incidents.
5. Identify characteristics of and EMS response to situations involving gangs, clandestine drug labs, and domestic violence.
6. Outline general safety tactics that EMS personnel can use if they find themselves in a dangerous situation.
7. Describe special EMS considerations when providing tactical patient care.
8. Discuss EMS documentation and preservation of evidence at a crime scene.

KEY TERMS

audible and visual warning devices Safety devices used in emergency responses to make vehicle presence known; examples include lights, sirens, and horns.

avoidance The act of keeping away from someone, something, or a situation, or of preventing the occurrence of something; it requires the paramedic to continually be aware of the scene by remaining observant and being knowledgeable about warning signs that may indicate a dangerous situation.

backlighting Positioning oneself between the ambulance lights and residence; a safety hazard.

clandestine drug lab A place of illegal drug manufacturing.

concealment A means of keeping out of sight; it provides no ballistic protection.

contact provider The person who initiates and provides direct patient care.

cover A type of concealment that offers ballistic protection.

cover provider The person whose role is to ensure safe cover for the contact providers while they provide patient care.

crime scene A location where any part of a criminal act has occurred, or a location where evidence relating to a crime may be found.

distraction A self-defense measure in which a diversion is created to attract a person's attention.

evasive tactics A self-defense measure in which an aggressor's moves and actions are anticipated, and unconventional pathways are used during retreat for personal safety.

gang Any group of people who engage in socially disruptive or criminal behavior.

graffiti Gang markings that usually indicate territorial boundaries; also known as "tagging."

hot zone In tactical response, the area where patient care activities occur inside the scene perimeter.

soft body armor Clothing that provides protection from some blunt and penetrating trauma; also known as *"bullet-proof vests."*

special weapons and tactics operations Violent and dangerous incidents where specially trained emergency personnel teams respond; also known as "SWAT operations."

staging A tactical response to avoid danger by waiting at a safe distance from the scene until the area has been secured by the appropriate authorities.

tactical EMS Emergency medical support provided by EMS personnel who are specially trained and equipped to provide prehospital emergency care in tactical environments.

tactical patient care Patient care activities that occur inside the scene perimeter, or hot zone, of a dangerous scene.

tactical retreat Leaving the scene when danger is observed or when violence or indicators of violence are displayed; requires immediate and decisive action.

turf Refers to territorial boundaries established by gangs.

Many violent crimes require an EMS response, and often EMS crews arrive at the scene before law enforcement personnel. Consequently, awareness and avoidance of dangerous situations are issues of concern for emergency responders. Although national studies have reported a decline in violent crimes in recent years, violence against EMS personnel from street gangs, threat groups, domestic disputes, and drug users is on the rise.[1,2] Personal safety and crime scene awareness must be top priorities on every call of this nature.

(Courtesy Ronald Olschwanger, St. Louis, Mo.)

CRITICAL THINKING
Why is it not always possible to identify a dangerous scene before arriving at the scene?

APPROACHING THE SCENE

For paramedics and other responders, determining personal safety is a basic part of analyzing a scene. It begins before paramedics arrive at the scene with information provided by a dispatching center. *A key point in ensuring personal safety is to identify and respond to potential dangers before they threaten.* Information may be available from a dispatching center that should alert the EMS crew to possible dangers. Such information includes known locations of unsafe scenes (e.g., through computer-aided dispatch systems) and/or the presence of the following:

- Large crowds
- People under the influence of alcohol or other drugs
- On-scene violence
- Weapons

Other information can sometimes be gathered en route to the scene from crew members, dispatchers, and other emergency responders monitoring the call who have had previous experience with a particular area or address. The paramedic also should be aware of additional inherent hazards that may exist at the scene. Examples include downed power lines, busy roadways, toxic substances, the potential for fire, dangerous pets, and vehicle hazards and dangers. If the scene is not safe, the EMS crew should retreat. The crew should stage at a safe location to await the arrival of law enforcement and/or other rescuers.

When responding to a scene with a potential for danger, the EMS crew should begin observation several blocks from the scene. They also should use **audible and visual warning devices** (AVW devices) that are appropriate for the call. For example, responding with AVW devices to an urban scene may draw a crowd of bystanders; lights generally are required for safety at highway scenes. As described in Chapter 53, joint fire-EMS-law enforcement responses should be defined through preplanning (for example, a fire-EMS emergency response with full use of AVW devices, and law enforcement response without AVW devices and at normal speed).

Scene safety considerations for all types of danger must continue throughout the EMS response. A scene that has been made safe can become unsafe, even when the police are present. This can happen if violence resumes, crowds gather or turn violent, or other people enter the scene. Violence against EMS providers also may occur if they are mistaken for police officers (because of uniform colors or badges) or when they exit an emergency vehicle that has AVW devices. The paramedic crew must be familiar with local protocols when intervening in violent situations. They also must have a strategic escape plan ready.

Scenes Known to Be Violent

If the scene is known to be violent, the EMS crew should remain at a safe, out-of-sight distance from the area until it has been secured ("out of sight—out of scene"). Remaining at a safe staging area away from a violent scene is important for several reasons:

- If paramedics can be seen, people will come to them.
- Entering an unsafe scene adds one or more potential victims.
- Paramedics may be injured or killed.
- Paramedics may be taken hostage.
- Paramedics may become additional patients in a scene that is already a multiple casualty incident.

It must be stressed that if the scene is unsafe, the EMS crew should not enter. Rather, they should retreat to a staging area and wait for resource personnel who can provide scene safety.

SHOW ME THE EVIDENCE

In this abstract, the authors describe their investigation of the type and frequency of violence experienced by EMS personnel in a metropolitan system that served a population of nearly one-half million people. They performed a prospective direct observation study for 737 hours and 342 ambulance runs. Of the calls, 81% were rated nonviolent, 5% violent, and 14% postviolent. Of the violence observed, 88% involved verbal abuse solely, 38% demonstrated physical aggression solely toward objects or self, and 38% demonstrated both verbal and physical aggression against others.

From Fowlie EJ, Eustis SW, et al: Prospective field study of violence in EMS, *Ann Emerg Med* 23(3):620, 1994.

Weapons at the Scene

Most states (excluding Illinois and Wisconsin, and the District of Columbia) have enacted laws that permit some citizens to carry a handgun or other weapon.[3] Therefore, paramedics will likely respond to emergency calls where weapons are present.

All weapons should be secured by law enforcement personnel if officers are present at the scene. If law enforcement is not present, paramedics should request that the weapons be safely secured away from the scene. This request should be explained as an additional safety measure for the EMS crew, patient, and any bystanders.

DANGEROUS RESIDENCE

A response to a residence is an everyday occurrence for most EMS personnel. However, even calls that appear "routine" require a scene size-up that begins before the EMS crew leaves the emergency vehicle. Warning signs of danger in residential calls include the following:

- A history of problems or violence
- A known drug or gang area
- Loud noises (e.g., screams, items breaking, possible gunshots)
- Seeing or hearing acts of violence
- The presence of alcohol or other drug use
- The smell of chemicals or the presence of empty chemical containers
- Evidence of dangerous pets (e.g., exotic snakes and reptiles, breeds of dogs that are often trained to be vicious)
- Unusual silence or darkened residence

If any of these or other warning signs are present, the EMS crew should retreat from the scene and call for law enforcement assistance.

When approaching a suspicious residence, the EMS crew should choose tactics that match the threat or situation. For example, avoiding the use of AVW devices, taking unconventional pathways (rather than using the sidewalk, for example), and avoiding a position between the ambulance lights and residence **(backlighting)** are safety measures that should be considered. In addition, paramedics should listen for sounds indicating danger before announcing their presence or entering the home. They should stand on the side of the entry door opposite the hinges (doorknob side) (Figure 56-1). If danger becomes evident, paramedics should immediately retreat from the scene.

DANGEROUS HIGHWAY ENCOUNTERS

As with calls to residences, a response to a traffic incident should never be considered routine. Such calls involve inherent dangers associated with traffic flow, emergency vehicle positioning, and extrication. Also, the danger of violence may exist. For example, a vehicle's occupants may be armed, wanted, or fleeing felons; intoxicated or drugged; or violent and abusive because of an altered mental state (Box 56-1).

When approaching a vehicle, a one-person approach is recommended. This allows the partner who remains in the ambulance to notify dispatch of the situation, location, license plate number, and state registration of suspicious vehicles. (Because the ambulance is elevated, it provides greater visibility of the vehicle.) At night, ambulance lights

FIGURE 56-1 If danger from inside a residence is suspected, paramedics should stand on the side of an entry door opposite the hinges (i.e., the doorknob side).

BOX 56-1 Street-Smart Safety Tips

- When working in a traffic way, always wear reflective clothing and make sure you can leave the scene quickly and safely if required.
- At nighttime, use the ambulance lights to illuminate a vehicle's interior.
- Before approaching a vehicle, consider using the public address (PA) system to get a response from passengers in the car.
- If a passenger in the car is adjusting the side or rear view mirror as you approach, retreat to safety. (This is a sign of danger.)
- Open or unlatched trunks may indicate that people are hiding or have been restrained in the compartment. If the trunk is slightly open, slam it shut without opening it further.
- Retreat to the ambulance (or another place of safety) at the first sign of danger.

should be used to illuminate the interior of the vehicle and the surrounding area.

The paramedic who approaches the car should do so from the passenger side of the vehicle. This provides protection from vehicular traffic. Furthermore, it usually is the opposite approach a driver would expect from law enforcement personnel. As another safety precaution, the paramedic should not walk between the ambulance and the other vehicle, to avoid being trapped and injured if the vehicle backs up. Also, the paramedic should walk around the rear of the ambulance and then to the passenger side of the vehicle.

Car posts A, B, and C (see Chapter 55) may provide the better ballistic protection as opposed to windows and doors. The paramedic should observe for unusual activity in the rear seat and not move forward of the post nearest the threat unless no threats exist in these areas. The paramedic should observe the front seat from behind post B and move forward only after ensuring it safe to do so (Figure 56-2). If signs of danger are present (e.g., weapons, suspicious behavior or movements in the vehicle, arguing or fighting among passengers), paramedics should immediately retreat to a safe staging area. From that area, they should request the help of law enforcement, if not already present at the scene.

LOOK AGAIN
See Chapter 55: Rescue Awareness and Operations, pp. 1508-1509.

CRITICAL THINKING
In your community, what type of EMS calls routinely merit a law enforcement response?

FIGURE 56-2 In approaching a car with potentially dangerous occupants, paramedics should observe the front seat from behind post B. They should move forward only after ensuring their safety.

VIOLENT STREET INCIDENTS

Murder, assault, and robbery are common occurrences in the United States. Many of these crimes involve dangerous weapons. Violence may be directed toward EMS personnel from perpetrators at the scene (or who return to the scene). The violence may even come from injured and distraught patients. In addition, dangerous crowds and bystanders quickly can become large in number and volatile. They may direct violence toward everyone and everything in the surrounding area. Warning signs of potential danger in violent street incidents include the following:

- Voices that become louder, escalating in tone
- Pushing and shoving
- Hostility toward people at the scene (e.g., perpetrator, police, victim)
- A rapid increase in the size of the crowd
- The use of alcohol or other drugs by people at the scene
- Inability of law enforcement personnel to control the crowd

Paramedic crews should constantly monitor crowds and retreat from the scene if necessary. The location and careful parking of the emergency vehicle are important for personal safety. The EMS crew should position the ambulance so that it cannot be blocked by other vehicles (allowing for easy retreat from the scene). When possible and when it is safe to do so, the patient should be removed from the scene as the crew retreats. (This may eliminate the need to return to the scene.)

VIOLENT GROUPS AND SITUATIONS

According to a study completed by the Department of Justice's Office of Juvenile Justice and Delinquency Prevention (OJJDP), more than 770,000 gang members currently belong to more than 27,500 gangs throughout the United States[4] (Box 56-2). Most gangs and other threat groups operate through intimidation and extortion (Box 56-3).

Gang Characteristics

A **gang** can be defined as any group of people who engage in socially disruptive or criminal behavior. They usually are territorial, and often but not always of the same gender. Gangs also operate by creating an atmosphere of fear in a community. The gang may choose a name, logo, specific color, or method of dress to identify its own members and counterparts.

CRITICAL THINKING

In addition to consulting police sources and familiarizing yourself with gang markings, dress, and colors, how can you obtain information about gang activity in your community?

BOX 56-2 Short History of Gangs

Modern-era gangs first emerged in the United States in the late 1960s. Two of the best-known gangs, the Crips and the Bloods, started in Compton, California, when two rival high schools began to sport their school colors. The Bloods wore red to denote their gang affiliation; the Crips wore blue. Other gangs' ancestries originated in the prison system. The Black Gangster Disciples (now known as the Gangster Disciple Nation) was the most noteworthy of these. This gang started in the Chicago prison system and competed for the drug market in that city. In recent years, gangs have evolved to include all ethnic origins and backgrounds (e.g., Asian, Hispanic, Latin, and white threat groups). Most operate in secrecy with codes of honor and pledges that frequently involve acts of violence. Gang membership often is a lifetime commitment.

BOX 56-3 Some Gangs and Other Threat Groups in the United States

- 18th Street Gang
- Bad Boy Club
- Banditos
- Bloods
- Crips
- Gangs for Disciples
- Hell's Angels
- Latin Kings (Almighty Latin King & Queen Nation)
- Mara Salvatrucha 13 (MS-13)
- Mexican Posse (MP)
- Norteños
- Pagans
- Skin Heads
- Sureños
- Outlaws

GRAFFITI AND CLOTHING

Graffiti ("tagging") is probably the most visible sign of gang criminal activity. It can be seen in neighborhood parks and on the backs and side walls of stores, fences, retaining walls, and any other prominent structure that is paintable (Figure 56-3). Gang graffiti usually marks territorial boundaries. (This is known as **turf**.) Gang-related clothing often is unique and specific to a group. It is worn to identify affiliation and rank. Common gang-related clothing and styles are listed in Box 56-4.

SAFETY ISSUES IN GANG AREAS

Common gang activities include fighting, vandalism, armed robbery, weapon offenses, automobile theft, battery, and drug dealing. (Not all gang members are engaged in illegal activities.) The criminal activity usually is committed for status or monetary benefit, either for the gang in general or for a single member. The likelihood for those violent acts and the fact that EMS personnel often "look like" law enforcement officials require that paramedics be very cautious about personal safety when working in gang areas.

Clandestine Drug Labs

As described in Chapter 34, the illegal manufacture of drugs can pose significant hazards for emergency personnel. Activities that take place in some **clandestine drug labs** include creating drugs (*synthesis*) from chemical precursors (e.g., lysergic acid diethylamide [LSD], methamphetamine). Also, a drug's form can be changed (*conversion*). For example, cocaine hydrochloride may be changed to a base form. The processes of drug synthesis and conversion can produce oxygen-depleted atmospheres. They also can create highly explosive and toxic gases (e.g., phosgene). These gases can readily be absorbed through the skin in amounts that can be fatal. Toxic solvents involved in drug-making processes also can lead to lab explosions and exposure to dangerous chemicals.

FIGURE 56-3 Blood graffiti on a wall in Los Angeles. (Courtesy Lisa Taylor-Austin, Milford, Conn.)

BOX 56-4 Gang Clothing and Styles

Male

- Shaved, bald head or extremely short hair; gang name or symbols shaved into hair
- Tattoos (variable) and jewelry
- Bandanas
- White, oversized T-shirt that is creased in the middle
- White, athletic-type undershirt
- Polo-type knit shirts (oversized), usually worn buttoned to the top and not tucked in; other types of oversized shirts
- Oversized Dickie, Ben Davis, or Solos pants
- Pants worn low, or "sagging," and cuffed inside at the bottom or dragging on the ground
- Baseball caps worn backward (usually black and sometimes having the gang's initials)
- Cutoff, below-the-knee short pants worn with knee-high socks
- A predominance of dark or dull clothing or clothing of one particular color
- Black stretch belt with chrome or silver gang initial belt buckle
- Clothing a mixture of gang colors, black and silver, or white

Female

- Exaggerated use of mousse, gel, or baby oil in the hair
- Tattoos (variable) and jewelry
- Black or dark clothing and shoes
- Black oversized jackets, sweatshirts, or athletic football jerseys
- Oversized shirts worn outside of pants
- Oversized T-shirts
- Dark jackets with lettering (cursive or Old English style)
- Baggy, long pants that drag on the ground
- Heavy makeup, dark and excessive eye shadow, shaved eyebrows, dark lipstick, dark fingernail polish
- Tank tops or revealing blouses
- Stretch belt with initial on belt buckle

From Texas Youth Commission: *Gang related clothing,* www.tyc.state.tx.us/prevention/clothing.html, accessed 10-31-10.

Other safety hazards that are associated with clandestine drug labs include *booby traps* that can maim or kill an intruder. Also, those who operate these labs are sometimes armed or otherwise violent. Clandestine labs usually are located in an area that ensures privacy. They generally are well ventilated. They also usually have access to water, electric, and gas utilities, which are required for the drug-making process. Suspicious individuals, activities, and deliveries often are at the site.

CRITICAL THINKING

What type of calls might EMS crews respond to at a drug lab?

DID YOU KNOW?

Shake n' Bake Meth

A new and popular way to manufacture small quantities of methamphetamine is called the *Shake n' Bake* or "one-pot method." The method uses one sealed container, such as a soft drink bottle. The container is usually flipped upside-down to cause the chemical reaction needed to turn the ingredients into meth. The chemical reaction causes an extremely high pressure inside the container after being shaken. This is one of the most dangerous ways to produce the drug because the pressure can cause a large explosion. The *Shake n' Bake* method is fast and portable. The method is often "cooked" while driving an automobile. Driving while making meth releases the fumes from the chemical process into the air. Once the drug is produced, the container is then thrown from the car. EMS personnel must be aware of the explosive danger of this method of meth production when approaching an automobile or the trunk of a car. Explosions also pose a hazard to children, who naturally want to explore things they find on the ground. EMS personnel should not investigate these containers and should alert law enforcement if found.

When responding to a scene that may be a site of illegal drug manufacture, EMS crews should be alert for suspicious signs. These may include chemical odors and the presence of chemical equipment (e.g., glassware, chemical containers, heating mantles, burners). If a drug lab is identified, the EMS crew should:

1. Leave the area at once.
2. Notify law enforcement and request appropriate agencies and personnel (e.g., hazardous materials [hazmat] teams, fire service personnel, U.S. Drug Enforcement Administration [DEA] personnel, chemistry specialists).
3. Initiate an incident management system and hazmat procedures per protocol.
4. Assist law enforcement personnel to evacuate the surrounding area in an orderly fashion to ensure public safety.

NOTE

EMS crews should never touch anything found in or around a clandestine drug lab. Only specially trained personnel should try to alter drug-making equipment or stop chemical reactions in a drug lab.

Domestic Violence

As described in Chapter 50, *domestic violence* is violence that occurs between people in a relationship. The perpetrator may be male or female. The individuals may be in an opposite-sex or same-sex relationship. Domestic violence results in physical, emotional, sexual, verbal, or economic

abuse. It may occur in several combinations. To review, many signs indicate domestic violence and abuse. Some of these include the following:

- Apparent fear of a household member
- Different or conflicting accounts by parties at the scene
- One party preventing another from speaking
- A patient who is reluctant to speak
- Injuries that do not match the reported mechanism of injury
- Unusual or unsanitary living conditions or personal hygiene

EMS personnel who respond to a scene of domestic violence should be aware that acts of violence may be directed toward them by the perpetrator. They should take all safety precautions. If the scene is considered safe for the EMS crew, paramedics should treat the patient's injuries. They also should notify medical direction and other authorities consistent per standard procedures and protocol. (Mandatory reporting may be required.) To help ensure scene safety for the crew and the abused person, paramedics should not be judgmental about the relationship. They should not direct accusations toward the abuser or the victim. When appropriate, paramedics should supply the victim with phone numbers for domestic violence hotlines, community support programs, and available shelters.

SAFETY TACTICS

Tactics that help ensure personal safety include avoidance, tactical retreat, cover and concealment, and distraction and evasive maneuvers. Many programs in the United States teach tactics for safety and patient care. Some EMS providers are specially trained and equipped to work in tactical law enforcement settings (Box 56-5).

Avoidance

Avoidance is the action of keeping away from a dangerous situation or preventing the development of a dangerous situation. Avoidance is always preferable to confrontation. To practice avoidance, paramedics must continually be aware of the scene. They can stay aware by being observant and by being knowledgeable about warning signs that may indicate a dangerous situation. In addition, they must be knowledgeable about tactical responses for avoiding danger or for dealing with danger that cannot be avoided. An example of avoidance is **staging.** With staging, the dispatching center learns of danger and advises the EMS crew not to approach the scene until it has been secured by the appropriate authorities.

Tactical Retreat

Tactical retreat describes leaving the scene when danger is observed or when violence or indicators of violence are displayed. Tactical retreat requires immediate and decisive action. Retreat on foot or by vehicle (in a calm, safe manner) involves choosing the mode and route of retreat that provides the least exposure to danger. During tactical retreat, the EMS crew should be aware that the risks they faced are now located behind them. They must stay alert for associated dangers. Of course, the required distance from danger for a safe tactical retreat must be guided by the nature of the incident. In general, a safe distance must:

- Protect the crew from any potential danger
- Keep the crew out of the immediate line of sight

BOX 56-5 Tactical EMS

The term *tactical EMS (TEMS)* refers to EMS personnel who are specially trained and equipped to provide prehospital emergency care in tactical law enforcement settings. Such settings may include hostage-barricaded situations, high-risk search warrants, and other adverse situations involving law enforcement and/or rescue operations in which standard EMS units may be inappropriate.

The concept of training emergency medical technicians (EMTs) and paramedics in TEMS started in the late 1980s. It has since expanded nationwide. Forward-thinking law enforcement departments have adopted TEMS programs as a way to increase the safety of their special weapons and tactics (SWAT) officers and the innocent hostage or bystander. They also are a means of addressing liability exposure. Tactical training for EMS personnel also is recognized as a valuable tool for personal safety when EMS personnel find themselves in an unsafe situation.

Many tactical medical teams use the Counter Narcotics and Terrorism Operational Medical Support (CONTOMS) program for initial training of their personnel. CONTOMS is a joint federal program supported by the U.S. Department of Health and Human Services, U.S. Department of Homeland Security, and U.S. Park Police, with assistance from the Department of Justice, as well as many state and local law enforcement agencies. The CONTOMS program leads to certification as an EMT-Tactical (EMT-T) or SWAT medic. The focus of the training is to integrate specific skills to complement an agency's standard operating procedures. These skills include the ability to:

- Assess and plan for preventive medicine needs in sustained operations
- Provide preventive medical care in sustained operations
- Recognize and treat unique wound patterns resulting from deliberate interpersonal aggression
- Use medical care skills appropriate to hostile and austere environments
- Explain medical and physiological parameters that lead to performance decrement and implement plans that minimize those effects
- Develop and apply injury control strategies
- Access and analyze medical information and make a medical threat assessment
- Apply special law enforcement principles to the delivery of medical care

See www.trueresearch.org/contoms/, accessed 10-27-10.

- Protect the crew from gunfire (i.e., provide cover)
- Keep the crew far enough away to give them time to react if danger reappears

CRITICAL THINKING
Could the EMS crew be charged with abandonment if they make a tactical retreat and leave the patient?

Once tactical retreat has been achieved, the EMS crew must notify other responding units and agencies of the danger. They notify other units using interagency EMS and law enforcement standard operating procedures and agreements. (Interagency procedures that deal with violent situations should be established in the preplanning stages so that each agency is aware of its specific duties.)

Documentation also is essential to reducing liability if injuries or deaths occur. Thorough documentation should include observations of danger at the scene; names of persons notified of the danger; actions at the scene; and accurate times that retreat or return to the scene occurred. Most legal authorities do not consider tactical retreat for appropriate circumstances to be patient abandonment.

Cover and Concealment

Cover and **concealment** provide protection from injury. *Cover* provides ballistic protection and is often in the form of large, heavy structures. Examples of such structures include large trees, telephone poles, and a vehicle's engine block. *Concealment* hides the body. However, it offers little or no ballistic protection. Examples of concealment include bushes, wall-boards, and the doors of vehicles.

Cover and concealment should be integrated into tactical retreat or used when the EMS crew is "pinned down" (e.g., by gunfire) or in other dangerous settings. When the need for cover or concealment arises, paramedics should:

- Constantly be aware of their surroundings
- Be aware that "stepping off" cover may actually provide more protection than "hugging" your cover (Figure 56-4)
- Constantly look for ways to improve protection and location
- Be aware of reflective clothing (e.g., trim, badges) that may draw attention or serve as a target

CRITICAL THINKING
What parts of your ambulance provide cover?

Distraction and Evasive Tactics

Distraction and **evasive tactics** can be used as self-defense measures during retreat. They also can be used when retreat and cover and concealment are not available options (Box 56-6). For example, equipment may be used to provide distraction (e.g., a stretcher may be wedged in a doorway to block an aggressor) or equipment may be thrown to trip or slow a pursuer. These actions may allow the EMS crew to make a safe retreat or gain adequate cover and

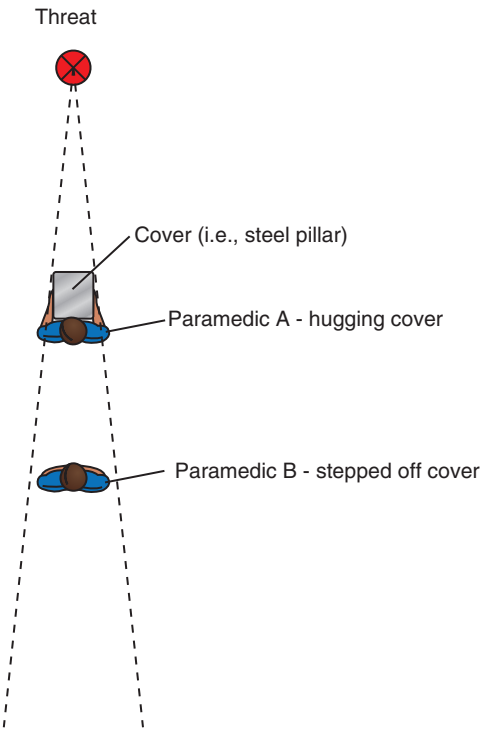

FIGURE 56-4 At times stepping-off cover provides more protection than hugging cover. Paramedic B is less exposed and must expose far less of him/herself to visualize the threat if needed as compared to paramedic A.

BOX 56-6 Self-Defense Measures

Training in self-defense is probably appropriate for all emergency responders. Avoidance is always superior to confrontation. However, some violent situations may call for self-defense. Examples include physical attacks that cannot be avoided, armed confrontation or robbery, hostage situations, and dangerous animals. A person can be controlled with physical or chemical restraints (see Chapter 35). Equipment (e.g., metal clipboards, jump kits, stretchers) or other items (e.g., furniture) can be used to block an aggressor. In addition to these techniques, self-defense measures may include training in the use of pepper sprays or other chemical deterrents and defensive physical maneuvers that can allow escape.

Sometimes escape is impossible, and paramedics may be caught in a dangerous situation. (For example, they may be held as a hostage.) In such cases paramedics should:

- Remain as calm as possible
- Avoid any confrontation
- Play an active role with the captor in resolving the incident
- Focus on a peaceful resolution and escape

BOX 56-7 Warning Signs of Possible Violent Aggression

People who are about to escalate to violence often give subtle warning signs of this development. Such a person may:

- Conspicuously ignore emergency responders
- Be verbally abusive
- Invade the responder's personal space
- Have a violent history or background
- Shift the body weight from side to side or foot to foot (boxer stance)
- Clench the fists
- Tighten the muscles (e.g., have stiff arms and/or shoulders)
- Maintain eye contact by staring

concealment. Evasive tactics involve anticipating the moves of the aggressor (Box 56-7) and using unconventional pathways during retreat.

Paramedic crews trained in **tactical EMS** often use preassigned roles for distraction and evasive maneuvers. One paramedic usually is the **contact provider,** who initiates and provides direct patient care. This includes patient assessment and most elements of interpersonal scene contact. Another crew member serves as the **cover provider.** In a tactical context, the cover provider's role is to ensure safe cover for the contact providers while they provide patient care. This role includes monitoring the scene for danger. The cover provider generally does not perform patient care duties that would prevent observation of the scene. The cover provider also may be responsible for ensuring the safekeeping of equipment, drugs, and supplies while at the scene.

Methods of communication between the contact and cover providers should be developed in advance. That way, they can alert team members of potential dangers without alerting the aggressor. This often can be done with subtle verbal and nonverbal signals, such as using coded terms, scratching the neck, or rubbing the nose. It is crucial in these situations to maintain radio contact with the dispatching center. The crew also should involve the dispatcher in the danger signal process. For example, if the dispatcher hears a coded term that means danger, a priority response of the proper personnel can be initiated.

TACTICAL PATIENT CARE

The term **tactical patient care** describes patient care activities that occur inside the scene perimeter. This is also known as the **hot zone.** The provision of EMS in the hot zone requires special training and authorization, body armor and a tactical uniform, compact and functional equipment, and, in some operations, personal defensive weapons. Tactical EMS in the hot zone often requires risks not taken in standard EMS situations. *Tactical medics*

FIGURE 56-5 Tactical patient care. (Courtesy Ray Kemp. St. Charles, Mo.)

provide immediate medical care to the injured during a **special weapons and tactics** (SWAT) **operation.** These medics treat the injured on-site or stabilize them and extract them from the scene. Tactical medics generally work alongside law enforcement officers. Some agencies use individuals who are cross-trained in law enforcement and tactical EMS (Fig. 56-5).

Body Armor

As described in Chapter 37, **soft body armor** (also known as *bulletproof vests*) offers protection from some blunt and penetrating trauma. It absorbs and distributes the impact of a ballistic missile or penetrating object. This equipment is effective against most handgun bullets. The equipment does not protect against knives or pointed, sharp objects.[5] However, they do not provide protection from high-velocity rifle bullets or thin or edged weapons (e.g., ice picks). Like all other protective clothing, body armor is effective only when it is properly worn. It also must be in good condition. Some body armor (e.g., Kevlar) degrades with age. This armor may carry a ballistic expiration date that should be observed. Wet or worn vests do not provide optimum protection. A type III or higher level of protection generally is recommended for tactical EMS providers.

When wearing body armor, paramedics should take care not to develop a false sense of security. *A general rule is: "Never try a maneuver that wouldn't normally be done without body armor."* Also, paramedics should keep in mind that body armor does not cover the entire body. Severe injury can still result from the forces of blunt trauma (in the absence of penetration) even when the vest is properly worn. This "back-face signature" (transmitted impact

energy) is variable according to the type of vest and projectile.

EMS CARE IN THE HOT ZONE

As previously stated, the provision of EMS care in tactical situations calls for special training and authorization. Most tactical medics (EMT-Ts and SWAT medics) are trained in the following[6]:

- Team health and management
- Care under fire
- Officer rescue
- Medical operations planning and medical intelligence
- Responding to the active shooter
- Special medical gear for tactical operations
- Personal protective gear
- Special needs for extended operations
- Preventive medicine
- Management of weapons of mass destruction and toxic hazards

Most programs involve training exercises. Some of these include the following:

- Physical assessment under sensory deprivation/overload conditions
- Medical threat assessment
- Advanced medical-tactical techniques
- Field expedient decontamination
- New technologies for safe searches
- Management of dental injuries
- "Officer down" rescue and extraction
- Aeromedical evacuation
- Medical management of clandestine drug lab raids
- Safe search techniques
- Remote physical assessment

Patient care in dangerous settings involves a number of special concerns. These include the frequent need to remove a patient from the area safely; the frequent care of trauma patients; the need to modify patient care; and medical and transport actions that must be coordinated with the incident commander. Often tactical EMS providers work under protocols and standing orders that differ from those of "standard" EMS practice. These medical direction issues regarding patient care are dictated by the nature of the event. They also are determined by the uncontrolled and hazardous scene in which emergency medical services are provided. Awareness programs are available for those who supervise or manage personnel assigned to a tactical team. Programs are also available for physicians (and others) who provide medical direction for rescuers who work with tactical law enforcement teams. Quality assurance programs and direct physician involvement at the local level are recommended.

EMS AT CRIME SCENES

A **crime scene** is a location where any part of a criminal act has occurred. It also can be a location where evidence relating to a crime may be found. Important physical evidence that may be found at a crime scene includes fingerprints, footprints, and blood and other body fluids. Fingerprints and footprints are unique to an individual. No two people have identical prints. These ridge characteristics often are left behind on a surface, along with oil and moisture from the skin. Blood and other body fluids can be tested for deoxyribonucleic acid (DNA) and ABO blood typing; they also have characteristics that may be unique to the individual. In addition, particulate evidence (e.g., hair, carpet, and clothing fibers) can provide useful information and is considered valuable at a crime scene.

The paramedic's observations at a crime scene are important. They should be documented carefully on the patient care report or other appropriate form. For example, victims' positions and injuries and conditions at the scene may be helpful to law enforcement personnel in solving the crime. Documentation also should include any statements made by the patient or other people at the scene and any **dying declarations.** Paramedics should be careful to (1) record their observations objectively; (2) record patients' or bystanders' words in quotes; and (3) avoid personal opinions that are not relevant to patient care. Paramedics must keep in mind that patient care reports are legal documents; they may be used in court. Paramedics should avoid labeling ballistic injuries as "entrance" or "exit" wounds. Rather, the wound and characteristics of the wound should be described and documented in the patient care report.

NOTE

A *dying declaration* is a statement(s) made by a person who believes he or she is about to die. The statement concerns the cause or circumstance surrounding his or her impending death. An example is an assault victim who makes a dying declaration implicating a certain person as being her attacker.

Preserving Evidence

Patient care is the paramedic's ultimate priority, even at crime scenes. However, evidence can be protected while caring for the patient. This can be accomplished by being careful not to disturb the scene unnecessarily or destroy evidence. For example, paramedics should be observant of the scene and surroundings; they should touch only what is required for patient care; and they should wear latex gloves for infection control and to avoid leaving additional fingerprints at the scene. Other measures that aid crime scene preservation are listed in Box 56-8.

CRITICAL THINKING

If the main goal is caring for the patient, why should a paramedic be concerned about preserving evidence?

BOX 56-8 Considerations for Crime Scene Preservation

Paramedics should observe the following rules when called to a known or a possible crime scene:

1. Approach no crime scene until it has been secured for your safety.
2. Park your vehicle as far away as conveniently possible to preserve skid marks, tire prints, or other evidence.
3. Survey and assess the scene before proceeding to the victim.
4. Try to approach the victim from a route different from the assailant's probable route.
5. Follow the same path to and from the victim.
6. Avoid stepping on blood stains or spatter if possible.
7. Disturb the victim and the victim's clothing as little as possible while performing your assessment and during treatment.
8. When cutting clothing from a victim, try to do it in a way that preserves the points of wounding.
9. Report your actions and any disturbances you make to the crime scene investigator.
10. Keep all unnecessary people away from the victim.
11. Do not smoke or eat at the crime scene.
12. Do not touch any evidence if at all possible.
13. Make no comments to bystanders about the situation.
14. Save the victim's clothes and personal items in a paper bag. The bag should be labeled, sealed, and turned over to law enforcement personnel.
15. Be alert to any dying declarations the patient makes.
16. Keep accurate, detailed records.
17. Keep in mind that law enforcement personnel are in charge of the crime scene; you are in charge of the patient.

Modified from Vollrath R: Crime scene preservation: it's everybody's concern, *J Emerg Med Serv* 20(1):53, 1995.

SUMMARY

- A key point in ensuring scene safety is to identify and respond to dangers before they threaten. If the scene is known to be violent, the EMS crew should remain at a safe and out-of-sight distance from the area. They should remain at this distance until the scene has been secured.
- The paramedic should look for warning signs of violence during response to a residence. He or she should retreat from the scene if danger becomes evident.
- A response to a highway incident may present the dangers associated with traffic and extrication. However, it may present danger from violence as well. Occupants may be armed, wanted, or fleeing felons; intoxicated or drugged; or violent/abusive from an altered mental state.
- The paramedic should monitor for warning signs of danger in violent street incidents. He or she should retreat from the scene if necessary.
- A gang is any group of people who take part in socially disruptive or criminal behavior. Some gangs are involved in violent criminal activities. EMS personnel often look like law enforcement officers. Thus, they should be very cautious about personal safety when working in gang areas.
- Clandestine drug lab activities can produce explosive and toxic gases. Other risks include booby traps that can maim or kill an intruder, and armed or violent occupants.
- EMS personnel who respond to a scene of domestic violence should be aware that acts of violence may be directed toward them by the perpetrator; they should take all safety precautions.
- Tactics for safety include avoidance, tactical retreat, cover and concealment, and distraction and evasive maneuvers.
- Tactical patient care refers to care activities that occur inside the scene perimeter. This is known as the "hot zone." Providing care in this area calls for special training and authorization, body armor and a tactical uniform, compact and functional equipment, and, in some operations, personal defensive weapons.
- The paramedic's observations at a crime scene are important. They should be carefully documented. Evidence should be protected while caring for the patient. This can be done by not unnecessarily disturbing the scene or destroying evidence.

CHAPTER

57 Hazardous Materials Awareness

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Define hazardous materials terminology.
2. Identify legislation about hazardous materials that influences emergency health care workers.
3. Describe resources to assist in identification and management of hazardous materials incidents.
4. Identify the protective clothing and equipment needed to respond to selected hazardous materials incidents.
5. Describe the pathophysiology and signs and symptoms of internal damage caused by exposure to selected hazardous materials.
6. Identify the pathophysiology, signs and symptoms, and prehospital management of selected hazardous materials that produce external damage.
7. Outline the prehospital response to a hazardous materials emergency.
8. Describe medical monitoring and rehabilitation of rescue workers who respond to a hazardous materials emergency.
9. Describe emergency decontamination and management of patients who have been contaminated by hazardous materials.
10. Outline the eight steps to decontaminate rescue personnel and equipment at a hazardous materials incident.

KEY TERMS

asphyxiants Gases that displace the oxygen in the air and also dilute the oxygen concentration of the air.

carcinogens Cancer-causing agents.

cardiotoxins Hazardous materials that can cause myocardial ischemia and dysrhythmias.

cold zone A safety zone in a hazmat response that encompasses the warm zone; usually considered safe, requiring only minimal protective clothing.

corrosives Hazardous materials that are either acids or bases (alkaline).

cryogenics Refrigerant liquid gases that can freeze human tissue on contact.

decontamination The process of making patients, rescuers, equipment, and supplies safe by eliminating harmful substances.

dose response The physical change or effect caused by exposure to a chemical; dependent on the concentration of the chemical to which the person was exposed.

formal product identification A method of identifying a hazardous material through written means.

hazard and risk assessment An analysis of the consequences and probability that exposure to a chemical may cause danger or peril.

hazardous material Any substance or material capable of posing an unreasonable risk to health, safety, and property.

hemotoxins Hazardous substances that may cause the destruction of red blood cells.

hepatotoxins Hazardous substances that damage the liver.

hot zone The area of a hazmat incident that includes the hazardous material.

informal product identification A method of identifying a hazardous material through unwritten means.

irritants Substances that affect the respiratory system, including the surfaces of the eyes, nose, mouth, and throat.

liquefaction Conversion of solid tissues to a fluid or semi-fluid state.

material safety data sheets Written product identification as required by OSHA for each chemical produced, stored, or used in the United States.

medical monitoring The ongoing evaluation of rescuers who are at risk for illness or injury from operations at the incident.

nephrotoxins Hazardous materials that are especially destructive to the kidneys.

nerve poisons Poisonous substances that act on the nervous system.

neurotoxins Poisons that affect the nervous system.

placards Four-sided, diamond-shaped signs displayed on hazardous materials containers that usually are yellow, orange, white, or green. They have a four-digit United

Nations identification number and a legend to indicate the contents of the container.

primary contamination Exposure to a hazardous substance that is harmful only to the person exposed and that poses little risk of exposure to others.

rehabilitation Activities that are provided at an incident to sustain the energy of rescuers, improve performance, and decrease the likelihood of on-scene injury or death; also known as rehab.

safe distance factor The minimum safe distance for personal safety from hazardous materials as outlined in the reference guides.

secondary contamination Exposure to a hazardous substance whereby liquid and particulate substances are transferred easily to others by touching.

self-contained breathing apparatus A respiratory protection device that provides an enclosed system of air.

shipping papers Descriptions of the hazardous materials that include the substance name, classification, and United Nations identification number.

supplied-air breathing apparatus A device that provides a nearly unlimited supply of air from a source located outside the confined space.

synergistic effects The effects of one chemical enhancing the effects of a second chemical.

UN/NA number The United Nations class (or division) identification number and North American number for a hazardous material.

warm zone In a hazmat incident, a buffer area that surrounds the hot zone with "cold" and "hot" end corridors; usually considered a safer environment for workers.

Hazardous materials incidents create added responsibilities for EMS personnel. Large incidents may involve a number of political jurisdictions. In addition, cooperation in mass evacuations and mass decontamination may be required. Specialized roles and responsibilities include, among others, recognition and identification of hazardous material, scene safety, responsibilities to stage at major scenes, containment and cleanup of the material, extrication and decontamination of exposed individuals, provision of emergency care, and continual medical monitoring of team members involved in the incident.

SCOPE OF HAZARDOUS MATERIALS

A **hazardous material** is defined as "any substance or material capable of posing an unreasonable risk to health, safety, and property."[1] More than 50 billion tons of hazardous materials are made in the United States each year. About 2 billion tons are shipped within the United States. From 1998 to 2007, the U.S. Department of Transportation (DOT) reports there were 141 hazmat transportation-related fatalities, approximately 14 per year. Of these, 124 deaths were on the highways and 17 were rail-related.[2] Emergency responses to vehicular crashes are common; thus the potential for exposure to hazardous materials is great. Other possible causes of hazardous materials incidents include mishaps in the storage of materials and manufacturing operations, illicit drug manufacturing (e.g., "meth labs"), and acts of terrorism (see Chapter 58).

CRITICAL THINKING

Consider the industries in your area. Do any of these have the potential for a hazardous materials exposure?

As described in Chapter 34, injury or illness can also result from exposure to household chemicals, pesticides, and industrial toxins. The following statistics emphasize the importance of emergency medical service (EMS) personnel knowing how to manage hazardous materials exposure[3]:

- About 9000 deaths occur each year from exposure to poisonous solids, liquids, and gases.
- An estimated 100,000 industrial workers are exposed to respiratory tract irritants each year.
- Pesticide poisoning accounts for more than 3000 hospitalizations each year.
- Most fire-related deaths result from inhalation of toxic products of combustion.

LAWS AND REGULATIONS

In recent years much focus has been placed on the handling of hazardous materials. Major incidents have attracted the attention of employee and citizen groups. These incidents also have drawn the attention of local, state, and federal officials. Some of these incidents include the Union Carbide disaster in Bhopal, India (1984); the Chernobyl nuclear accident in the Soviet Union (1986); the Three Mile Island incident in the United States (1979); the Criticality accident in Tokaimura, Japan (1999); threats and acts of bioterrorism (e.g., the sarin gas attack on Tokyo subways in 1995); anthrax attacks in the United States (2001); and the need for proper disposal of hazardous wastes. This attention has resulted in more laws and regulations to ensure strict control of hazardous materials.

The Superfund Amendments and Reauthorization Act (the Superfund Act) of 1986 established requirements for federal, state, and local governments and industry regarding emergency planning and the reporting of hazardous materials–related incidents. This act was intended to help communities better manage a chemical emergency. The Superfund Act helped increase public knowledge about hazardous materials in communities and helped to improve public access to this information. The act required owners and operators of facilities using or storing any of the extremely hazardous substances identified by the Environmental Protection Agency (EPA) to notify the local fire department, the local emergency planning committee, and the state emergency response commission.

In 1989 the Occupational Safety and Health Administration (OSHA) and the EPA published rules to govern training requirements, emergency plans, medical checkups, and other safety precautions for workers at uncontrolled hazardous waste sites and for those responding to hazardous chemical releases or spills.[4] The Superfund Act mandates that states adopt these rules. The training requirements apply to five groups of persons who may respond to an emergency that involves hazardous materials (see chapter appendix).

In addition to these training levels outlined by OSHA, the National Fire Protection Association (NFPA) has published standards that address competencies for EMS personnel at hazardous materials (hazmat) scenes.[5] According to these standards, paramedics who transport patients who pose no risk of **secondary contamination** must be trained to NFPA standard 473 Level I. Paramedics who may have to decontaminate rapidly or assist in the **decontamination** area must be trained to NFPA standard 473 Level II.

IDENTIFICATION OF HAZARDOUS MATERIALS

At the center of dealing with hazardous materials is identifying the substance. Two methods used to identify such materials are **informal product identification** and **formal product identification.**

Informal Product Identification

Arriving emergency personnel may be able to determine the presence and type of hazardous materials at the scene. Informal methods of identification include the following:

- Visual inspection of the scene with binoculars before entering the site
- Verbal reports by bystanders or other responsible individuals
- Occupancy type (intended use of a particular structure such as fuel storage or pesticide plant)
- Incident location (probable location for presence of hazardous materials)
- Location within a building (what is stored in that area)
- Visual indicators (vapor clouds, smoke, leakage)
- Vehicle types (named carriers or company)
- Container characteristics (size, shape, color, deformed containers)
- Senses (peculiar smell reported by bystanders)
- Signs and symptoms of victims of exposure

These informal ways to identify a product should be used as a quick means to determine the presence of any hazardous materials. The paramedic should always identify a product formally before taking any action that may pose a threat to the safety of all responders.

NOTE

Personal safety is the number one priority when responding to a hazardous materials incident. If the scene is not safe, the EMS crew should retreat and not enter the scene until it has been made safe by trained personnel.

Formal Product Identification

Traditionally, hazardous materials have been labeled by one or more of the following six systems:

1. The American National Standards Institute uses a label to identify a specific hazard (e.g., explosives, flammable liquids, radioactive materials) rather than a specific chemical.
2. The U.S. Department of Transportation (DOT) uses labels and placards with pictographs and printed hazard categories. In addition, DOT requires specific information on shipping manifests.
3. The United Nations Labeling System uses pictographs, symbols, or both, similar to those used by DOT, to identify a specific hazard rather than a specific chemical.
4. The International Air Transport Association uses the United Nations pictographs and indicates written emergency precaution measures in case of an incident.
5. The National Fire Protection Association uses color and a numerical rating scale (NFPA 704 System) to identify the degree of hazard for health, fire, and reactivity. Many state and local fire codes require the diamond-shaped identification symbols on fixed facilities (Figure 57-1). The numbering system rates each category from 1 (least harmful) to 4 (most harmful).

FIGURE 57-1 The National Fire Protection Association placard. It consists of four diamonds within a larger diamond. The red (flammability) diamond is at "12 o'clock"; the yellow (instability) diamond is at "3 o'clock"; the white (special hazards) diamond is at "6 o'clock"; and the blue (health hazard) diamond is at "9 o'clock." The degree of hazard severity is indicated by a numerical rating that ranges from 4, indicating the most severe hazard, to 0, indicating no hazard. Special hazards are indicated in the white section and refer to chemicals that react with water (W) and those that are oxidizers (OX).

6. The U.S. Department of Labor requires material safety data sheets (also known as MSDSs) for hazardous chemicals that are stored, handled, or used in the workplace.

CRITICAL THINKING
The next time you are on the highway, see if you can easily spot the placards on large trucks.

PLACARDS AND SHIPPING PAPERS

A number of identification systems may be used. However, hazardous materials usually are identified by **placards** (Figure 57-2) and **shipping papers.**

The United Nations class (or division) identification number and the North American number **(UN/NA number)** may be displayed on the bottom of a placard. Or the number may be displayed on the shipping paper after the listed shipping name or names. In certain cases this class or division number may replace the written name of the hazard class in the shipping paper description. Box 57-1 shows the meanings of the class and division numbers.

The location and type of paperwork that identifies hazardous materials varies according to the mode of transport. Most shipping papers are kept near the operator (e.g., driver, pilot, or captain) of the vehicle, aircraft, train, or ship. Several chemical agents may have the same UN/NA number. Thus it is important to refer to specific guidelines for hazardous material by chemical name in addition to this number.

NOTE
Shippers are responsible for tracking hazardous loads in transit. If shipping papers are difficult to obtain or too dangerous to recover, law enforcement personnel or the dispatch agency can contact the shipper by phone with a description of the vehicle (e.g., truck or car number and license plate number). This will help identify the type of hazardous material.

BOX 57-1 International Classification System for Hazardous Materials

Class or division numbers may be displayed in the bottom of placards, or they may be displayed in the hazardous materials description on shipping papers. In certain cases a class or division number may replace the written name of the hazard class description on the shipping paper. The class and division numbers have the following meanings:

Class 1	**Explosives**
Division 1.1	Explosives with a mass explosion hazard
Division 1.2	Explosives with a projection hazard
Division 1.3	Explosives with predominantly a fire hazard
Division 1.4	Explosives with no significant blast hazard
Division 1.5	Very insensitive explosives
Division 1.6	Extremely insensitive explosive articles
Class 2	**Gases**
Division 2.1	Flammable gases
Division 2.2	Nonflammable gases
Division 2.3	Poison gases
Division 2.4	Corrosive gases (Canadian)
Class 3	**Flammable Liquids**
Division 3.1	Flashpoint below –18° C (0° F)
Division 3.2	Flashpoint –18° C and above but less than 23° C (73° F)
Division 3.3	Flashpoint of 23° C and up to 61° C (141° F)
Class 4	**Flammable Solids, Spontaneously Combustible Materials, Materials That Are Dangerous When Wet**
Division 4.1	Flammable solids
Division 4.2	Spontaneously combustible materials
Division 4.3	Materials that are dangerous when wet
Class 5	**Oxidizers and Organic Peroxides**
Division 5.1	Oxidizers
Division 5.2	Organic peroxides
Class 6	**Poisonous and Etiological (Infectious) Materials**
Division 6.1	Poisonous materials
Division 6.2	Etiological (infectious) materials
Class 7	**Radioactive Materials**
Class 8	**Corrosives**
Class 9	**Miscellaneous Hazardous Materials**

From U.S. Department of Transportation: *North American emergency response guidebook,* Washington, DC, 2008, The Department.

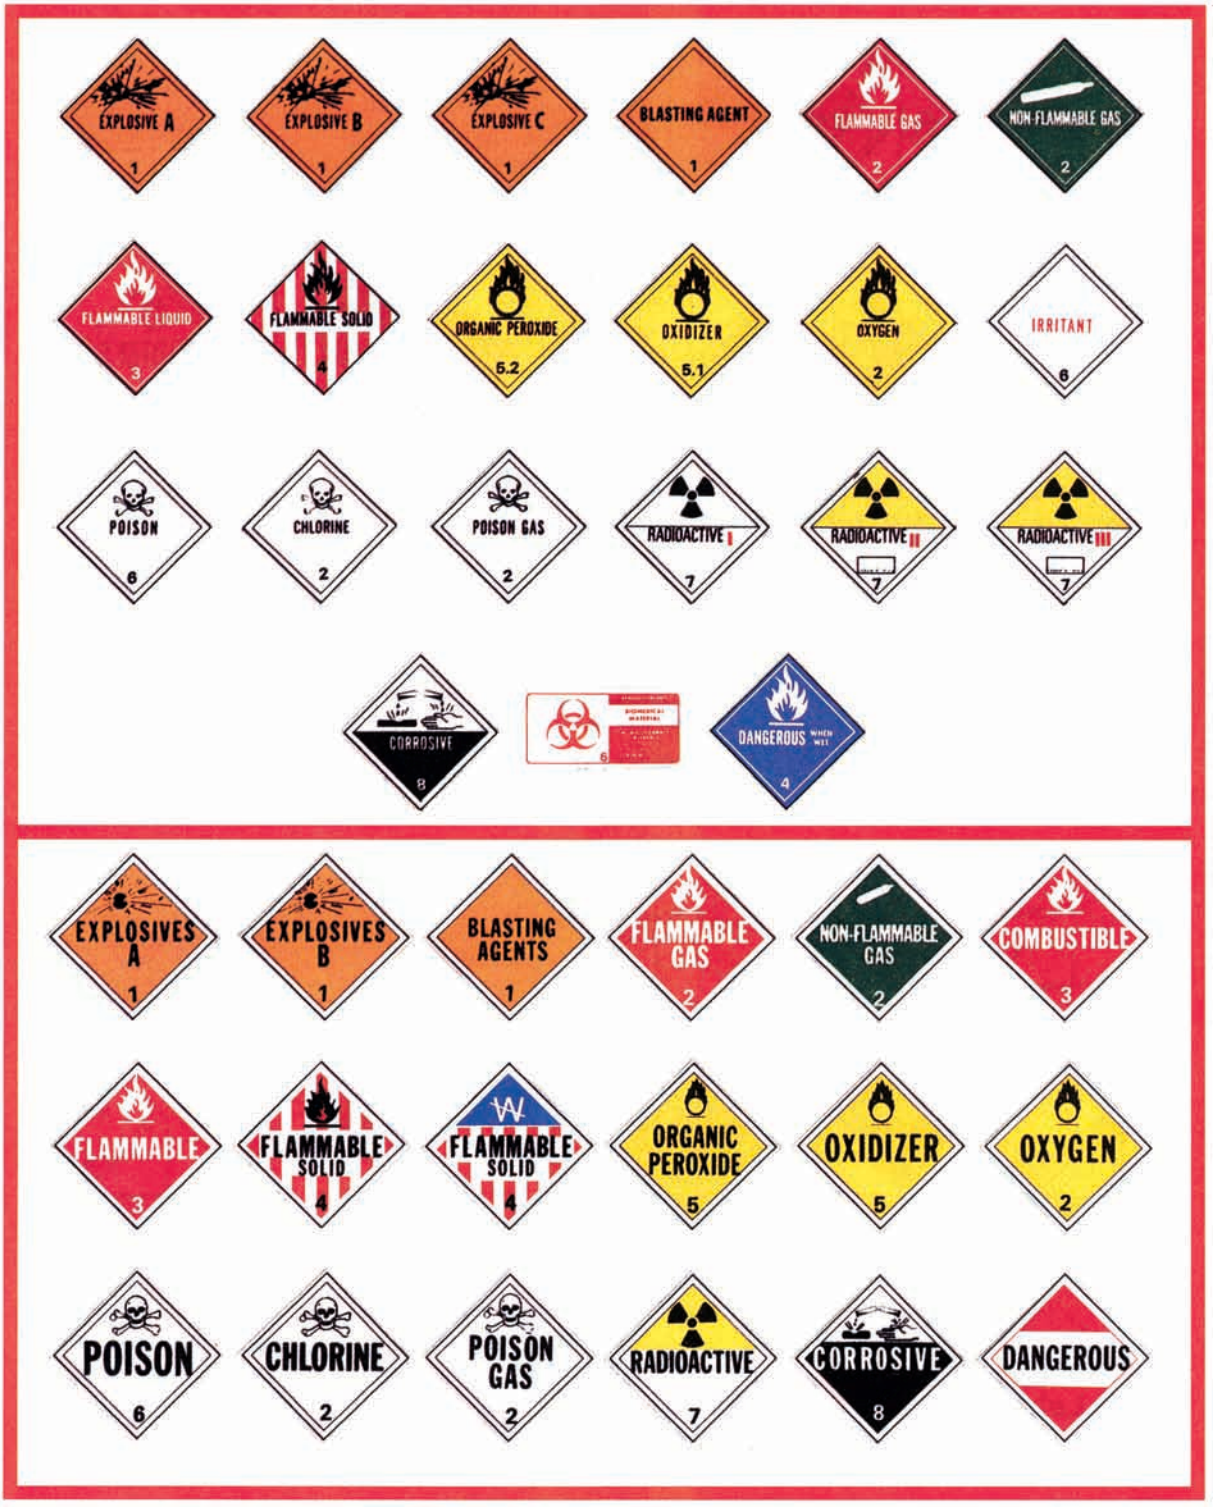

FIGURE 57-2 Hazardous materials warning placards and labels.

MATERIAL SAFETY DATA SHEETS

Material safety data sheets (MSDSs) are required by OSHA for each chemical produced, stored, or used in the United States. Material safety data sheets are supplied by the manufacturer. They contain information for the safe and proper handling and storage of the material. They also have information on emergency actions needed following exposure. Material safety data sheets also classify the potential of significant health hazards from exposure to a material.

The potential health hazard of a material may be defined in a number of different ways. This may depend on the

degree of inherent toxicity and type of exposure. Material safety data sheets provide useful information. However, they should not be used as the sole source of chemical information, information on health risks, or treatment recommendations. Paramedics should consult with medical direction, a poison control center, or another appropriate authority.

OTHER SOURCES OF INFORMATION ON HAZARDOUS MATERIALS

A number of resources are available for hazardous materials reference. These references include books, telephone support through emergency hazmat agencies, computer databases, and Internet sources. Product information should be referenced through more than one source. (Preferably three sources should be used, if time and availability permit.) One such reference is the *North American Emergency Response Guidebook* published by the DOT, Transport Canada, and the Secretariat of Communications and Transportation of Mexico. This guidebook lists more than 1000 hazardous materials. It also lists the basic first aid procedures for managing an exposure. It includes names and identification numbers of substances. The book is cross-referenced in alphabetical and numerical order. This free reference is carried in emergency vehicles by many EMS, fire, and other public service agencies. One should note that the *Emergency Response Guidebook* is designed to assist first responders with initial actions for evacuation only. The book also includes the distance and area from the incident that should be evacuated. The book is not the only guide that should be referenced when dealing with hazmat emergencies.

NOTE

When a hazardous substance cannot be precisely identified, trained personnel may use sophisticated devices to ensure scene safety and to aid in product identification. These devices include air and gas monitoring equipment, and special equipment for pH testing, chemical testing, and colorimetric tube testing.

As described in Chapter 34, regional poison control centers have been established throughout most of the United States. They are a valuable asset in any EMS system. Many of these centers are available 24 hours a day. They are staffed with specialists who provide information, consultation, treatment recommendations, patient follow-up, and data collection. Poison control centers are linked to many agencies that deal with toxic substances. In addition, they are tied closely to all area hospitals. These centers maintain a listing of more than 350,000 drugs, toxic substances, and other products. The Universal Poison Control number is 1-800-222-1222.

LOOK AGAIN

See Chapter 34: Toxicology, pp. 982-983.

The Chemical Transportation Emergency Center (CHEMTREC) is a public service of the Chemical Manufacturers Association. The center provides immediate advice to on-scene personnel about the management of known or unknown hazardous materials. The agency also contacts the shipper of the material for more information or assistance when needed. The Chemical Transportation Emergency Center operates 24 hours a day, 7 days a week. The center can be reached in the United States and Canada through the emergency toll-free number 1-800-424-9300 (in Alaska 0-202-483-7616). The paramedic should contact CHEMTREC as soon as possible during a hazmat incident. EMS personnel should provide the center with the name of the substance, its identification number, and the nature of the problem. Involving CHEMTREC in the management of a hazmat incident is usually part of the standard operating procedure of any emergency response team.

ChemTel is an emergency response communications center. It serves the United States and Canada. The office can provide specific product information. It also can provide referral to the proper state and federal authorities for incidents that involve radioactive material. ChemTel can be reached 24 hours a day, 7 days a week, through the toll-free number 1-800-255-3924.

Computer-aided management of emergency operations (CAMEO) systems are designed to assist emergency responders quickly in the management of hazmat incidents. The program is available to municipalities. It uses computer modeling to predict the effects of chemical spills and toxins released in plumes of smoke. The system helps communities prepare emergency response plans. CAMEO currently provides information on more than 6000 chemicals. The systems also contain more than 80,000 chemical synonyms and identification numbers that can be quickly searched to identify unknown substances during an incident. Box 57-2 lists other government and private sector agencies that may assist in a hazmat incident.

There are many Internet sources for hazmat identification and management. These include federal, state, and local governmental agencies; colleges and universities; businesses and industry; trade associations; and nonprofit groups who have established easily accessible websites. Box 57-3 lists federal Internet websites for hazmat reference.

PERSONAL PROTECTIVE CLOTHING AND EQUIPMENT

The potential for injury from exposure to hazardous materials is related to the toxicity, flammability, and reactivity of a particular substance. Use of the right protection is crucial for anyone dealing with hazardous materials. This includes the use of the proper respiratory protection and personal protective equipment (PPE).

Protective Respiratory Devices

The potential for exposure of the respiratory system to hazardous materials is of paramount importance to the

BOX 57-2 Agencies That Assist in Hazardous Materials Incidents*

Federal Agencies

Centers for Disease Control and Prevention
Department of Transportation
Environmental Protection Agency
Federal Aviation Administration
National Response Center

- Armed Forces (Army, Navy, Air Force, Marines)
- Coast Guard
- Department of Energy

Regional and State Agencies

National Guard
State emergency management agencies
State environmental protection agency
State health departments
State police

Local Agencies

Emergency management
Fire service (hazardous materials units)
Law enforcement agencies
Poison control center
Public utilities
Sewage and treatment facilities

Commercial Agencies

American Petroleum Institute
Association of American Railroads and Hazardous Materials Systems
Chemical Manufacturers Association
Chevron (provides assistance with Chevron products)
HELP (the Union Carbide Emergency Response System for company shipments)
Local industry
Local contractors

- Local: carriers and transporters
- Railway industry

*This box lists only a sampling of the agencies; the list is not all-inclusive.

emergency responder. The respiratory system can be protected by air purification devices and by equipment that supplies clean air (atmosphere supplying device).

Air purification relies on respirators or filtration devices. These devices remove particulate matter, gases, or vapors from the atmosphere. These devices do not use a separate source of air. They also require constant monitoring for contaminants and oxygen levels. As a rule, they are not recommended for use in a hazardous materials release and must be fitted to the wearer. Filtration devices are material-specific ("must match the gas"). They are not used in the presence of multiple types of chemicals. These devices cannot be used in an environment with a low oxygen concentration.

Atmosphere supplying devices rely on a separate source of positive pressure to supply air. They provide the highest level of respiratory protection. Two basic types are available. One is the **self-contained breathing apparatus** (SCBA). The other is the **supplied air breathing apparatus** (SABA), or air lines. The use of either requires training, recertification, and proper fit-testing as governed by regulations from OSHA.

The self-contained breathing apparatus provides respiratory protection in oxygen-deficient and toxic atmospheres. Only SCBAs that maintain positive pressure in the facepiece during inhalation and exhalation should be used when working with hazardous materials. The SCBA usually is considered excellent protection in hazardous environments. However, the rescuer should be aware of potential facepiece penetration and contamination by certain toxic substances, such as methyl bromide, Telone (1,3-dichloropropene and chloropicrin), and ethyleneimine.

The supplied air breathing apparatus supplies air to the rescuer via an air-line hose away from the scene. These devices often are used at hazardous material sites when extended working times are required. The SABA must have an escape capability for operations in atmospheres classified as immediately dangerous to life and health. Respiratory protection devices that combine SCBAs and air-line hose units are available. However, because of their dependence on air supply via a line, they limit the distance entry personnel can enter into a contaminated area (hot zone).

FIGURE 57-3 Level A protective clothing. (Courtesy Creve Coeur Fire District, Creve Coeur, Mo.)

FIGURE 57-4 Level B protective clothing. It offers the highest level of respiratory protection and a higher level of skin protection than Level C protective clothing. (Courtesy Creve Coeur Fire District, Creve Coeur, Mo.)

BOX 57-4 Forms of Chemical Intrusion

Degradation: The physical destruction or decomposition of a clothing material caused by exposure to chemicals, use, or ambient conditions.

Penetration: The flow of a hazardous liquid chemical through zippers, stitched seams, pinholes, or other imperfections in a material.

Permeation: The process by which a hazardous liquid chemical moves through a material on a molecular level.

Classifications of Protective Clothing

Protective clothing is categorized in two ways: disposable or reusable. The clothing is made from a variety of materials that are designed specifically for certain chemical exposures. (Training in the use of this clothing should take place in a safe environment before it is used at emergency scenes.) Examples of this material include Tyvek/Saranex, nitrile rubber, Teflon, and Viton. No single material is compatible with all chemicals. Thus the manufacturer's guidelines and recommendations must be followed (Box 57-4). Protective clothing is classified in several ways. The classifications defined by OSHA and the EPA follow[6,6a]:

Level A: Level A provides the highest level of skin, respiratory, and eye protection (Figure 57-3). Level A equipment typically is used by hazmat teams for entry into the incident site. Level A equipment includes a positive-pressure (pressure demand), full-facepiece SCBA or positive-pressure supplied air respirator with escape SCBA, approved by the National Institute of Occupational Safety and Health (NIOSH). This level of protection also includes a totally encapsulating (gastight) chemical protective suit, coveralls and long underwear (optional), outer and inner gloves that are chemical resistant, an undersuit hard hat (optional), and a disposable protective suit (including gloves and steel-toed boots) that may be worn over a totally encapsulating suit. (Unless specified by the manufacturer, these disposable suits are not to be worn in flammable atmospheres.)

Level B: Level B provides the highest level of respiratory protection. However, it provides a lower level of skin protection (Figure 57-4). Level B protection typically is worn by the decontamination team. Level B equipment includes positive-pressure, full-facepiece SCBA or positive-pressure supplied air respirator with escape SCBA (NIOSH approved); hooded, chemical-resistant clothing (overalls, long-sleeved jacket, coveralls, one-or two-piece chemical splash suit, disposable chemical overalls); coveralls (optional); inner and outer chemical-resistant gloves; chemical-resistant boots with steel toe and shank; outer chemical-resistant boot covers (optional); an optional hard hat and face shield.

Level C: Level C protection is used during the transport of contaminated patients. Level C protection is used when the concentration and type of airborne substance (or substances) is known and the criteria for using air-purifying respirators are met. Level C equipment includes full face or half mask air-purifying respirators (NIOSH approved); hooded, chemical-resistant clothing (overalls, two-piece chemical splash suit, disposable chemical-resistant overalls); coveralls (optional); outer and inner chemical-resistant gloves; outer chemical-resistant boots with steel toe and shank (optional); disposable outer

FIGURE 57-5 Level D protective clothing. (Courtesy Creve Coeur Fire District, Creve Coeur, Mo.)

chemical-resistant boot covers (optional); and optional escape mask and face shield.

Level D: Level D is a work uniform that affords minimal protection (used for nuisance contamination only; Figure 57-5). Level D protection commonly is known as firefighter "turnout" gear. (Turnout gear with SCBA may be considered level B protection for some chemicals that do not pose danger for skin contact or absorption.) Level D equipment includes coveralls; optional gloves, chemical-resistant boots or shoes with steel toe and shank; disposable outer chemical-resistant boots (optional); safety glasses or chemical splash goggles; and optional hard hat, escape mask, and face shield.

CRITICAL THINKING

What types of patient care do you think you will be able to provide when wearing each of the levels of hazardous materials protective gear?

Regardless of the type of PPE used during a hazmat incident, all avenues through which hazardous materials can enter the body must be protected. The following points should be of particular concern to any rescuer involved in hazmat response:

- Protective clothing should not be affected adversely by the hazardous materials involved.
- Protective clothing should seal all exposed skin.
- Contact with the hazardous materials should be of the absolute minimal duration required.
- Protective clothing and equipment should be decontaminated properly. Or it should be discarded properly.
- The safety standards and methods for cleaning and disposing of clothing and equipment should be followed strictly.
- Contaminated patient clothing should be left at the scene for proper and safe disposal. It should not be transported with the patient. This will limit the contamination of the ambulance.

HEALTH HAZARDS

As described in Chapter 34, hazardous materials may enter the human body by inhalation, ingestion, injection, and absorption. Entry by means of any of these routes may result in internal and external damage to the rescuer. Exposure to dangerous substances may affect the body in several different ways. It may produce numerous injuries or illnesses.

Exposure to poisons can produce acute toxicity, delayed toxicity, and local and systemic effects. The way that the body responds depends on the concentration of the chemical to which the body is exposed (also called the **dose response**). The paramedic also should be aware that drug treatment can result in **synergistic effects** (the effects of one chemical enhancing the effects of a second chemical). Thus all treatment methods must be guided by medical direction, a poison control center, or other appropriate authority.

Internal Damage

Internal damage to the human body from exposure to hazardous materials may involve the respiratory tract, the central nervous system (CNS), or other internal organs. Some substances injure all cells on contact. Others have a more direct effect on specific organs (target organs), such as the kidneys and liver.

Depending on the hazardous materials, the physical injury may vary. It may range from minor irritation to more serious complications, including cardiorespiratory compromise and death. Chronic illness (e.g., chronic obstructive pulmonary disease) and various forms of cancer also may result. Some substances can cause abnormal fetal development and changes in gene structure. For example, penetrating radiation (described in Chapter 39) can lead to cell and chromosomal changes and can cause genetic changes, cell death, and sterility.

IRRITANTS

Irritants that affect the respiratory system are a common complaint of rescuers and patients who have been exposed to hazardous materials. Chemical irritants emit vapors that affect the mucous membranes of the body. These include the surfaces of the eyes, nose, mouth, and throat. As these irritants combine with moisture, acidic or alkaline reactions may occur. Exposure to these irritants may result in damage to the upper, lower, and deep respiratory tract. Examples of chemical irritants are hydrochloric acid, halogens, and ozone.

Self-defense chemical sprays used by some civilians and law enforcement officers are common and can present a hazard to responders. These sprays are irritants and produce excessive tearing of the eyes. They include chloroacetophenone, *ortho*-chlorobenzalmalononitrile, and capsicum oleoresin (*pepper spray*).

ASPHYXIANTS

Asphyxiants are gases that displace the oxygen in the air and also dilute the oxygen concentration of the air. Examples of simple asphyxiants are carbon dioxide, methane, and propane. Other gases not only displace oxygen in the air but also interfere with tissue oxygenation; these are referred to as *blood poisons* or *chemical asphyxiants.* They tend to interrupt the transport or use of oxygen by tissue cells. Through various mechanisms, these toxic gases deprive body tissue of needed oxygen. Examples include hydrogen cyanide, carbon monoxide, and hydrogen sulfide (Box 57-5).

NERVE POISONS, ANESTHETICS, AND NARCOTICS

Nerve poisons, anesthetics, and narcotics act on the nervous system. These agents affect either the cardiorespiratory mechanisms of the brain or the ability to transmit impulses required for adequate heart and lung function.

Nerve poisons were developed by the military. They often are referred to as *war gases, nerve gases,* or *nerve agents* (see Chapter 58). Similar substances are used in solid pesticides. Exposure to these chemicals may result in fatal complications. Examples of these poisons include carbamates, organophosphates, parathion, and malathion. Anesthetics and narcotics are less hazardous than nerve poisons. However, continuous exposure or exposure to large concentrations may result in unconsciousness or death. Examples include ethylene oxide, nitrous oxide, and ethyl alcohol.

HEPATOTOXINS

Hepatotoxins are substances that damage the liver. The poisons accumulate in the body and destroy the ability of the liver to function. Examples include chlorinated and halogenated hydrocarbons.

CARDIOTOXINS

Cardiotoxins are hazardous materials that can cause myocardial ischemia and dysrhythmias. Examples include some nitrates and ethylene glycol. Acute myocardial infarction and sudden death have been reported in healthy young persons who were exposed to these substances. Short-term exposure to fluorocarbons and other halogenated hydrocarbons also has been known to cause cardiac abnormalities.

NEPHROTOXINS

Nephrotoxins are hazardous materials that are especially destructive to the kidneys. Examples include carbon disulfide, lead, high concentrations of organic solvents, and inorganic mercury. Exposure to carbon tetrachloride, used as a solvent for dry cleaning or as a fire-extinguishing agent, can damage the kidneys.

BOX 57-5 Hydrogen Sulfide

Hydrogen sulfide (H_2S) is considered a poison that affects several systems of the body, mostly the nervous system. It is a colorless, flammable, and extremely hazardous gas with a rotten egg smell. Hydrogen sulfide is similar to cyanide, and it is five to six times more toxic than carbon monoxide.[7] Exposure to the gas can be lethal within a few minutes.

Hydrogen sulfide can be easily produced by combining common household chemicals. It is sometimes used as a method of suicide (*detergent suicide*). Most of these suicides in the United States have involved young adults who make the hydrogen sulfide in their cars.[8] All rescuers working in a confined space or who are responding to a possible suicide in a confined space (e.g., automobile, closet) should[9]:

- Be aware of the possibility of poisonous gas
- Remember that hydrogen sulfide has a pungent odor similar to rotten eggs
- Retreat to a safe area and use PPE and SCBA if hydrogen sulfide is suspected
- Be aware that confined spaces will temporarily continue to discharge noxious gas
- Know that a person and his or her clothing will release the gas for a brief period
- Expect the need for decontamination of the chemicals spilled
- Request hazmat support with a cyanide antidote kit

NEUROTOXINS

Neurotoxins are poisons that affect the nervous system. Neurological and behavioral toxicity may result from exposure to hazardous substances such as arsenic, lead, mercury, and organic solvents. In some cases, cerebral hypoxia may occur as a result of decreased oxygen in the blood.

HEMOTOXINS

Hemotoxins are hazardous substances that may cause the destruction of red blood cells. This destruction can result in hemolytic anemia (see Chapter 32). Substances that can produce hemolytic anemia include aniline, naphthol, quinones, lead, mercury, arsenic, and copper. Pulmonary edema and cardiac and liver injury also may be caused by hemotoxin exposure.

CARCINOGENS

Carcinogens are cancer-causing agents. Many hazardous materials are carcinogenic or are suspected carcinogens. The exact amount of hazardous materials exposure required for cancer to develop is unknown. However, short-term exposure to specific agents is known to produce long-term effects. Disease and complications have been reported 20 years after exposure to hazardous materials.[10]

Of particular interest to rescuers involved in firefighting is that all fossil and organic fuels produce dioxins when they are burned. **Dioxin** is a general term that describes a group of hundreds of chemicals that are highly persistent in the environment. These chemicals are an unintentional byproduct of many industrial processes (e.g., waste incineration, pesticide manufacturing).[11] Many of the dioxins are carcinogens. (For example, burning wood produces carcinogenic formaldehyde.) A positive-pressure SCBA is the most important piece of protective equipment to protect against these carcinogenic vapors and respiratory poisons. All rescuers should avoid exposure to smoke or clouds of fumes as a standard practice in scene safety.

NOTE

An important sign of a critical exposure is several persons having the same symptoms at the same time. Any time two or more members of the team report that they "feel" similar symptoms, a toxic gas or agent should be suspected. Emergency personnel should immediately report the onset of symptoms to their crew members and other emergency responders at the scene.

GENERAL SYMPTOMS OF EXPOSURE

Health effects from exposure to hazardous materials vary by individual. They also depend on the chemical involved, the concentration of the chemical, the duration of exposure, the number of exposures, and the route of entry (inhalation, ingestion, injection, absorption). In addition, a person's age, gender, general health, allergies, smoking habits, alcohol consumption, and medication use influence how that person is affected.

Various symptoms may result from exposure to hazardous materials. Some symptoms may be delayed or masked by common illnesses such as influenza or by smoke inhalation. If any of the following symptoms is present after exposure to hazardous materials, the rescuer or patient should seek immediate medical attention:

- Changes in skin color or blushing
- Chest tightness
- Confusion, light-headedness, anxiety, dizziness
- Coughing or painful respiration
- Diarrhea and involuntary urination or defecation (or both)
- Dim, blurred, or double vision; photophobia
- Loss of coordination
- Nausea, vomiting, abdominal cramping
- Salivation, drooling, rhinorrhea
- Seizure
- Shortness of breath, burning of the upper airway
- Tingling or numbness of extremities
- Unconsciousness

CRITICAL THINKING

Two rescuers complain of similar symptoms on the scene of a rescue that may involve hazardous materials. What actions should be taken immediately?

External Damage

Body surface tissue may be injured by hazardous materials. Many substances have corrosive properties or become corrosive when mixed with water. Exposure to these substances may produce chemical burns and severe tissue damage. Examples include hydrochloric acid, hydrofluoric acid, and caustic soda.

SOFT TISSUE DAMAGE

Corrosives are acids or bases (alkaline). Exposure to either may cause pain on contact. However, alkalis generally burn more extensively than acids. Exposing human tissue to a base corrosive such as lye may result in **liquefaction** (a breakdown of fatty tissue) that produces a greasy or slick feeling to the skin. These signs should alert the rescuer to decontaminate immediately and seek medical attention. Unless the substance is identified, decontamination should begin by brushing off the dry powder and flushing the skin with copious amounts of water. (Different areas of the skin absorb chemicals at different rates.) Paramedics should never try to neutralize an acid or base; doing so could produce great heat and cause further burns. The area should be flushed copiously with water, and the patient should be transported for care. Rescuers should be aware of possible "off-gassing" or fumes resulting from the decontamination of a wound site and take appropriate protective measures.

Cryogenics are refrigerant liquid gases that can freeze human tissue on contact. These liquids vaporize as soon as they are released from their containers. They may cause tissue damage. Extreme caution should be used when near any refrigerated liquids. They can produce freeze burns, frostbite, and other cold-related injuries. Examples include Freon, liquid oxygen, and liquid nitrogen.

CHEMICAL EXPOSURE TO THE EYES

Chemical exposure to the eyes (described in Chapter 39) may cause damage ranging from superficial inflammation to severe burns. Patients with these conditions have local pain, visual disturbance, tearing, edema, and redness of surrounding tissues. Basic management guidelines include immediately flushing the eyes with water. This should be done using a mild flow from a hose, intravenous tubing, water from a container, or irrigation lens (per protocol). A rapid assessment of visual acuity is important. However, assessment should not delay flushing or irrigation of the eyes.

LOOK AGAIN

See Chapter 39: Burns, pp. 1136-1137.

RESPONSE TO HAZARDOUS MATERIALS EMERGENCIES

When an EMS crew is dispatched to a scene involving the potential for hazardous materials, decisions must be made about rescuer safety, the type and degree of the potential hazard, the involvement of other agencies, and protection for the general public. As discussed in Chapter 54, preplanning and early coordination of activities in these major incidents is important. In addition, medical direction should be advised of the incident as soon as possible to prepare personnel and facilities. Not all hazmat incidents are large-scale events. Sometimes, a single event involving only one patient may require a full hazmat response.

The first rescue personnel to arrive at the scene of a hazmat incident may not be the most qualified or best equipped. However, most communities look to the first responders to provide immediate safety and direction. Thus the EMS crew must be capable of the initial management of hazmat incidents.

Hazard and Risk Assessment

While en route to the scene, EMS personnel should begin to research hazmat references. They also should begin a **hazard and risk assessment.** In hazmat incidents, *hazards* are the chemical properties of a material that may cause danger or peril (Box 57-6). *Risk* refers to the possibility of suffering harm or loss. Risk levels vary and are influenced by several factors, including the following[12] (Figure 57-6):

- Hazardous nature of the material involved
- Worst-case scenario situations
- Quantity of the material involved
- Weather conditions that might affect the scene adversely
- Containment system and type of stress applied to the container
- Proximity of exposures (e.g., schools, nursing homes, and shopping centers)
- Level of available resources
- Lead time for mutual aid

A hazard and risk assessment also includes consideration of the potential hazards to the public and environment, the potential risk of **primary contamination** to patients, and the potential risk for **secondary contamination** to rescuers (Box 57-7).

If the product can be identified through hazmat references, the EMS crew should familiarize themselves with potential health hazards, recommended PPE, initial first aid, and the **safe distance factor** (the minimum safe distance for personal safety) as outlined in the reference guides. Most emergency response guides offer only general management actions. After formal product identification, the appropriate hazmat agencies (e.g., CHEMTREC and poison control) can give more exact information.

BOX 57-6 Hazardous Materials Terminology and Definitions

Toxicological Terms Used to Determine Toxicity of a Compound

IDLH (immediately dangerous to life and health): Any atmosphere that poses an immediate hazard to life or that produces immediate, irreversible debilitating effects on health.

LD50 (lethal dose, 50% kill): The amount of a dose that, when administered to laboratory animals, kills 50% of them.

PEL (permissible exposure limit): The maximum time-weighted concentration at which 95% of exposed, healthy adults suffer no adverse effects over a 40-hour workweek.

ppm/ppb: Parts per million/parts per billion.

TLV-C (threshold limit value—ceiling level): The maximum concentration that should not be exceeded even instantaneously.

TLV-STEL (threshold limit value—short-term exposure limit): A 15-minute, time-weighted average exposure that should not be exceeded at any time or repeatedly more than 4 times a day, with 60-minute rest periods required between each STEL exposure.

Specific Terminology for Medical Hazardous Materials Operations

Alpha radiation: Large radioactive particles that have minimal penetrating ability.

Beta radiation: Small radioactive particles that can penetrate subcutaneous tissue and usually enter the body through damaged skin, ingestion, or inhalation.

Boiling point: The temperature at which a liquid changes to a vapor or a gas; the temperature at which the pressure of the liquid equals atmospheric pressure.

Flammable/exposure limits: The range of gas or vapor concentration that will burn or explode if an ignition source is present.

Flashpoint: The minimum temperature at which a liquid disperses enough vapors to ignite and flash-over but not to continue to burn without additional heat.

Gamma radiation: The most dangerous form of penetrating radiation, which can produce internal and external hazards.

Ignition temperature: The minimum temperature required to ignite gas or vapor without a spark or flame being present.

Specific gravity: The weight of a material as compared with the weight of an equal volume of water.

Vapor density: The weight of a pure vapor or gas compared with the weight of an equal volume of dry air at the same temperature and pressure.

Vapor pressure: The pressure exerted by the vapor within the container against the sides of a container.

Vapor solubility: The ability of a vapor to mix with water.

From Noll G, et al: *Hazardous materials: managing the incident,* Stillwater, Okla, 2004, Fire Protection Publications.

Approaching the Scene

The paramedic should approach the scene cautiously from uphill and upwind. The EMS crew should be alert to environmental clues. These include wind direction, unusual odors, leakage, and vapor clouds. Other environmental clues that are good indicators for the presence of hazardous

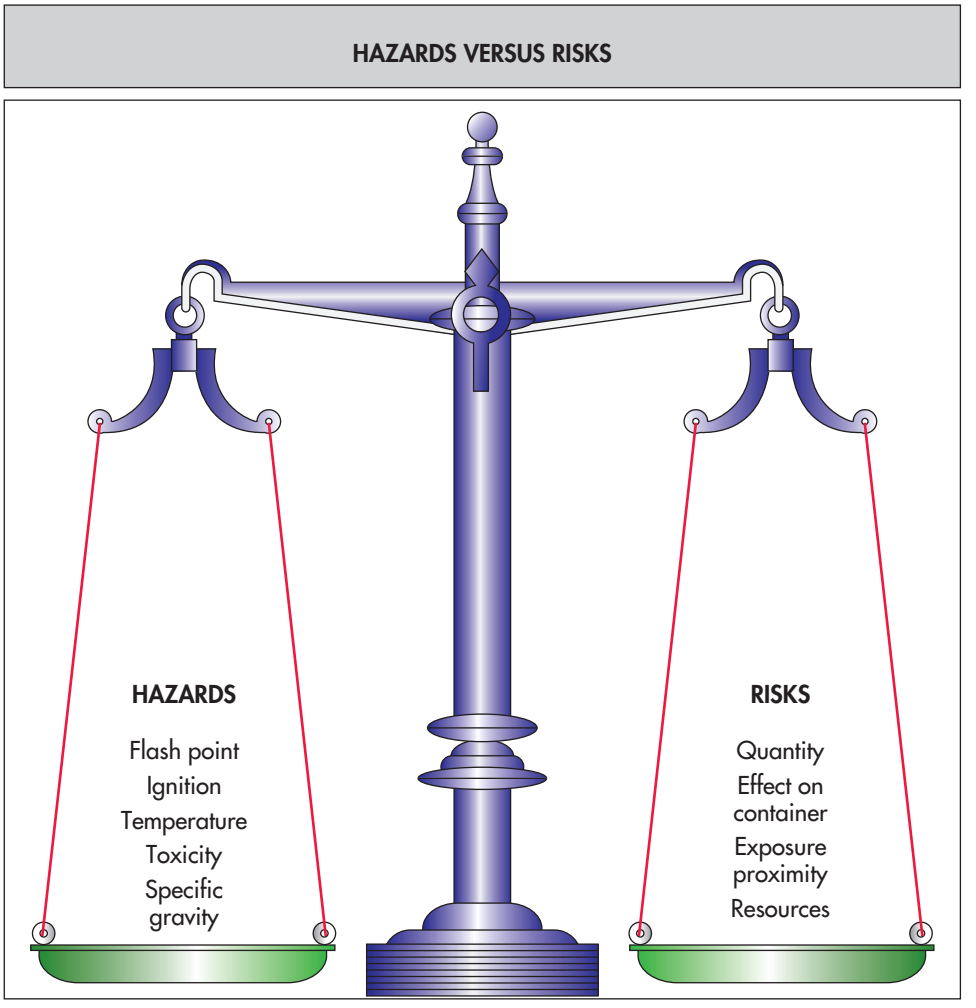

FIGURE 57-6 Hazards versus risk.

BOX 57-7 Types of Contamination

Primary Contamination
Exposure to substance
Substance only harmful to exposed person
Little chance of exposure to others

Secondary Contamination
Exposure to substance
Liquid and particulate substances easily transferred by touching

materials include affected or afflicted wildlife and plant life (e.g., dead birds and wilted or discolored plants). Paramedics can use binoculars initially to observe the scene from a safe distance. Emergency vehicles should never be driven through leakage or vapor clouds or smoke. In addition, personnel should not enter the incident area until it has been determined to be safe. In addition to these guidelines, rescuers should do the following as recommended in the *Emergency Response Guidebook*[13]:

- *Approach cautiously.* Resist the urge to rush into the incident area; you cannot help others until you know what you are facing.
- *Identify the hazards.* Placards, container labels, shipping papers, and knowledgeable persons on the scene are valuable sources of information. Evaluate all of them and then consult the recommended guide page before you place yourself or others at risk. Do not be alarmed if new information from a CHEMTREC expert changes some of the emphasis or details of the guide page warnings. You must remember that the guide page provides only the most important information for your initial response with a family or class of hazardous materials. As more accurate, material-specific information becomes available, your response becomes more appropriate for the situation.
- *Secure the scene.* Without entering the immediate hazard zone, do what you can to isolate the area and ensure the safety of persons and the environment. Move and keep

persons away from the scene and the perimeter. Allow enough room to move and remove your own equipment.

- *Obtain help.* Advise your headquarters to notify responsible agencies and call for assistance from trained experts through CHEMTREC and the National Response Center, which can be reached through CHEMTREC or dialed directly.
- *Decide on site entry.* Any efforts you make to rescue persons or protect property or the environment must be weighed against the possibility that you could become part of the problem. Enter the area with the appropriate protective gear (if trained to do so). Above all, *do not walk into or touch spilled material.* Avoid inhaling fumes, smoke, and vapors, even if no hazardous materials are known to be involved. Do not assume that gases or vapors are harmless because of lack of smell.

CRITICAL THINKING

Which of these guidelines would it be easy for the first arriving crew to miss?

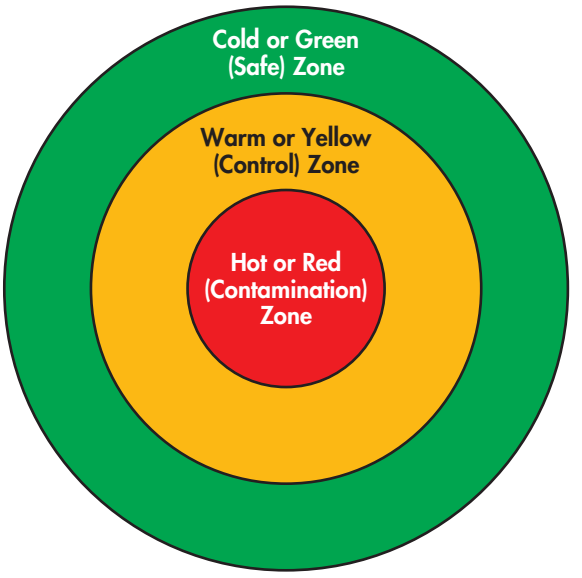
Control of the Scene

The first agency to arrive at the scene has several responsibilities. Its members must detect and identify the materials involved, assess the risk of exposure to rescue personnel and others, consider the potential risk of fire or explosion, gather information from on-site personnel or other sources, and confine and control the incident. In addition, a command post should be established per the preplanned incident command structure. Members also must define the safety distances and zones.

Safety Zones

After the presence of hazardous materials has been confirmed, the scene should be separated into hot, warm, and cold zones (Figure 57-7). These zones should have access and egress corridors between them. (Corridors provide control points. They also allow responders working in the zones to know where they should exit and enter for decontamination, accountability, and debriefing.) Safety zones should be established and enforced early in the incident (Box 57-8). The dispatch center and responding units should be advised of the location of the hot zone and safe approach directions.

The **hot zone** is the area of the incident that includes the hazardous material. It also includes any surrounding area that may be exposed to gases, vapors, mist, dust, or runoff. All rescue personnel and vehicles should be stationed outside this zone. Anyone entering this zone must wear high-level PPE. Only specially trained EMS personnel should attempt patient care activities in this area. Some EMS agencies and incident command system structures refer to the hot zone as the *exclusion zone,* a *restricted area,* or the *red zone.*



Hot or Red (Contamination) Zone

- Contamination is actually present.
- Personnel must wear appropriate protective gear.
- Number of rescuers limited to those absolutely necessary.
- Bystanders never allowed.

Warm or Yellow (Control) Zone

- Area surrounding the contamination zone.
- Vital to preventing spread of contamination.
- Personnel must wear appropriate protective gear.
- Life-saving emergency care and decontamination are performed.

Cold or Green (Safe) Zone

- Normal triage, stabilization, and treatment are performed.
- Rescuers must shed contaminated gear before entering the cold zone.

FIGURE 57-7 Zones at a hazmat incident.

BOX 57-8 Hazardous Materials Zones

Hot Zone
Contamination present
Site of incident
Entry with high-level personal protective equipment
Entry limited

Warm Zone
Buffer zone outside hot zone
Contains decontamination corridor with "hot" and "cold" end

Cold Zone
Safe area
Staging area for personnel and equipment
Site of medical monitoring
One end of corridor

The **warm zone** is a larger, buffer area that surrounds the hot zone with "cold" and "hot" end corridors. Although protective clothing is required, it usually is considered a safer environment for workers. However, if the hot zone becomes unstable, the warm zone may be exposed to the

hazardous materials. This zone is where most EMS activities, such as decontamination and patient care, are performed. Some agencies refer to this zone as the *limited-access zone,* the *containment reduction corridor,* or the *yellow zone.*

The **cold zone** is the area that encompasses the warm zone. The cold zone also is restricted to emergency personnel. This area usually is considered safe, requiring only minimal protective clothing. The cold zone contains the command post and other support agencies necessary to control the incident. This area is referred to by some agencies as a *support zone* or the *green zone.*

REHABILITATION AND MEDICAL MONITORING

The safety of rescue personnel is of prime importance in any emergency. Thus a rehab and medical monitoring program should be part of any incident where rescue personnel may be at risk for physical and emotional stress. In addition, the United States Fire Administration (USFA) and the National Fire Protection Association (NFPA) recommend and require rehab and medical monitoring at all emergency scenes where personnel exceed a safe level of physical or mental endurance.[14,15]

Rehabilitation

The purpose of **rehabilitation** (*rehab*) is to sustain the energy of rescuers, improve performance, and decrease the likelihood of on-scene injury or death. As described in Chapter 54, rehab is part of the incident command structure and is a responsibility of command. The rehab area (or areas) usually is established near the incident, but away from operations. The location must ensure safety and must provide for rest and recuperation. Depending on weather and the nature of the incident, these areas may be outdoors, in a building, or in a specially designed rehab vehicle. Activities that may take place in a rehab sector include:

- Relief from environmental extremes (active or passive cooling or warming)
- Rest and recovery
- Rehydration
- Food and drink replacement

NOTE

In most management systems, emergency medical procedures are not performed in the rehab area. If emergency care is needed for a rescuer, that care is provided by EMS personnel in the treatment sector, located away from or in a separate part of the rehab area.

Medical Monitoring

Medical monitoring is the ongoing evaluation of rescuers who are at risk for illness or injury from operations at the incident. *Medical monitoring* should not be confused with *treatment.* The purpose of medical monitoring in the rehab area is to identify personnel who may need treatment (provided in the treatment sector) or transport. In hazmat operations, medical monitoring may also include accountability, record-keeping, and periodic evaluation of the surveillance program.

NOTE

OSHA requires medical examinations for members of hazmat response teams and employees who may have been exposed to hazardous substances during an emergency.

Medical monitoring should include assessment protocols that involve a "presuit" examination before entering a hazardous area. The purpose of the examination is to establish a health history and baseline vital signs for any rescuer who will be exposed to a hazardous substance. During the presuit exam, rescuers should be advised of the expected symptoms of illness or exposure before entering the hazardous area. In addition to injury from exposure, responders working in protective clothing and equipment can become dehydrated and develop heat illnesses. Rescue protective suits protect, but they also prevent cooling through evaporation, conduction, convection, or radiation. Heat-stress factors are affected by the prehydration of the rescuer, degree of physical fitness, ambient air temperature, and degree and duration of physical activity. The parameters of the presuit evaluation should include the following:

- Temperature, pulse, respiration, and blood pressure measurements
- Cardiac rhythm
- Body weight
- Cognitive and motor skills
- Hydration
- Significant recent medical history (e.g., medications or illnesses)

After entry into the hazardous area, medical monitoring should note the amount of time a rescuer has been in protective clothing. Rescuers should be observed for any signs of heat-related illness or exposure (described in Chapter 45). If illness or injury occurs to any team member, all entry team members should be removed from the hot zone for treatment. A backup team should be ready to assist the entry team members in the hot zone at all times.

After the incident, rescue personnel should be reevaluated in the "rehab sector," using the same parameters as in the presuit examination. This exam determines the rescuer's ability to be released to reenter the operation if needed. As a rule, rescuers are not allowed to reenter the site until vital signs and hydration level are normal. Body weight generally is used to estimate fluid loss and the need for oral or intravenous fluid replacement (per protocol) (Figure 57-8).

FIGURE 57-8 Rehabilitation branch.

CRITICAL THINKING

What might prevent personnel from seeking emergency medical services for medical monitoring unless there is a strict procedure to guarantee they are monitored?

SHOW ME THE EVIDENCE

Researchers in a mid-size southwestern metropolitan area retrospectively reviewed hazardous materials incidents fire departments responded to over 3 years. Their goal was to discover which chemicals were involved and identify patient needs. During the study period there were 6232 hazmat incidents, 11% of which met criteria for hazmat control team dispatch. Of these 428 incidents, there were 489 materials involved; 4.5% of incidents had more than 1 chemical involved. The most common chemical was methane gas (26%); automotive fluids accounted for 32% of incidents. Of the hazmat responses 7% involved patient exposure. Inhalation was the most common exposure route. Fourteen patients were firefighters, EMTs, or paramedics exposed after responding to the scene. A total of 45 patients were transported to the hospital. The researchers concluded that most incidents did not have contaminated patients. The patients exposed often had inhalation exposures and usually only needed oxygen administration.

From Walter FG, Bates G, Criss E, et al: Hazardous materials responses in a mid-size metropolitan area, *PEC* 7(2):214-218, 2003.

Documentation

Detailed records are a necessary part of hazmat medical monitoring and rehabilitation. At a minimum, records should include the following:

- The name of the hazardous substance
- The toxicity and danger of secondary contamination
- Use of appropriate PPE and any permeation ("breakthrough") that occurred
- The level of decontamination performed or required
- Use of antidotes and other medical treatment
- The method of transportation and destination

Baseline statistics from preentry and postentry screenings also should be included in the records. (Many agencies use preprinted forms for these.)

EMERGENCY MANAGEMENT OF CONTAMINATED PATIENTS

Patient care activities, triage, and evacuation should be part of a preplanned incident command system structure. Identifying a specific hazardous substance may take some time. Thus rescue efforts, decontamination, possible evacuation, and timely treatment of toxic exposures are important. The primary goals of decontamination are to reduce the patient's dosage of material, decrease the threat of secondary contamination, and reduce the risk of rescuer injury. The specific substance and route of contamination affect triage and decontamination methods. The following guidelines for rapid decontamination are general. They should not supersede any organizational approach in scene management of hazmat incidents or treatment recommendations for chemical exposures:

1. The paramedic should not enter a contaminated area or initiate care without adequate PPE. The paramedic also must possess training that is specific to the incident. Victims who can walk should be encouraged to extricate themselves from the scene. They should be advised to stay together for treatment or until they are escorted individually to decontamination.
2. Patients who cannot walk should be removed from the hot zone by trained personnel. Removal usually is performed by fire service personnel, specialized hazmat teams, or both. Patient care activities in the hot zone should be limited to gross airway management, spinal immobilization, and hemorrhage control. Decontamination and further patient care should be done in the warm zone by a properly equipped decontamination team.
3. All patients exposed to the hot zone should be considered contaminated. They should be treated as such until they have been properly assessed, triaged, and decontaminated.
4. Patient care provisions of airway, breathing, and circulatory support should begin as soon as the patient is contacted and conditions allow. The rescuer safety information received from hazmat agencies should be used when performing basic life support procedures.
5. Intravenous therapy should be administered only under a physician's direction. This and other invasive procedures may allow the hazardous materials to enter the patient.
6. Decontamination procedures should avoid any unnecessary exposure to the rescuer. EMS personnel assisting in decontamination should be well protected with two or three layers of gloves, head coverings, positive-pressure SCBA, and proper protective clothing. Decontamination teams or anyone working in the warm zone should be wearing the same PPE (or no less than one protection level down) as those working in the hot zone.

7. When the hazardous material is a dry agent, lightly brush the material from the patient. Ensure that the dry agent is not introduced into the patient's airway. Cutting or removing clothing often removes most of the contaminating material. After the dry agent has been removed, the decontamination should continue as follows:
   a. Wash the patient with copious amounts of water and mild detergent soap. Make sure that all water and runoff is contained in the warm zone. Depending on the exposure, other patient decontamination procedures may be warranted. Pay special attention to irrigation of the eyes, hair, ears, underarms, and pubic areas and thorough cleaning of the body creases of the neck, groin, elbows, and knees. Be careful not to abrade the skin, which may promote absorption of the material involved.
   b. Leave all patient clothing, rescuer clothing, and decontamination equipment in the decontamination area. Safely move the patient to the support zone for further triage, treatment, and transport.

NOTE
Water is considered the universal decontamination solution to dilute the concentration of a substance. Water generally does not alter the chemical structure of a compound. Degradation solutions may be recommended for some exposures. These include water and mild soap, isopropyl alcohol, and vegetable oil (among others). These solutions should be used only when advised by medical direction or other appropriate authority. They should not be applied directly to the skin, and should not be used for exposures to chemicals that react with water.

One should note that the field decontamination procedures described represent only a gross decontamination. The resources needed for full decontamination usually are not available at the scene. Thus the patient should be isolated from the environment. This will help to contain any contamination that has been missed during these procedures. This is accomplished by placing the patient in a body bag (or similar containment) to the neck and covering the patient's hair. In the absence of body bags, the victim may be packaged for transport by folding one side of a sheet or blanket over the patient and using the other side to overlap and package the patient. If necessary, the patient's arm may be exposed through an opening in the sheet for vital sign assessment and fluid and drug administration.

NOTE
Rapid decontamination is a two-step process. In the first step, remove the patient from danger. In the second step, provide gross decontamination.

Decontamination Decision Making

Hazardous materials incidents often are "fast breaking" and may require rapid decision making. For example, a group of walking, contaminated persons at the scene may be trying to reach rescuers; others self-rescue by walking out of the hot zone; and some may become impatient and leave the hot zone while waiting for rescue teams to arrive. In these situations the paramedic crew must be prepared for quick gross decontamination and treatment, rapid application of PPE, and quick transport and isolation procedures.

If the patient's condition is critical (and it is unknown if the exposure involved a life-threatening material), the paramedic should perform decontamination and treatment simultaneously. This is done by removing the patient's clothing, treating life-threatening problems, lavaging the patient with copious amounts of water, and providing for isolation and transportation. Patients who are not in critical condition can be managed in the same manner with a more contemplative approach, particularly if the hazardous substance is known.

A hazmat incident that is well controlled (not a fast-breaking event) can be managed over longer duration. In these cases, rescue should not be attempted for patients in the hot zone. Rather the paramedic crew should wait for a hazmat team and for a decontamination corridor to be established (Figure 57-9). (This may take an hour or more.) Longer-duration events allow for more thorough decontamination, better use of PPE, less chance of secondary contamination, and better environmental protection.

CRITICAL THINKING
What type of hazardous materials response resources does your community have?

FIGURE 57-9 Patient decontamination area. (Courtesy Creve Coeur Fire District, Creve Coeur, Mo.)

Preparing the Ambulance for Patient Transfer

Contamination of ambulances and equipment can be minimized by preparing the vehicle before transporting a partly decontaminated patient. These measures include using as much disposable equipment as necessary. They also include removing all items from cabinets that will not be needed for patient use. Ideally, the patient should be isolated completely in a stretcher decontamination pool. This should be covered in plastic and secured to the stretcher. Immediate notification of the hospital staff that they will be receiving contaminated patients is crucial. The emergency department will need time to prepare and manage the patients adequately and efficiently.

On arrival at the hospital, the EMS crew should follow the decontamination protocols of the hospital. The crew should not return to regular service until rescue personnel, vehicle, and equipment have been monitored for contamination. Equipment decontamination should follow the recommendations of local, state, and federal authorities or standard operating procedures of medical direction. Specific solutions may be required for a particular hazmat exposure. However, most equipment can be cleaned adequately and made ready for use with soap and water.

DECONTAMINATION OF RESCUE PERSONNEL AND EQUIPMENT

Decontamination procedures of rescue personnel vary by agency and protocol. Decontamination typically involves eight steps and begins in the decontamination corridor (Figure 57-10). These steps include the following:

1. An entry point is established at the "hot" end of the corridor where "dirty" personnel and equipment are set up to start the decontamination process.
2. A tool drop is designated. Outer gloves and boots are removed and placed in a receptacle.
3. Gross surface contamination is removed. Generally this is done by washing with copious amounts of water.
4. Contaminated SCBA bottles are removed (doffed) for personnel who must reenter the dirty area; at this step they receive clean SCBA bottles.
5. Protective clothing is removed and handled (stored, decontaminated) as required.
6. Other clothing is removed. This step depends on the seriousness of the hazardous materials involved.
7. Personnel wash their bodies using overhead showers. Usually two washings are required. Personnel dry off and receive new or clean, uncontaminated clothing.
8. Personnel going through the decontamination system receive medical evaluation. The person is then transported to a medical facility for continued medical evaluation.

In addition, the following safety precautions should be followed by any rescuer exposed to hazardous materials:

- Do not touch your face, mouth, nose, or genital area before full body decontamination.
- Shower first with a cold rinse (no scrubbing) to wash off potential contaminants without opening pores of the skin and then thoroughly wash with warm water, surgical soap, sponge, and brush; pay particular attention to hair, body orifices (especially the ears), and any body parts that come in contact with each other (arms and chest, thighs, fingers, toes, and buttocks). Repeat shower and rinse.
- Shampoo hair several times and rinse thoroughly.

CRITICAL THINKING

Why do you think that extensive preplanning and drills are needed to make this system work well?

Care and Maintenance of Clothing and Equipment

After the hazmat incident, the rescuer should take the following precautions:

- Properly dispose of any protective clothing that has been torn or worn through.
- Properly and thoroughly clean all clothing and equipment. This will reduce the risk of chemical reactions at future incidents. It also will lessen the potential for chronic exposure to absorbed chemicals. Some hazardous materials can destroy or penetrate protective clothing and equipment. For this reason, product compatibility tables should be evaluated during the decontamination procedure. Decontamination provides no assurance that protective clothing is clean or that the process of chemical penetration has stopped.
- Do not wash or dispose of clothing or equipment at home. This helps to avoid exposing family members and contaminating home articles.
- Follow all local codes and laws regarding disposal or decontamination of equipment and clothing.
- Carefully maintain personal SCBA.

When the incident is over, all personnel operating at the scene (in any capacity) should be debriefed. The debriefing session should include identification and explanation of the substances. It also should include information regarding possible acute and chronic health issues that may arise and any associated signs and symptoms. Information describing follow-up procedures for long-term effects also should be provided. The documentation for possible work-related exposures should follow standard department/company policies.

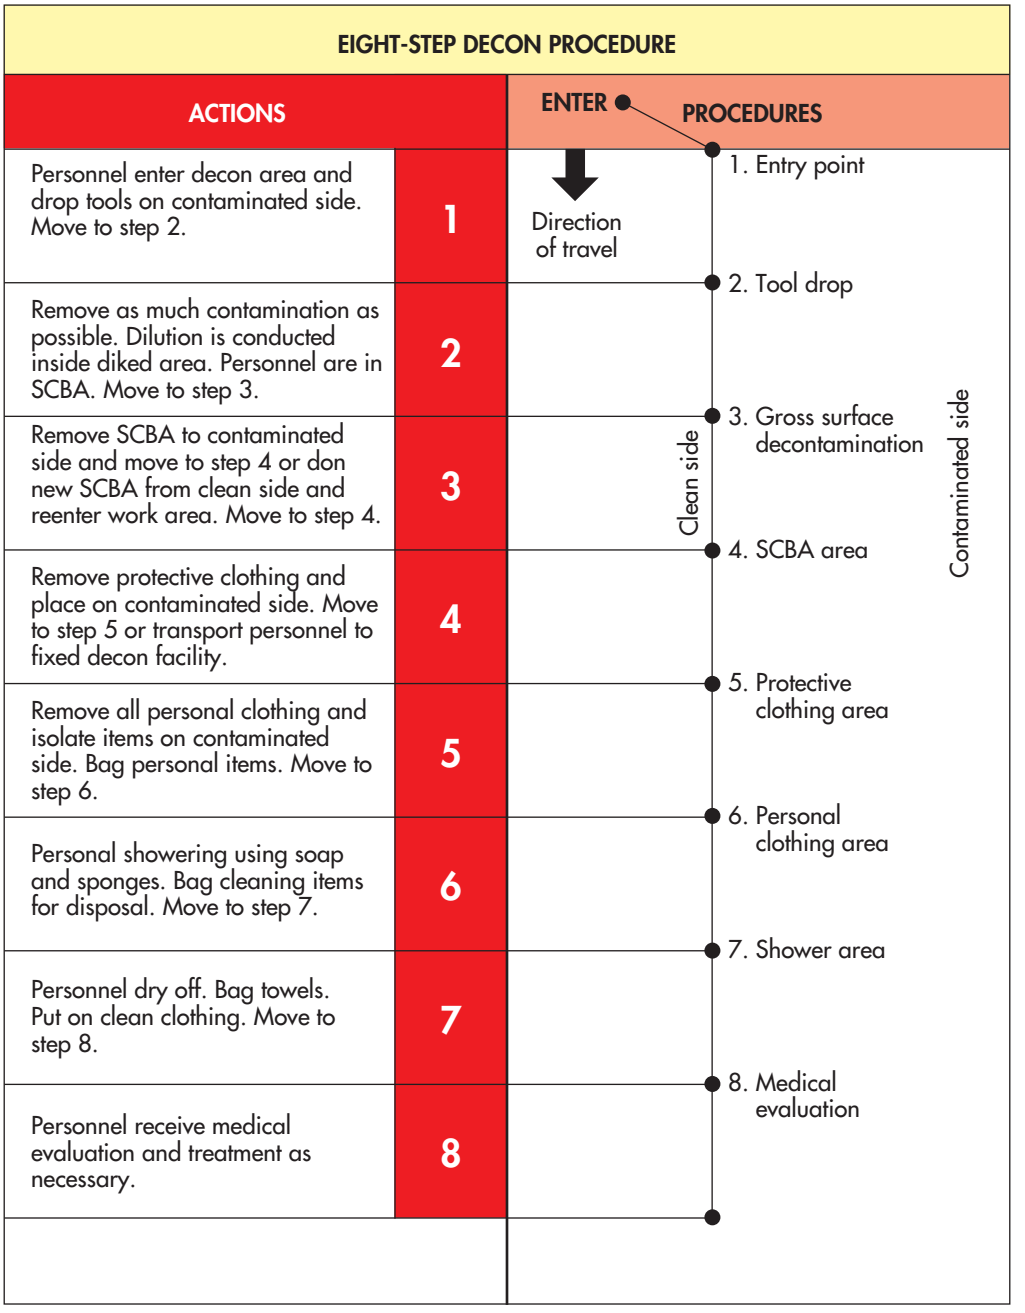


FIGURE 57-10 Eight-step decontamination process.

SUMMARY

- A hazardous material is any substance or material that is capable of posing an unreasonable risk to health, safety, and property.
- The Superfund Amendments and Reauthorization Act of 1986 established requirements for federal, state, and local governments and industry regarding emergency planning and the reporting of hazardous materials–related incidents. In 1989 OSHA and the EPA published rules to govern training requirements, emergency plans, medical checkups, and other safety precautions for workers at uncontrolled hazardous waste sites and for those responding to hazardous chemical spills. In addition, the NFPA has published standards that address competencies for EMS workers at hazmat scenes.
- There are two methods used to identify hazardous materials. One is informal product identification. (This includes visual, olfactory, and verbal clues.) The other is formal product identification. (This includes, for

Continued

example, placards and shipping papers.) Resources for hazardous materials reference include the *North American Emergency Response Guidebook,* regional poison control centers, CHEMTREC, ChemTel, and CAMEO.

- It is crucial that anyone dealing with hazardous materials use proper protection. This includes using the proper respiratory devices. It also includes wearing protective clothing. This clothing is made of a variety of materials. The clothing is designed for certain chemical exposures. Thus, the manufacturer's guidelines must be followed.
- Hazardous materials may enter the body through inhalation, ingestion, injection, and absorption. Internal damage to the human body from hazardous materials exposure may involve the respiratory tract, CNS, or other internal organs. Chemicals producing internal damage include irritants, asphyxiants, nerve poisons, anesthetics, narcotics, hepatotoxins, cardiotoxins, nephrotoxins, neurotoxins, and carcinogens.
- Exposure to hazardous materials may result in burns. It also may result in severe tissue damage.
- The first agency to arrive at the scene of a hazardous materials incident must detect and identify the materials involved, assess the risk of exposure to rescue personnel and others, consider the potential risk of fire or explosion, gather information from on-site personnel or other sources, and confine and control the incident.
- A hazmat medical monitoring program may include medical examination for members of hazmat response teams, provision of medical care, record-keeping, and periodic evaluation of the surveillance program.
- The primary goals of decontamination are to reduce the patient's dosage of material, decrease the threat of secondary contamination, and reduce the risk of rescuer injury.
- Rescuers should follow strict protocols for proper decontamination of themselves, their clothing, and any contaminated equipment.

APPENDIX

Overview of Training Requirements for EMS Personnel Responding to a Hazardous Materials Incident as Established by OSHA/EPA and the NFPA*

OSHA/EPA TRAINING REQUIREMENTS

1. *First responder awareness.* This category pertains to individuals who are likely to witness or discover a hazardous substance release but who do not have emergency response duties pertaining to hazardous materials as part of their job functions. This applies to most law enforcement officers. Individuals in this category must have sufficient training to demonstrate the following:
   a. An understanding of what hazardous materials are and the risks associated with them in an accident
   b. An understanding of the possible outcomes of an emergency in which hazardous materials are present
   c. The ability to recognize the presence of hazardous materials in an emergency
   d. The ability to identify the hazardous materials (if possible)
   e. An understanding of the role of the first responder in the emergency response plan
   f. The ability to recognize the need for additional resources
2. *First responder operations.* Individuals are included in this category if they respond to hazardous materials incidents to protect nearby persons, property, or the environment without trying to stop the hazardous release. Firefighters and emergency medical services (EMS) personnel are in this category. In addition to the knowledge base of first responder awareness, these individuals must have training in the following:
   a. Basic hazard and risk assessment techniques
   b. Personal protective clothing and equipment
   c. Basic control, containment, and confinement operations
   d. Basic decontamination procedures
3. *Hazardous materials technicians.* Individuals in this category respond to hazardous materials emergencies for the purpose of stopping the release. Hazardous materials technicians usually are considered members of a hazardous materials response team. These individuals have additional training in the following:
   a. Emergency response plans
   b. The use of survey instruments and equipment to identify hazardous materials
   c. Incident command systems
   d. Specialized protective clothing and equipment
   e. Specialized containment and confinement operations
4. Hazardous materials specialists. The duties of these individuals require specific knowledge of the various hazardous substances. Hazardous materials specialists respond with and provide support to hazardous materials technicians and act as site liaisons with federal, state, and local government authorities. In addition to the knowledge base of the hazardous materials technician, hazardous materials specialists have training in the following:
   a. The use of advanced survey instruments and equipment
   b. In-depth hazard and risk assessment
   c. Implementation of decontamination procedures
   d. Site safety and control
   e. Chemical, radiological, and toxicological terminology relevant to hazardous substance behaviors
5. On-scene incident commander. The on-scene incident commander is trained to assume control of a hazardous materials event. In addition to the first responder awareness level of training, the on-scene incident commander's responsibilities include the following:
   a. Implementation of an incident command system
   b. Implementation of emergency response plans
   c. Knowledge of state and federal regional response teams
   d. Knowledge of medical hazards and risks for individuals working in protective clothing and equipment

NPFA 473: COMPETENCIES FOR EMS PERSONNEL RESPONDING TO HAZARDOUS MATERIALS INCIDENTS†

Level I Responders

The goal of the competencies at EMS/HM Level I shall be to provide the individual with knowledge and skills

necessary to safely deliver emergency medical care in the cold zone (and meet the following requirements):

1. Analyze a hazardous materials emergency to determine what risks are present to the provider and the patient by completing the following tasks:
   a. Determine the hazards present to the Level I responder and the patient in a hazardous materials incident
   b. Assess the patient to determine the risk of secondary contamination
2. Plan a response to provide emergency medical care to persons involved in hazardous materials incidents by completing the following tasks:
   a. Describe the role of the Level I responder in a hazardous materials incident
   b. Plan a response to provide the appropriate level of emergency medical care in a hazardous materials incident
   c. Determine if the personal protective equipment provided is appropriate
   d. Determine if the equipment and supplies provided are adequate (that is, will meet the patient care needs)
3. Implement the planned response by completing the following tasks:
   a. Perform the necessary preparations for receiving the hazardous materials patient and preventing secondary contamination
   b. Treat the hazardous materials patient
   c. Transport the patient as appropriate
   d. Terminate the incident

Level II Responders

The goal of the competencies at EMS/HM Level II shall be to provide the Level II responder with the knowledge and skills necessary to perform and/or coordinate patient care activities and medical support of hazardous materials response personnel in the warm zone. The Level II responder should be able to perform the following:

1. Analyze a hazardous materials incident to determine the magnitude of the problem in terms of outcomes by completing the following tasks:
   a. Determine the hazards present to the Level II responder and the patient in a hazardous materials incident
   b. Assess the patient to determine the patient care needs and the risk of secondary contamination
2. Plan a response to provide the appropriate level of emergency medical care to persons involved in hazardous materials incidents and to provide medical support to hazardous materials response personnel by completing the following tasks:
   a. Describe the role of the Level II responder in a hazardous materials incident
   b. Plan a response to provide the appropriate level of emergency medical care in a hazardous materials incident
   c. Determine if the personal protective equipment provided to EMS personnel is appropriate
3. Implement the planned response by completing the following tasks:
   a. Perform the preparations for receiving the patient
   b. Provide treatment to the hazardous materials patient
   c. Coordinate and manage the EMS component of the hazardous materials incident
   d. Perform medical support of hazardous materials incident response personnel
4. Terminate the incident

**OSHA*, Occupational Safety and Health Administration; *EPA*, Environmental Protection Agency; *NFPA*, National Fire Protection Association.

CHAPTER

58 Bioterrorism and Weapons of Mass Destruction

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. List five types of weapons of mass destruction.
2. Identify actions, signs and symptoms, methods of distribution, and management of biological weapons of mass destruction.
3. Identify actions, signs and symptoms, methods of distribution, and management of chemical weapons of mass destruction.
4. Identify actions, signs and symptoms, methods of distribution, and management of nuclear weapons of mass destruction.
5. Describe security threat alerts as defined by the Department of Homeland Security.
6. Identify measures to be taken by paramedics who respond to incidents with suspected weapons of mass destruction involvement.

KEY TERMS

anthrax An acute infectious disease caused by the spore-forming bacterium *Bacillus anthracis.*

bioterrorism The use of biological agents, such as pathogenic organisms or agricultural pests, for the express purpose of causing death or disease, to instill a sense of fear and panic in the victims, and to intimidate governments or societies for political, financial, or ideological gain.

B-NICE An acronym used for identifying categories of weapons of mass destruction: *Biological, Nuclear, Incendiary, Chemical,* and *Explosives.*

botulism An often fatal paralytic disease caused by the bacillus *Clostridium botulinum*.

CBREN An acronym used for identifying categories of weapons of mass destruction: *Chemical, Biological, Radiological, Explosive,* and *Nuclear* agents.

chlorine A poisonous, yellow-green gas with an odor that has been described as a mixture of pineapple and pepper.

cutaneous anthrax Anthrax that affects the skin, caused by the spore-forming bacterium *B. anthracis.*

Ebola An infectious viral hemorrhagic fever.

explosive Refers to bombs that can be made from a variety of dangerous materials.

foodborne botulism Illness that results from eating foods that contain the bacillus *Clostridium botulinum*.

improvised explosive device A "homemade" bomb constructed of explosives attached to a detonator; also known as a *roadside bomb*.

incendiary devices Firebombs.

infant botulism Illness caused by consumption of the spores of the botulinum bacteria, which then grow in the intestines and release toxin.

inhalational anthrax Anthrax caused by inhaling the spore-forming bacterium *B. anthracis.*

intestinal anthrax Anthrax caused from consuming meat contaminated with the bacterium *B. anthracis*.

Marburg An infectious viral hemorrhagic fever.

nerve agents Chemicals that disrupt the nerve transmissions in the central and peripheral nervous systems.

oropharyngeal anthrax A rare form of anthrax that occurs when the mouth and throat are infected with the spore-forming bacterium *B. anthracis.*

phosgene A poisonous gas that appears as a grayish white cloud and smells of newly mowed hay.

plague A disease caused by the bacteria *Yersinia pestis,* found in rodents (e.g., chipmunks, prairie dogs, ground squirrels, and mice) and their fleas in many areas around the world.

pneumonic plague An infectious pulmonary disease caused by exposure to the bacteria *Yersinia pestis.*

radiological dispersion device A nuclear explosive device; also called a "dirty nuke" or "dirty bomb."

ricin A potent protein cytotoxin derived from the beans of the castor plant (*Ricinus communis*).

riot control agents Chemicals that can produce sensory irritation or disabling physical effects that disappear within a short time after termination of exposure.

sarin A clear, colorless, and tasteless liquid that has no odor in its pure form; may be used as a nerve agent.

smallpox A highly contagious viral disease caused by the variola virus; characterized by fever, prostration, and a vesicular, pustular rash.

soman A clear, colorless, tasteless liquid with a slight camphor odor; may be used as a nerve agent.

tabun A clear, colorless, tasteless liquid with a faint fruity odor; may be used as a nerve agent.

tularemia A serious illness that is caused by the bacterium *Francisella tularensis* found in animals (especially rodents, rabbits, and hares).

vesicants Chemicals with severely irritating properties that produce fluid-filled pockets on the skin and damage to the eyes, lungs, and other mucous membranes.

viral hemorrhagic fevers A group of illnesses caused by several distinct families of viruses that include arenaviruses, filoviruses, bunyaviruses, and flaviviruses.

VX A thick, amber-colored, odorless liquid that resembles motor oil; may be used as a nerve agent.

weapons of mass destruction Large conventional biological, nuclear, incendiary, chemical, or explosive weapons.

wound botulism Botulism caused by toxins produced from a wound infected with *C. botulinum*.

International conventions have long prohibited the use of chemicals and biological agents during war and bar any country from making or acquiring biological weapons.[1] A number of countries and terrorist groups, however, maintain them. This chapter serves as an overview of ***bioterrorism*** *and* ***weapons of mass destruction*** *(WMD). Bioterrorism is the intentional release of biological products to cause illness or death. Weapons of mass destruction are weapons that can kill or bring harm to a large number of people. The chapter also provides general guidelines for emergency response.*

NOTE

B-NICE is an acronym that can be used for identifying five categories of weapons of mass destruction. It stands for *Biological, Nuclear, Incendiary, Chemical,* and *Explosives*. Another acronym is **CBREN.** It stands for *Chemical, Biological, Radiological, Explosive,* and *Nuclear* agents.

HISTORY OF BIOLOGICAL WEAPONS

The use of biological agents as weapons has occurred throughout history, dating back to 184 BC when Hannibal ordered that pots filled with venomous snakes be thrown onto the decks of enemy ships (Box 58-1).[2] However, many countries agreed to stop biological weapons research and development in 1972. Some of these countries included the United States, the former Soviet Union, Canada, and the United Kingdom. Some countries, however, continue to have biological warfare programs. In addition, the use of biological agents against civilians through acts of bioterrorism recently has appeared. The serious reality of bioterrorism became clear in the United States in 2001 when anthrax cases occurred following exposure to contaminated mail in New York, New Jersey, and Washington, DC.

CRITICAL BIOLOGICAL AGENTS AND RESPONDER DATABASES

The Centers for Disease Control and Prevention (CDC)[4] has published a list of critical biological agents. The list is divided into categories A, B, and C (Box 58-2).

NOTE

Acts of terrorism can pose significant risk to civilian populations. If airplanes sprayed chemical and biological agents on a city on a clear, breezy night, thousands and perhaps millions of persons would be killed. For example, 200 lb of anthrax sprayed over a city the size of Omaha would kill as many as 2.5 million persons; 200 lb of botulinum toxin would kill as many as 40,000 persons in an area the size of the Mall of America; and 200 lb of VX sprayed over an area the size of Disneyland would kill about 12,500 persons.[3]

Category A agents are the highest priority. They pose a risk to national security. They can be spread easily by person-to-person contact. They cause a high death rate and have the potential to cause a major public health problem. They might cause public panic and disruption. Category A agents require special action for public health preparedness. An example of a category A agent is *Bacillus anthracis* (anthrax).

Category B agents are the second highest priority. They are fairly easy to disseminate. They cause moderate illnesses and have a lower death rate than category A agents. These

DID YOU KNOW?

The BioWatch Program

In 2003 it was announced that the federal government was deploying an early warning network of sensors to detect biological attack (the "BioWatch Program"). The Department of Homeland Security (DHS) is responsible for the program, which has three main elements that are each coordinated by different agencies[5]:

1. The Environmental Protection Agency (EPA) maintains the sampling component—the sensors that collect airborne particles.
2. The Centers for Disease Control and Prevention (CDC) coordinates analysis—the laboratory testing of the samples.
3. The Federal Bureau of Investigation (FBI) is designated as the lead agency for the law enforcement response if a bioterrorism event is detected.

The installation of the sensor network is ongoing, with over 30 cities chosen as locations for these sensors. Selected cities include Philadelphia, New York City, Washington DC, San Diego, Boston, Chicago, San Francisco, St. Louis, Houston, and Los Angeles.

agents require specific enhancements of diagnostic capacity and disease surveillance. An example of a category B agent is *Coxiella burnetii* (Q fever).

Category C agents are the third highest priority. They include new pathogens that could be engineered for mass dissemination in the future. These agents are widely available. They also are easy to produce and dispense. They have the potential to cause a high rate of death and sickness. An example of a category C agent is Nipah virus.

Emergency Response Safety and Health Database

The CDC in conjunction with the National Institute of Occupational Safety and Health (NIOSH) has developed the Emergency Response Safety and Health Database (ERSH-DB). The ERSH-DB was developed for the emergency response community. The database contains accurate and concise information on high-priority chemical, biological, and radiological agents that could be encountered by

BOX 58-1 Time Line of Suspected or Reported Use of Biological Weapons

Early Examples

- The Tartar army catapulted bodies of plague victims into the city of Caffa in 1346.
- The British army provided the Delaware Indians in 1763 with blankets that had been used by smallpox patients.

Pre–World War II

- The Germans used various human and animal pathogens as agents of germ warfare in Europe during World War I. They are reported to have shipped horses, sheep, and cattle inoculated with *Bacillus anthracis* and *Pseudomonas pseudomallei* to the United States and other countries.
- Germany was accused of spreading cholera in Italy and plague in Russia in 1915.

World War II

- The Japanese used germ warfare against the Chinese and the Soviets by scattering *Yersinia pestis*–contaminated rice and fleas by airplane. This was followed by an outbreak of bubonic plague in those areas.
- The Japanese experimented with biological agents by exposing prisoners of war to anthrax, botulism, brucellosis, cholera, dysentery, gas gangrene, meningococcal infection, and plague. More than 1000 prisoners died from the experiments.
- The British performed trials with *Bacillus anthracis* off the coast of Scotland.
- The United States prepared about 5000 anthrax bombs at Camp Detrick, Maryland, in 1942 (although none were used during the war).

Post–World War II

- The United States dispersed stimulant aerosols over large areas around U.S. cities from 1949 to 1968.
- The United States exposed willing volunteer members of the Seventh Day Adventist Church (who were religious objectors to warfare) to aerosols of *Francisella tularensis* and *Coxiella burnetii* in 1953. (No deaths occurred and all recovered.)
- An unintentional release of anthrax spores from a biological warfare facility in the Soviet Union resulted in 66 deaths from inhalational anthrax in 1979.

The Gulf War

- The Iraqi government admitted that it had conducted research into the offensive use of *B. anthracis, Clostridium botulinum* toxin, and *C. perfringens* and had filled warheads with biological agents.

The Aum Shinrikyo

- The religious cult intentionally contaminated the Tokyo subway system with sarin in 1995, resulting in 5500 health care visits and 12 deaths.
- Several unsuccessful attempts were made to release anthrax or botulinum toxin to other areas around Tokyo.

Recent Terrorist Group Activities

- A religious commune deliberately contaminated several community salad bars in the United States with *Salmonella typhimurium,* resulting in more than 750 illnesses in 1984.
- Anthrax-laden envelopes were sent via U.S. mail in 2001, resulting to date in 11 cases of inhalational anthrax (including 5 deaths) and 12 cases of cutaneous anthrax.

From Darling R, et al: *Bioterrorism: the May 2002 issue of the Emergency Medicine Clinics of North America,* Philadelphia, 2002, Saunders.

BOX 58-2 Critical Biological Agents

Category A

Anthrax (*Bacillus anthracis*)
Botulism (*Clostridium botulinum* toxin)
Plague (*Yersinia pestis*)
Smallpox (variola major)
Tularemia (*Francisella tularensis*)
Viral hemorrhagic fevers (filoviruses [e.g., Ebola and Marburg] and arenaviruses [e.g., Lassa and Machupo])

Category B

Brucellosis (*Brucella* species)
Epsilon toxin of *Clostridium perfringens*
Food safety threats (e.g., *Salmonella* species, *Escherichia coli* O157:H7, and *Shigella*)
Glanders (*Burkholderia mallei*)
Melioidosis (*Burkholderia pseudomallei*)
Psittacosis (*Chlamydia psittaci*)
Q fever (*Coxiella burnetii*)
Ricin toxin from *Ricinus communis* (castor beans)
Staphylococcal enterotoxin B
Typhus fever (*Rickettsia prowazekii*)
Viral encephalitis (alphaviruses [e.g., Venezuelan equine encephalitis, eastern equine encephalitis, and western equine encephalitis])
Water safety threats (e.g., *Vibrio cholerae* and *Cryptosporidium parvum*)

Category C

Nipah virus
Hantaviruses
Tick-borne hemorrhagic fever viruses
Tick-borne encephalitis viruses
Yellow fever
Multidrug-resistant tuberculosis

From Centers for Disease Control and Prevention: *Bioterrorism agents/diseases,* www.bt.cdc.gov/agent/agentlist-category.asp#a, accessed 10-28-10.

BOX 58-3 Groups of Agents in the ERSH-DB

The database is composed of cards for the following groups of agents:

- Biotoxins
- Blister agents
- Incapacitating agents
- Lung damaging agents
- Nerve agents
- Riot control/tear agents
- Systemic agents
- Vomiting agents

DID YOU KNOW?

Riot Control/Tear Agents are solid chemicals with low vapor pressure that are dispersed in the air as fine particles. They produce sensory irritation or disabling physical effects that disappear within a short time after termination of exposure. Riot control agents often are referred to as "tear gas" and sometimes are used in military exercises, by law enforcement personnel for crowd control, and by individuals and the general public for personal protection (e.g., Mace and pepper spray). Paramedics and other emergency responders likely will encounter exposure to these agents during their careers. Personal protective equipment is needed to guard against the effects of these agents.

The most common riot control agent compounds are chloroacetophenone (CN) and chlorobenzylidenemalononitrile (CS). Other examples include chloropicrin (PS), bromobenzyl cyanide (CA), dibenzoxazepine (CR), and combinations of various agents. Riot control agents cause irritation to the area of contact (e.g., eyes, skin, and nose) within seconds of exposure. Signs and symptoms vary, depending on the location of exposure (open versus enclosed spaces) and the duration of contact with the agent, and may include some or all of the following:

- Eyes: excessive tearing, burning, blurred vision, redness
- Nose: runny nose, burning, swelling
- Mouth: burning, irritation, difficulty swallowing, drooling
- Lungs: chest tightness, coughing, choking sensation, wheezing, shortness of breath
- Skin: burns, rash
- Gastrointestinal system: nausea and vomiting

Although most effects from exposure to riot control agents are minor and last only 15 to 30 minutes, exposure to large doses or exposure in an enclosed area rarely may result in blindness, glaucoma, severe burns to airway structures, and life-threatening respiratory failure. Emergency care consists of moving persons away from the source to fresh air. In severe cases, oxygen administration, ventilatory support, burn care, and decontamination may be required.

From Centers for Disease Control and Prevention: *Facts about riot control agents,* www.bt.cdc.gov/agent/riotcontrol/factsheet.asp, accessed 10-28-10.

personnel responding to a terrorist event. The objectives of the ERSH-DB are[6]:

- To rapidly disseminate information to emergency response personnel on specific agents that may be used in terrorist events and that pose an occupational hazard of injury, illness, and death
- To provide information to be incorporated into management systems of emergency response operations for the purpose of reducing work-related injuries and illnesses
- To provide information that may be used in continuing education and training programs for the emergency response community

The information contained in the ERSH-DB represents a compilation of material from many sources. It is intended to address the safety and health information needs of a wide range of emergency response personnel. These groups include fire and rescue, emergency medicine, law enforcement, emergency management, public health, safety and health, and mortuary and funeral services. This central source of information allows different segments of the emergency response community to share information that is not readily accessible. It also helps to avoid duplication of effort (Box 58-3). Each response card includes information for:

- Agent Category
- Agent Characteristics
- Agent Name
- Agent Properties
- CAS #
- Common Names
- Emergency Response
- Decontamination (Environmental/Equipment)
- First Aid
- Decontamination (Human)
- Long-Term Implications
- Occupational Exposure Limits
- On-Site Fatalities
- Packaging and Labeling
- Personal Protective Equipment
- RTECS #
- Signs/Symptoms
- Trade Names and Other Synonyms

METHODS OF DISSEMINATION

Most biological agents used in bioterrorism are designed to enter the body through one of three ways. One of these is the inhalation of small particles into the lungs. Another is through the ingestion of contaminated food or water. The third way is by contamination of the skin that allows for absorption of the toxins. Because all category A agents can be disseminated through aerosolization, the inhalation route is of greatest concern.

Aerosols can be delivered in wet or dry form in closed or open spaces. Equipment that may be used to disseminate aerosols includes crop-dusting planes for open spaces, aerosol-generating devices for enclosed areas (e.g., subways and enclosed malls), ventilation systems in buildings, and contamination of items in the environment with fine powders that are aerosolized easily when disrupted. (The last example is the method of dispersal that occurred in the 2001 anthrax cases in the United States. Those were caused by opening contaminated mail.)

CRITICAL THINKING
Why would aerosolized agents of mass destruction pose a great risk to first responders?

SPECIFIC BIOLOGICAL THREATS

Hundreds of biological and chemical agents can be used in a bioterrorism attack. This section provides a brief overview of a few of these agents. The agents described in the following sections are considered most likely to be used as a threat to civilian populations. The most common biological threats are thought to be anthrax, botulism, plague, ricin, tularemia, smallpox, and viral hemorrhagic fevers.[7]

NOTE
Like all other hazardous materials incidents, it is assumed that all responders will wear the proper personal protective equipment. It also is assumed that they will use universal precautions at the scene and during patient care (see the chapter appendix). EMS personnel should not enter a scene with known or suspected biological or chemical threats until the scene has been made safe by the proper personnel.

Anthrax

Anthrax is an acute infectious disease caused by the spore-forming bacterium *Bacillus anthracis.* Anthrax most often occurs in warm-blooded animals. However, it also can infect human beings. Symptoms of disease vary. Usually, though, symptoms appear within 7 days after exposure. The most common form of anthrax is **cutaneous anthrax.** It results from direct contact with spores or bacilli. (Cutaneous anthrax also can occur from exposure to contaminated soil, and is not necessarily associated with a weapons of mass destruction [WMD] incident.) Cutaneous anthrax causes localized itching. This is followed by a papular lesion that turns vesicular and subsequent development of black eschar within 7 to 10 days of the initial lesion (Figure 58-1). Symptoms of **inhalational anthrax** often resemble a common cold in the initial stages. This is followed by severe respiratory distress and sepsis (Figure 58-2). (Inhalational

FIGURE 58-1 Cutaneous anthrax. (From Federal Emergency Management Agency: *Federal response plan, notice of change,* FEMA 229, Chapter 11, Feb 7, 1997, www.fas.org/irp/offdocs/pdd39_frp.htm, accessed 7-6-10.)

FIGURE 58-2 Respiratory distress and sepsis in anthrax.

anthrax usually results in death within 36 hours after onset of the acute symptoms.[8]) Other, less common forms of anthrax include **intestinal anthrax** from consuming contaminated meat and **oropharyngeal anthrax** when the mouth and throat are infected (rare).

TREATMENT

Direct person-to-person spread of anthrax most likely does not occur. Thus immunization or treatment of persons who have come in contact with a patient (e.g., household members, friends, and co-workers) is unnecessary. These persons do not need to be treated unless they also were exposed to the aerosol at the time of the attack. The disease is diagnosed by isolating *B. anthracis* from the blood, skin lesions, or respiratory tract secretions or by measuring specific antibodies in the blood of suspected cases. Treatment with antibiotics should be early; if left untreated, the disease can be fatal. Human anthrax vaccines (controversial) are available and are reported to be 93% effective against cutaneous anthrax.[9] Vaccination to protect against inhalational anthrax is recommended only for those at high risk.[10] This includes, for example, military personnel and workers in research laboratories that routinely handle anthrax bacteria.

Botulism

As described in Chapter 34, **botulism** is a rare but serious paralytic illness. The bacterium *Clostridium botulinum* produces a nerve toxin that causes paralysis. Botulinum toxin is one of the most potent and lethal substances known to man. There are three main types of botulism. One type is **foodborne botulism.** Eating foods that contain the botulism toxin causes it. The second type is **wound botulism** (Figure 58-3). This type is caused by toxin produced from a wound infected with *C. botulinum*. The third type is **infant botulism.** This type is caused by consumption of the spores of the botulinum bacteria, which then grow in the intestines and release toxin. All forms of botulism can be fatal and are considered medical emergencies.

LOOK AGAIN
See Chapter 34: Toxicology, pp. 990-991.

In a bioterrorism attack, inhaling the toxin as an aerosol weapon or ingesting the toxin via contaminated food or water are the most likely routes of exposure for serious illness. Foodborne botulism can be especially dangerous because small amounts of the bacterium in contaminated food can poison many persons. Signs and symptoms of the illness include nausea, dry mouth, blurred vision, dysphagia, fatigue, and dyspnea that may begin several hours to several days after the exposure.

TREATMENT

Botulism is not spread from person to person. If diagnosed early, foodborne and wound botulism can be treated with an antitoxin. The antitoxin blocks the action of toxin circulating in the blood. Recovery may take several weeks. As a result of the paralysis and respiratory failure that occur with botulism, the patient may be placed on a ventilator.

FIGURE 58-3 Wound botulism.

CRITICAL THINKING
What kind of resources would your community need to support hundreds of patients who need care on a ventilator?

Plague

Plague is caused by the bacterium *Yersinia pestis.* The bacteria are found in rodents (e.g., chipmunks, prairie dogs, ground squirrels, and mice) and their fleas in many areas of the world. The bacteria also can be grown in large amounts and disseminated by aerosol in a bioterrorism attack. This would result in an epidemic of the pneumonic form of the disease **(pneumonic plague)** with the potential for secondary contamination. Signs and symptoms include fever, extreme weakness, shortness of breath, chest pain, cough, and bloody sputum. Gastrointestinal symptoms are often present, including nausea, vomiting, abdominal pain, and diarrhea. The illness can lead to septic shock within 2 to 4 days.[11] Without treatment, plague has a high mortality rate.

NOTE
Pneumonic plague is one of three forms of the disease, all of which are caused by the bacteria *Yersinia pestis. Bubonic plague* is an infection of the buboes (lymph nodes). *Septicemic plague* is an infection of the bloodstream.

A bioterrorism attack with the bacteria would be characterized by pneumonic plague occurring at the same time

in persons following a common exposure. A secondary outbreak of illness would occur in others who had close contact with an infected person's respiratory droplets.

TREATMENT

The disease is diagnosed through testing for the bacteria. Plague must be treated early (within 24 hours) with antibiotic or antimicrobial agents. Persons who have been in close contact with the patient should be identified. These persons must be evaluated for postexposure drug therapy. Pneumonic plague is spread through the respiratory droplets of an infected person. Thus patients with the disease should be isolated. Universal precautions and personal respiratory protection for all caregivers are critical.

FIGURE 58-4 The seed pods of the castor bean plant are used to manufacture ricin.

CRITICAL THINKING

Your service notices a sudden increase in patients with severe respiratory distress. These patients also have pneumonia-like signs and symptoms. Would you initially consider bioterrorism as a cause of the outbreak?

Ricin
